The discovery of isotopes of oxygen by Giauque and Johnston in 1929 led to the acceptance by chemists and physicists of two different scales: chemists have continued to assign the value 16 to oxygen as found in nature, *i.e.*, to the naturally occurring mixture of isotopes; physicists, on the other hand, have consistently assigned the value 16 to the isotope O^{16}. The difference between these two scales is very small and conversions between them are readily made by means of a conversion factor (1.000275). However, following the discovery[3] that the isotopic composition of natural oxygen is not fixed and constant, the chemists are in the position of using an atomic weight scale based on a variable "constant." Although the variations in question are of no consequence with respect to present chemical atomic weight values, it has seemed desirable, for the sake of logic at least, to replace oxygen as the basis of the chemical scale by some anisotopic element.

Fluorine is a promising replacement for oxygen.[4] Its one serious disqualification is the simple fact that no strictly chemical atomic weight determination has been satisfactory, especially no determination relating fluorine to silver which, because of the part the latter plays in the Harvard atomic weight method, has become the "practical" basis of atomic weight values of a majority of the elements. The present investigation is the culmination of a series[5]

of studies which has been carried out for the purpose of finding a fluorine compound suitable for the determination of the atomic weight of fluorine by the Harvard method.

The preliminary experiments involved the preparation, purification and analysis of trifluoroacetyl chloride, trifluoroacetyl bromide and silver trifluoroacetate; samples of the last two compounds were painstakingly analyzed. Although these compounds appeared rather promising, a final series of these experiments with them was not undertaken because pure perfluorobutyric (heptafluorobutyric) acid became available commercially, and its acid chloride appeared to have a number of advantages over trifluoroacetyl bromide. For example, the heptafluoro compound has the higher boiling point (39° *vs.* −5°) and the higher percentage of fluorine (57% *vs.* 32%).

A pathfinding preparation and study of perfluorobutyryl chloride and silver heptafluorobutyrate were carried out by Swanson[6] in this Laboratory. These experiments showed that the acid chloride was very promising for atomic weight purposes; these experiments also laid the groundwork for a new preparation and analysis of perfluorobutyryl chloride described in this article.

Preparation and Purification of Materials

After some trial experiments a final sample of perfluorobutyryl chloride was prepared as follows.[7] A two pound sample of perfluorobutyric acid obtained from Minnesota Mining and Manufacturing Co. was twice fractionated using a 20-plate Oldershaw column with an automatic vapor-dividing head. In the first distillation concentrated sulfuric acid was present as a drying agent. In both distillations one-third of the charge in the pot was equally divided between the head and tail fractions which were rejected. The purified acid (1.7 moles) was converted to the acid chloride by slowly adding it to reagent grade phosphorus pentachloride (3.8 moles). The all-glass reaction system consisted of three flasks provided with ball and socket joints, so that they could be joined together, or disconnected and capped as desired. The first or reaction flask carried a separatory funnel; the third flask was essentially a stillpot since it was sealed to a 10-plate Oldershaw column. Considerable pains were taken to remove all moisture from the glass system prior to use and to prevent admission of moist air at any time. The preparation of the acid chloride was carried out in the first flask. During the reaction the flask temperature was kept at 0°; at the end of the reaction the temperature was raised to 80°. The acid chloride condensed in the middle flask kept at −70°. When the reaction was completed the product was distilled into the third flask, and then the connecting tube was sealed off. The acid chloride product which was light yellow at this stage was refluxed for 4 hours, the cold finger in the head being maintained at −50 to −20°. During this refluxing operation a very small amount of distillate was condensed in a receiver at −60°. This distillate was yellow and was discarded; it apparently was the contaminant originally in the main product since the latter became colorless during the first hour of the refluxing operation.

Without changing the apparatus the acid chloride was distilled three times at atmospheric pressure. The first was simply a careful distillation from the preparation apparatus. In the second distillation the large middle fraction from the first step was fractionally distilled through a 20-plate Oldershaw column with a vapor dividing head. The middle fraction (about nine-tenths of the charge) was again distilled, the procedure and apparatus being the same as in the preceding step.

The middle fraction from this (third) distillation was fractionated further in a new apparatus which included a 10-plate Oldershaw column. Although great care had been taken in the previous distillations to remove and exclude moisture there was always the possibility that the acid chloride had come into contact with trace amounts of moisture which would result in the formation of hydrogen chloride. The new apparatus was designed to exclude moisture completely; and the preliminary part of the distillation was carried out so as to eliminate hydrogen chloride if any were present. Following this a small light fraction was removed and the bulk (*ca.* 100 ml.) of the acid chloride was distilled (reflux ratio 1:10 to 1:50) into a flask fitted with a capillary "valve" for subsequent distillation under vacuum. Once the middle fraction was collected the "valve" flask was sealed off from the distillation column, and then evacuated in a manner to cause the vapor of the acid chloride product to sweep out most of the air present. The tube connecting the evacuated "valve" flask to the pump was then sealed.

The acid chloride material was finally distilled a fifth and sixth time in evacuated systems. The general scheme of distillations of this type has been described many times.[8] In the present experiments, however, the apparatus and technique involved two new features. It was found possible without using ground-glass joints or grease, to incorporate a 10-plate Oldershaw column in the vacuum system and so improve the degree of fractionation obtainable. Also, the usual solenoid-hammer device for breaking the capillary "valve" was modified so that the hammer dropped vertically[9] rather than being moved horizontally and was moved by a small magnet.

In the first vacuum distillation small head and tail fractions were taken and the bulk of the material was collected in a capillary valve flask. There was some evidence of a small amount of air in the system.

The second distillation employed the same apparatus as the previous one, except that small sample bulbs (*ca.* 2 cm. in diameter) were included in the system for collecting the entire charge. The apparatus was pumped down to 0.001 mm. for several days and repeatedly flamed. Then the middle fraction from the previous vacuum distillation was transferred to the pot through the capillary valve, refluxed for one-half hour, and distilled. A very minute trace of air was apparently present in the system during the filling of the first three bulbs (#8, 9 and 10), and was successfully trapped in bulb #11. In filling the remaining bulbs (#12–18) the vapor literally rushed into the bulb the instant it was cooled, indicating the complete absence of air. All the acid chloride was collected by the time bulb #18 was filled. Seven of the samples collected in this distillation were subsequently analyzed.

The silver used in these analyses were prepared by Kurt H. Nelson.[10] The purification process[11] involved the electrolytic transport of the silver three times through a saturated silver nitrate solution contained in long quartz trays. The electrolytic crystals were fused into buttons of suitable size in a quartz furnace on a bed of pure lime in an atmosphere of slightly moist hydrogen. The fused buttons were etched several times with nitric acid, washed and dried at 100° in air, then at 400° *in vacuo*. The standard silver solution employed for fine adjustment of the weight of silver in the analyses was made with a small quantity of electrolytic crystals which also had been heated to 400°. Samples of these electrolytic crystals were examined spectrographically[12] and the only impurities detected were Al, Fe, Mg, Si and Cu. The percentage of each of the first four fell in the range 0.0001–0.001; that of Cu was less than 0.0001.

Water, nitric acid and pyridine were purified by distillation. Hydrogen was commercial tank gas which, after passing through a Deoxo unit to remove oxygen, was passed through a set of six all-glass Emmerling towers containing the following solutions in the order given: alkaline plumbite; 20% NaOH; concd. sulfuric acid; concd. sulfuric

acid; 20% NaOH; water. To adjust the aqueous vapor pressure in the hydrogen to the desired value[11] the gas was finally passed through two cold towers, the first kept at 0° and the second, at −18°.

Comparison[13] of the perfluorobutyryl chloride with silver followed conventional lines.[14] The scheme of this comparison can be presented briefly. A weighed sample bulb was placed in a thick-walled flask containing 25 ml. of pyridine and 50 ml. of water, and the flask was closed with a tight-fitting, ground glass stopper. After the flask was cooled to about 4° in the cold room the bulb was broken inside the flask by violent shaking and the perfluorobutyryl chloride was allowed to react with the aqueous pyridine. Due to the presence of the pyridine, the chloride samples were completely soluble in this mixture. Although the white fog formed upon breaking the bulb disappeared within one-half hour, the flask was allowed to stand for a day before opening. The solution was filtered through a Munroe platinum crucible using a specially designed filtering apparatus[15]; the filtrate was collected in a liter round-bottom flask and transferred from this to a 4-liter glass stoppered bottle.

After obtaining the weight of perfluorobutyryl chloride, the equivalent weight of silver was calculated. In the early analyses, for the purpose of this calculation, the atomic weight of fluorine was assumed to be slightly greater than 19.00; in the last few analyses it was assumed to be slightly less than 19.00. The silver, after being weighed out, was transferred to a flask fitted with a tower of bulbs, and dissolved in 50–100 ml. of 1:1 nitric acid. The quantity of acid used was such as to make the final analytical solution 0.2–0.3 *M* in nitric acid.

The precipitation of the chloride was carried out in a dark room by adding the dissolved silver to the pyridine solution of perfluorobutyryl chloride in small portions with constant agitation. After the quantitative addition of the silver solution, the amount added was immediately adjusted to the calculated value by the addition of silver nitrate or sodium chloride from carefully prepared solutions of the purified substances. These standard solutions contained approximately 0.1 mg. of silver or its equivalent per milliliter. The final volumes of the analytical solutions were between 2,000 and 3,000 ml. The solutions were shaken vigorously four or five times a day following precipitation and during the preliminary nephelometric tests. Following these tests the solutions were allowed to stand with occasional shaking for a period of two years before they were subjected to the final nephelometric tests and "crossing of the end-point."

Nephelometric tests of the silver and chloride concentrations in the analytical solutions were made with the usual precautions. The nephelometric test suspensions were prepared by the "uniform" precipitation device described by Scott and Hurley.[16] The opalescence of a test suspension was determined by use of a new Coleman Nephelocolorimeter. It may be recalled here that Scott and Hurley,[14] in connection with their analyses of benzoyl chloride, found that the presence of pyridinium nitrate in the analytical solution has no significant effect on the opalescences of nephelometric test suspensions.

Preliminary determinations (summer 1953) of the opalescence ratios for the seven analytical solutions, immediately after precipitating the chloride, were encouragingly close to unity. Nothing further could be established at the time because of other obligations. When it was realized that the determination would have to be put off for a period of time, suitable additions of silver nitrate or sodium chloride, in the form of the very dilute standard solutions, were made to the analytical solutions of analyses #1–#5 to make the amount of silver present in each solution equal to that calculated on the assumption that the atomic weight of fluorine is 19.000. These additions were all small. No additions were made to the analytical solutions of analyses #6 and #7, the silver for which was calculated on the assumption that the atomic weight of fluorine is 18.997. All seven analytical solutions were kept in a light-tight cupboard in a dark room from the summer of 1953 to the summer of 1955 when the analyses were completed. It is believed that this two year period was advantageous for several reasons. It certainly must have reduced the amount of colloidal silver in suspension; it also favored the aging of the precipitate and the establishment of equilibrium between the precipitate and mother liquor.

The final determination of the end-point was performed by Marvin H. Lehr.[17] To begin with the solutions were well shaken and then allowed to stand for several days. Next, on two consecutive days test samples were withdrawn from the analytical solutions, and the opalescence ratios determined by means of the Coleman nephelometer. These two measurements of the opalescence ratios, which were in very satisfactory agreement, all showed a slight excess of silver ion. It was estimated that in no case was this excess of silver greater than 0.15 mg.; and on this assumption chloride ion equivalent to 0.15 mg. of silver was added to each analytical solution in the form of very dilute standard solution. The solutions were then shaken repeatedly, and three measurements of the new opalescence ratios were made in the course of a week. The last two sets of measurements were in satisfactory agreement. These new ratios showed that the end-point had been crossed except in the case of analysis #5 in which case the ratio was 1.07. From the known values of the ratios before and after the addition of the chloride ion (equivalent to 0.15 mg. silver) and assuming that the variation in opalescence ratio with added chloride ion is linear, it is possible to estimate readily the amount of chloride necessary to bring the opalescence ratio to unity. This estimate was used in calculating the amount of silver added or subtracted in solution to give the exact end-point. In passing it is interesting to note that from this final series of nephelometric tests one can derive a new estimate of the sensitivity of the opalescence ratio. On the average it was found that a change of 0.01 in the opalescence ratio is caused by 0.006 mg. of silver ion or its equivalent in chloride ion.

Results of Analyses

The results obtained from the analysis of seven samples of the perfluorobutyryl chloride are given in Table I.[18] These samples formed a consecutive series and no accidents or mishaps occurred. All the weights in the table are corrected to the vacuum basis. The additions of silver tabulated in column 4 are those made *after* the nephelometric tests were begun.

Discussion of Results

With a series of analyses such as that reported above an important question is whether the variations in the results are due to differences in the samples analyzed or arise from the analytical operations. At first glance it is disturbing to find

(13) These operations, up to the final nephelometric tests, were performed by the junior author, as a research associate, in the summer of 1953.

that the ratio values for the lightest (no. 8) and the heaviest (no. 18) fractions stand out as greater than the ratio values of the other five samples; for this might be an indication of a variation in the samples due to fractionation. This interpretation, however, appears to be contradicted by two lines of evidence. Most important is the fact that the results of adjacent fractions do not show any gradation in ratio values. Also significant is the fact that the most probable impurities (hydrogen chloride in the light fraction and phosphorus chloride or oxychloride in the heavy fraction) would result in low rather than high ratio values. Although the high ratio value of the lightest fraction (no. 8) presumably does not arise from the fractionation of the acid chloride material, it is conceivable that it is an indication of some impurity in the sample; for, as will be recalled, this fraction was the only one in the series which showed milkiness upon condensation of the sample, due possibly to a trace of air in the system.

If we assume the samples of acid chloride to have been uniform and the variations in the ratio values to have their origin in the analytical operations, we can treat the experimental data as follows. First, on the basis of the Pierce–Chauvenet criterion we find that the ratio value of analysis no. 4 most probably involves some mistake and can therefore be rejected as an aberrant measurement. Omitting no. 4 for the series we get the mean value "B" in Table I. If we also omit the result of analysis no. 1 on the ground that it is suspect because of the possible contamination with a trace of air as mentioned above, we get the mean value "C" of Table I. Information relating to the statistics of the experimental data is summarized in Table II.

TABLE II

INFORMATION PERTAINING TO THE PRECISION OF RATIO VALUES

Mean	No. of analyses in set	Mean value of ratio	Stand. dev.	Range of mean
A	7	2.15517	0.000081	
B	6	2.15514	.000043	±0.00004
C	5	2.15512	.000023	± .00002

The range of the mean represents the 90% confidence limits. As is evident, there is little difference between means B and C. Both values, however, will be carried along in the following discussion. It is of interest to note that the uncertainty of the mean values is 1–2 parts in 10^5.

First, following the traditional treatment we shall use the experimentally determined ratio C_4F_7OCl:Ag to calculate the atomic weight of fluorine. For this purpose we note first the necessary atomic weight values given in the most recent "Report on Atomic Weights"[19]

Oxygen	16
Chlorine	35.457
Silver	107.880
Carbon	12.011

There can be no question regarding the acceptability of the first three of these atomic weight values. They have been used in calculations of atomic weight determinations by the Harvard method for the past 30 years. Also there are no alternative values to consider.

Concerning the atomic weight of carbon the following notes are offered. The present accepted value for the chemical atomic weight of carbon 12.011 was derived from a combination of two physical measurements: mass determinations of C^{12} and C^{13} from observations of energy changes accompanying nuclear reactions; and mass spectrographic determinations of the relative abundance of the two isotopes. As a matter of fact, in the 1954 Report, the chemical atomic weight derivable from these physical measurements was estimated to range from 12.0113 and 12.0116, depending on the source of the carbon; and the value given (12.011) is a rounded-off figure. For our purposes we shall use the mean value 12.0114 as the best estimate of the chemical atomic weight of carbon. Finally, it may be noted that an uncertainty of 0.0002 unit in the atomic weight of carbon introduces an uncertainty of less than 0.0002 in the derived atomic weight of fluorine.

The atomic weight of fluorine calculated from the experimentally determined ratio C_4F_7COCl:Ag and the atomic weights of C, O, Cl and Ag given above are as follows, the last digit being of questionable significance.

Using mean ratio value	Atomic weight fluorine
"B"	18.9990
"C"	18.9987

These values can be compared with the value 18.9992 ± 0.0002 obtained by two physical methods. Nier[20] gives this figure as the best atomic weight value derivable from existing mass-spectrographic data; and exactly the same value is derived from the nuclear reaction data of Li, Whaling, Fowler and Lauritsen.[21] It is noteworthy, as Nier[20] points out, that the uncertainty in the physical values stems from the uncertainty in the conversion factor needed to convert from the physical to the chemical scale rather than from the physical measurements themselves. As is evident, the atomic weight of fluorine derived from our analyses of perfluorobutyryl chloride is in excellent agreement with the physical values. The evidence, therefore, is quite conclusive for revising the chemical atomic weight from the present value 19.00 to 18.999.

Since the chemical atomic weight of fluorine has been so well established by physical methods,[20,21] it is of interest to calculate the atomic weight of silver based on it. If we accept the usual values for Cl and O, and take F ± 18.9992 and C = 12.0114, we obtain from the results of our analyses of perfluorobutyryl chloride the following for the atomic weight of silver

Using mean ratio value	Atomic weight of silver
"B"	107.880
"C"	107.881

(19) E. Wichers, THIS JOURNAL, **76**, 3235 (1956).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The derived value is in excellent agreement with the figure 107.880 which has been accepted for many years by chemists. Although this outcome is just another way of showing that the results of our present series of analyses are consistent with the physical values for the atomic weights of fluorine and carbon, it is of particular importance because of the special position of the atomic weight of silver as the practical basis of the chemical atomic weight scale. The significance of this last point will be elaborated further in the section which follows.

The possibility of comparing fluorine and silver by the analysis of perfluorobutyryl chloride opens the way for a consideration of a number of questions. For one thing serious consideration can now be given to the adoption of fluorine as the basis of the chemical atomic weight scale. Some of the arguments in favor of the change may be noted here: The element is anisotopic[22] and hence, unlike oxygen, its chemical atomic weight is constant. Further to go from natural oxygen (16) to an assigned value of 19 for fluorine would mean an increase in the chemical atomic weight values of the other elements by less than 1 part in 20,000, a very minor change which should not present serious practical problems. Finally, since the atomic mass of fluorine can be established quite accurately on the physical scale by physical methods, fluorine could serve as a bridge between the two scales. Naturally, if fluorine were to be accepted as the basis of the chemical scale there would be need of further work to establish as accurately as possible the relationship between fluorine and silver. It would be desirable not only to repeat the analyses of perfluorobutyryl chloride and undertake the analyses of a pure sample of the corresponding bromide, but it would be important to explore the suitability of the acid halides of other perfluoroaliphatic acids for comparing the atomic weights of fluorine and silver.

In the latest "Report on Atomic Weights" Wichers[19] presents a most enlightening discussion of the "Problem of Two Scales" and raises the question of unifying the chemical and physical atomic weight scales. Of the various possibilities Wichers regards a common scale, based on fluorine with an assigned mass of 19, as the most attractive one. The fact that our work gives a comparison between the atomic weights of fluorine and silver (the practical basis of many chemical atomic weight values) lends support to Wicher's conclusion.

Acknowledgments.—This work on atomic weight of fluorine has received partial support from several grants to the senior author. Small grants from the Cyrus M. Warren Fund and the Permanent Science Fund of the American Academy of Arts and Sciences in 1937–38 were of great help; in fact a Troemner No. 10 balance, purchased at that time, was used in the present series of experiments. All the work on derivatives of trifluoroacetic acid carried out immediately following the war was supported by funds from an ONR Contract (onr #71600). A contract with the Division of Research, A.E.C., and a grant from the National Science Foundation, both primarily in support of other atomic weight projects, provided invaluable assistance at critical points in the present set of experiments. The senior author acknowledges gratefully all of this financial assistance.

PORTLAND, OREGON

(22) This term has been proposed by H. E. Duckworth (private communication) as more correct etymologically than the older terms "monoisotopic" and "simple" to describe an element having only one atomic species. For further discussion of term "anisotopic," see footnote 46, ref. 19.

The Preparation and Properties of Rhenium Oxychloride (ReO_3Cl)[1]

BY CLARENCE J. WOLF,[2] A. F. CLIFFORD AND W. H. JOHNSTON

RECEIVED APRIL 15, 1957

Rhenium oxychloride has been prepared in good yields by direct chlorination of rhenium trioxide. The gaseous infrared spectrum, the gas density and the vapor pressure were determined at room temperature. The general handling procedure and some properties of this compound are discussed.

Introduction

Rhenium oxychloride has been prepared by several investigators.[3–7] All of these preparations use essentially one of two procedures, either the reaction between rhenium(VII) oxide and rhenium tetrachloride ($ReCl_4$)[5] in a combustion tube or the oxidation of rhenium trichloride ($ReCl_3$). The present paper describes a direct procedure which gives a superior product which needs only be vacuum distilled to remove dissolved chlorine.

A limited number of physical properties of rhenium oxychloride have been reported. In 1932 Bruke and Ziegler[1] described it as a colorless liquid melting at 4.5°, boiling at 131°, and hydrolyzing immediately in air to perrhenic ($HReO_4$) and hydrochloric acids. In the following year Geilmann and Wrigge[5] reported it to be light sensitive, turning purple in sunlight and becoming colorless in the

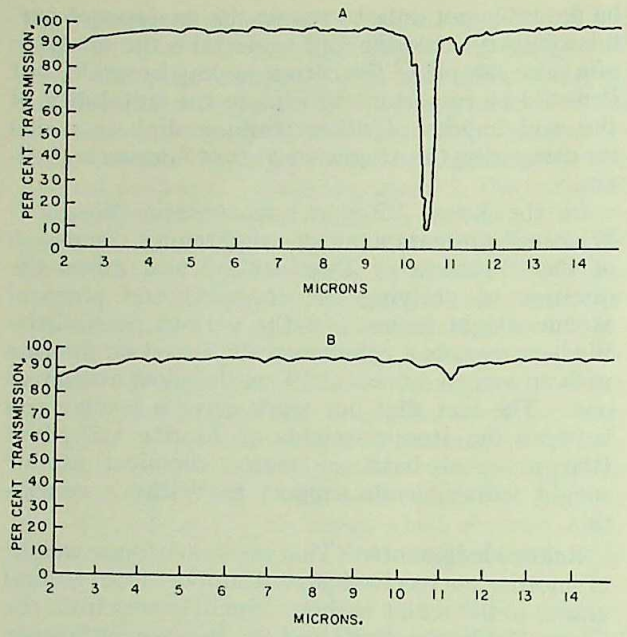

Fig. 1.—Infrared absorption spectrum of ReO_3Cl: upper (A), gaseous ReO_3Cl; lower (B), evacuated gas cell.

dark. In 1952 the microwave spectrum was studied by Amble, *et al.*,[8] who reported the structure as a symmetric top with an Re–Cl distance of 2.230 ± 0.004 Å., and Re–O distance of 1.761 ± 0.003 Å., and the Cl–Re–O angle as 108° 20′ ± 1°. Recently Eichhoff and Weigel[9] studied the Raman spectrum of rhenium oxychloride but encountered difficulty in photodecomposition of the sample. Some additional properties of this compound are reported in the present work.

Experimental

Rhenium(VII) oxide (Re_2O_7) readily is converted to rhenium(VI) oxide (ReO_3) by reduction with dioxane.[10] The reactions are

$$Re_2O_7 + xC_4H_8O_2 \longrightarrow Re_2O_7\cdot(C_4H_8O_2)_x$$

$$Re_2O_7\cdot(C_4H_8O_2)_x \xrightarrow{125\text{–}145^\circ} ReO_3 + \text{decomposition products}$$

The rhenium(VI) oxide is then allowed to react with chlorine in a dry combustion tube between 160 and 190°

$$2ReO_3 + Cl_2 \xrightarrow{160\text{–}190^\circ} 2ReO_3Cl$$

The yield obtained from these reactions is above 70%. The product is quite pure and is colored slightly yellow due to dissolved chlorine; this, however, may be removed readily by vacuum distillation leaving a clear colorless liquid boiling at 128° (uncor.). Analyses for chlorine were 12.74 and 12.71% as compared to the theoretical value of 13.14%. This slightly low value was caused by some hydrolysis in air during weighing.

Some precautions are necessary in the handling of this compound. Rhenium oxychloride reacts immediately with mercury and with ordinary stopcock grease; therefore, it must be trapped before reaching the diffusion pump. Furthermore, a special stopcock grease such as "Halocarbon grease" (Halocarbon Products Corporation) should be used to minimize the decomposition. Even this grease, however, caused some slight decomposition of the oxychloride leaving a purple colored substance, probably rhenium(VI) oxide (ReO_3).

To test the hypothesis that the purple color was due to this oxide, some ReO_3 was dissolved in a small amount of the oxychloride. It is interesting to note that a similar purple solution was formed.

The rhenium oxychloride can be kept without decomposition in a greaseless system of glass, Kovar and Monel. In this manner, we were able to keep the liquid colorless for several weeks.

Rhenium oxychloride is extremely reactive toward mercury, silver and a large number of organic compounds. Carbon tetrachloride, however, was found to be a good solvent, giving a clear, colorless, solution. The oxychloride does not appear to react with brass that has been first chlorinated, or with stainless steel.

The infrared spectrum of gaseous rhenium oxychloride was measured in a ten centimeter gas cell with potassium bromide windows, using a double beam Perkin–Elmer Recording Infrared Spectrometer Model 21. The spectrometer is shown in Fig. 1. Curve A is the absorption spectrum of the vapor in the cell and curve B is the absorption spectrum of the cell after removal of the oxychloride. The vapor pressure as measured with a Bourdon gage is 4.5 ± 0.5 mm. of mercury at room temperature. The vapor density of rhenium oxychloride at room temperature is 6.5×10^{-5} g./ml. (average of two determinations). Assuming the ideal gas law, the experimental molecular weight was 268 g. compared to a theoretical value of 270 g.

The Thermal Decomposition of Uranium Peroxide, $UO_4\cdot 2H_2O$

BY JAMES E. BOGGS AND MUNZIR EL-CHEHABI

RECEIVED APRIL 1, 1957

$UO_4\cdot 2H_2O$ decomposes slowly in the temperature range 90–195° to form a different peroxide, U_2O_7. The rate of this reaction has been followed and the properties of U_2O_7, which has not been isolated previously, have been investigated.

Uranium peroxide, $UO_4\cdot 2H_2O$, has been known since 1876[1] and has been subjected to intensive investigation in recent years. Nevertheless, its constitution is still unknown, some authors considering it to be a true peroxide hydrate, others a peroxy acid, and others an addition compound of uranium oxide, $UO_3\cdot H_2O_2\cdot H_2O$.

The existence of one other peroxide of uranium, U_2O_7, has been suggested. Evidence for a hydrated form of this substance was found by Hüttig and von Schroeder[2] in their experiments on the decomposition of hydrated UO_4. Later, Kraus[3] ob-

tained a red powder with the composition $UO_{3.14}$ to $UO_{3.38}$ by heating $UO_4 \cdot 2H_2O$ at 139° for 24 hours, then raising the temperature to 300°. Based on our experiments, this was probably a mixture of U_2O_7 and UO_3.

Hüttig and von Schroeder[2] studied the decomposition of $UO_4 \cdot xH_2O$ under 15 mm. water vapor pressure between 20 and 500°. They report that $UO_4 \cdot 4.5H_2O$ is stable up to about 55°, at which temperature water begins to be lost. At about 63°, one-half of the peroxide oxygen is lost, resulting in a composition corresponding to $U_2O_7 \cdot 6H_2O$. Between 63 and 162° the oxygen content remains unchanged while the water content gradually falls to $U_2O_7 \cdot 4H_2O$. At about 162°, water and oxygen are lost together, forming the hydrated oxide $UO_3 \cdot 0.5H_2O$. These results are very difficult to understand in view of the repeated success of many workers in preparing $UO_4 \cdot 2H_2O$ by drying freshly precipitated uranium peroxide at 100° for a short time.

More recently, Duval[4] has studied the decomposition of hydrated uranium peroxide, using a thermogravimetric balance. He concludes that water is smoothly driven off up to a temperature of 90°, at which point the composition corresponds to $UO_4 \cdot 2H_2O$. Between 90 and 180°, one molecule of H_2O_2 is lost, forming $UO_3 \cdot H_2O$. This is followed by the gradual loss of water, leaving anhydrous UO_3. From this he concludes that "uranium peroxide" must really be $UO_3 \cdot H_2O_2 \cdot H_2O$, although, as he points out, it is surprising that a substance containing a combined molecule of hydrogen peroxide is still relatively stable in the 100° region.

We have reinvestigated the decomposition of $UO_4 \cdot 2H_2O$ between 90 and 200° in a controlled atmosphere, making certain that the time of heating was adequate to ensure equilibrium.

Experimental

Materials.—Hydrated uranium peroxide was precipitated from $UO_2(NO_3)_2 \cdot 6H_2O$ (Calcd.: U, 47.4. Found: U, 47.5) purchased from Baker Chemical Co., using the procedure described by Watt, Achorn and Marley.[5] The resulting precipitate was washed with distilled water, dried at 100° for 4 hours, and stored over $CaCl_2$. (Calcd. for $UO_4 \cdot 2H_2O$: U, 70.4; peroxidic oxygen, 9.46. Found: U, 69.9; peroxidic oxygen, 9.25.)

Analytical Methods.—Uranium was determined either by ignition to U_3O_8[6] or by a volumetric method.[7] Peroxidic oxygen was determined by dissolving the compound in dilute sulfuric acid and titrating with potassium permanganate.

Experimental Method.—A tube furnace was constructed, the temperature of which could be regulated and maintained within ±0.5° by means of an automatic controller. A stream of oxygen or air was allowed to bubble through water at a controlled temperature, below the temperature of the room, in order to pick up a controlled quantity of water vapor, then passed over a sample of 2 to 2.5 g. of $UO_4 \cdot 2H_2O$ in a porcelain boat in the furnace. Samples of the decomposed uranium peroxide were removed periodically and analyzed for peroxidic oxygen. These analyses were checked at intervals by analysis for uranium and by determination of the total weight loss.

Results

The first experiments were performed by heating $UO_4 \cdot 2H_2O$ at a constant temperature in an atmosphere of oxygen containing 30 mm. water vapor pressure. Subsequent experiments showed that the same results were obtained using an atmosphere of air instead of oxygen and using water vapor pressures down to 8 mm. All of the experiments at temperatures up to 195° showed the slow decomposition of $UO_4 \cdot 2H_2O$ according to the equation

$$4UO_4 \cdot 2H_2O \longrightarrow 2U_2O_7 + O_2 + 8H_2O \qquad (1)$$

The reaction was followed to completion at temperatures of 130° and above. At lower temperatures, down to 90°, the reaction was still incomplete after a month of heating at constant temperature, but the resulting mixture showed the characteristic properties of U_2O_7.

Pure U_2O_7 (Calcd.: U, 80.96. Found: U, 80.72) was an orange hygroscopic solid which decomposed to UO_3 and oxygen gas in contact with water, and to uranyl salts and oxygen gas in contact with acids. The addition of U_2O_7 to acid permanganate solutions did not decolorize them, although oxygen was liberated. At higher temperatures U_2O_7 slowly loses oxygen to form UO_3. A weighed sample of U_2O_7 was added to dilute sulfuric acid and the oxygen released was collected. The volume obtained was 94% of that predicted from the equation

$$2U_2O_7 + 8H^+ \longrightarrow 4UO_2^{++} + 4H_2O + O_2$$

and the remaining 6% can be accounted for by solubility in the water.

U_2O_7 was pelleted with KBr and the infrared spectrum scanned between 2 and 16 μ on a Baird model 4–55 recording spectrophotometer. In addition to the usual absorption above 10 μ, which can be attributed to the U–O bond, U_2O_7 showed a sharp peak at 7.1–7.2 μ. This peak was not found in UO_3 or $UO_4 \cdot 2H_2O$.

The time required for reaction 1 to reach completion is very long. As an illustration, the data at 130° are presented in Table I. The $KMnO_4$ titration used in the analysis determined the peroxidic oxygen in the undecomposed $UO_4 \cdot 2H_2O$, but not that in the U_2O_7 produced. Even at 90°, reaction 1 occurred very slowly, as evidenced by the evolution of oxygen when $UO_4 \cdot 2H_2O$ which had been heated at this temperature for a long time

TABLE I

RATE OF CONVERSION OF $UO_4 \cdot 2H_2O$ TO U_2O_7 AT 130°

was added to water. At temperatures of 200° and above, the decomposition of $UO_4 \cdot 2H_2O$ leads to UO_3 without the formation of U_2O_7.

The rate of decomposition of $UO_4 \cdot 2H_2O$ to U_2O_7 was found to give surprisingly good agreement with first-order kinetics, the rate of decomposition being proportional to the quantity of undecomposed peroxide. Table I shows the first-order rate constant calculated at 130°, the agreement being as good as could be expected from the accuracy of the measurements. In a similar manner the rate constant was found to be 4.4×10^{-4} hr.$^{-1}$ at 100°, 4.0×10^{-3} hr.$^{-1}$ at 120°, and 1.3×10^{-1} hr.$^{-1}$ at 150°. An Arrhenius plot of these data gives a very good fit to a straight line, from which the activation energy can be calculated to be 35 kcal./mole. It is questionable whether such good results would have been obtained if preparations of radically different crystal size had been used.

Discussion

The results obtained in this investigation are in striking disagreement with those reported by Duval[4] and in the earlier work by Hüttig and von Schroeder.[2] The explanation may lie in the extremely long time required for reaction 1 to reach completion. In the thermogravimetric method used by Duval, sufficient time for reaction 1 to reach completion could not possibly have been allowed, and Hüttig and von Schroeder do not state the length of time they heated their samples.

It may also be significant that both Hüttig and von Schroeder and Duval started with moist UO_4, containing an amount of water in excess of that required by the formula $UO_4 \cdot 2H_2O$, while in this investigation dried $UO_4 \cdot 2H_2O$ was employed.

On the basis of our experiments it may be concluded that $UO_4 \cdot 2H_2O$ decomposes to U_2O_7 in the temperature range between 90 and 195° and that the decomposition reaction does not give any evidence to support the formulation of uranium peroxide as $UO_3 \cdot H_2O_2 \cdot H_2O$.

Hydrolysis of $A^{III}B^{V}$ Intermetallic Compounds[1]

BY J. A. KAFALAS, H. C. GATOS AND M. J. BUTTON

RECEIVED APRIL 3, 1957

$A^{III}B^{V}$ intermetallic compounds hydrolyze to a varying degree. Phosphides hydrolyze readily in acid media at room temperature with formation of phosphine. Arsenides and antimonides hydrolyze to a lesser extent.

Intermetallic compounds of the type $A^{III}B^{V}$ (InSb, GaAs, etc.) have become of considerable importance in recent years because of their semi-conducting properties.[2] During and after their preparation these compounds are generally brought into contact with aqueous media. They are usually prepared, for example, using an excess of constituent A; A is subsequently leached by an acid which does not appreciably attack the compound itself. Furthermore, for certain applications the crystal surfaces are treated with acid or basic solutions. The purpose of this study was to determine whether the above intermetallic compounds hydrolyze in aqueous media to form highly toxic hydrides of the type $B^{V}H_3$ (*viz.*, PH_3, AsH_3, SbH_3) according to the reaction

$$A^{III}B^{V} + 3H_2O \longrightarrow A^{III}(OH)_3 + B^{V}H_3$$

Preparation of Samples.—The representative intermetallic compounds used were InP, GaAs and GaSb, containing radioactive P, As and Sb, respectively. They were prepared as follows.

InP.—Elementary P, containing P^{32}, and In were placed in a quartz tube which was subsequently evacuated and sealed off. The mixture was then heated for one hour at 1050°.[3] The resulting sample was treated briefly with cold concentrated HNO_3 in order to remove the excess indium. An X-ray powder pattern confirmed the formation of InP. The radioactive P^{32} was obtained from $Ca_3(PO_4)_2$, containing P^{32}, by reduction with charcoal and SiO_2 at 1300°.

GaAs.—Elementary arsenic containing radioactive As^{73-74} together with non-radioactive GaAs was placed in a quartz tube which was then evacuated and sealed off. The end of the tube containing the GaAs was heated for several hours above the melting point (1280°) of GaAs. This treatment ensured homogeneous distribution of radioactive arsenic throughout the GaAs. The radioactive arsenic was obtained from radioactive $AsCl_3$ by reduction with H_3PO_2 and $SnCl_2$.

GaSb.—Radioactive Sb^{125} was homogeneously distributed in GaSb in the manner described for GaAs (m.p. of GaSb 725°). The radioactive antimony was obtained from $SbCl_3$ by reduction with iron and $SnCl_2$ in 16% HCl solution.

Experimental Technique.—The above compounds were crushed to coarse powders and were employed in this form. Measurements of the radioactive content of weighed fractions showed that the radioactive species were distributed homogeneously throughout the samples.

The apparatus employed in this study is shown in Fig. 1. The various coarse powders were placed on a fritted disk F in the reaction chamber S. A solution of known *p*H was added through the funnel P and a moderate stream of nitrogen was bubbled through the solution and through the adsorption traps T_1 and T_2 which contained an oxidizing solution of iodine, KI and $NaHCO_3$. The stream of nitrogen was employed for the purpose of stirring the reaction mixture and for carrying any SbH_3, AsH_3, PH_3 or other volatile hydrides formed into the adsorption traps as rapidly as possible. The reaction chamber S was designed so that no radioactivity was carried into the traps other than that associated with the gaseous products. Several blank tests were performed in which chamber S contained a radioactive solution, but not radioactive gases. In all cases, the nitrogen stream carried no detectable radioactivity into the traps.

Each sample of the intermetallic compounds was exposed to the solution for 16 hours. Upon completion of each run,

(1) The research reported in this document was supported jointly by the Army, Navy and Air Force under contract with Massachusetts Institute of Technology.

(2) L. Pincherle and J. M. Radcliffe, *Advances in Phys.*, **5**, 271 (1956).

(3) Because the vapor pressure of free P is very high at this temperature one end of the quartz tube was kept at a lower temperature. In this way explosions were prevented. Similar precautions were taken in the preparation of arsenides.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar.

Digitized by Arya Samaj Foundation Chennai and eGangotri

liquid samples were withdrawn from the adsorption traps and counted by means of a cylindrical, well-type scintillation counter. All experiments were performed at room temperature.

Results.—The results obtained are summarized in Table I. It can be seen that InP reacts readily in acid solutions to form volatile hydrides of phosphorus. This result is to be expected in view

of the fact that PH_3 is best prepared from AlP and H_2SO_4.[4] PH_3 prepared in this way usually contains traces of P_2H_4. It is of interest to note that InP reacts with HCl solutions, dilute or hot concentrated HNO_3, but it does not react with concentrated HNO_3 at room temperature. In this respect InP behaves like germanium which exhibits chemical passivity in concentrated HNO_3.[5] Similarities in crystalline structure and physical properties between the $A^{III}B^{V}$ intermetallic compounds and the Group IV_A elements are already known.[2] GaAs reacts to a lesser extent in acid solutions than does InP. AsH_3 is presumably formed in this reaction; it is the only known hydride of arsenic and its preparation from arsenides, such as Zn_3As_2, with H_2SO_4

(4) L. Moser and A. Brukl, *Z. anorg. Chem.*, **121**, 73 (1922).
(5) M. C. Cretella and H. C. Gatos, to be submitted for publication to the *J. Electrochem. Soc.*

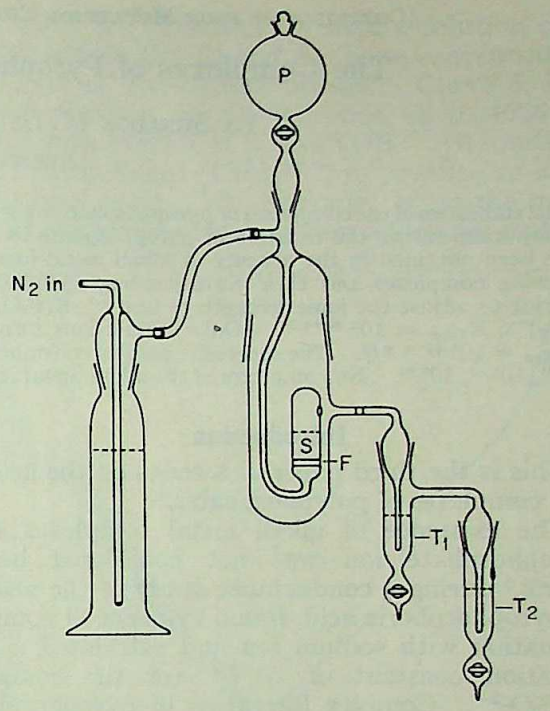

Fig. 1.—Apparatus for studying the hydrolysis of intermetallic compounds.

is well known.[6] GaAs, like InP, becomes passive in concentrated HNO_3 at room temperature. GaSb reacts to an even lesser extent in acid solutions than does GaAs. The formation of SbH_3 is known to take place by the action of H_2SO_4 on Sb–Mg alloys.[7] Apparently, SbH_3 can be prepared in any appreciable amounts in the presence of excessive nascent hydrogen.

From the above it follows that InP and, in general, all $A^{III}P$ compounds should be considered as potential health hazards when in contact with acid solutions. Arsenides and antimonides also represent potential hazards in acid solutions but to a lesser degree than the corresponding phosphides.

It should be pointed out that the amounts of volatile hydrides recovered in the adsorption traps do not represent quantitatively the extent of hydrolysis of the above intermetallic compounds. Since the hydrides are rather unstable, particularly that of antimony, they undoubtedly undergo a certain amount of decomposition in the solution. In this study, however, we were concerned only with that portion of volatile products which persists in the gaseous phase and, thus, constitute a health hazard.

The Complexes of Pyrophosphate Ion with Alkali Metal Ions

BY SHELDON M. LAMBERT[1] AND JAMES I. WATTERS[2]

RECEIVED MARCH 18, 1957

The stabilities of the complexes of pyrophosphate ion with sodium, potassium and lithium ions have been calculated from the *p*H lowering during the titration of pyrophosphate ion with hydrogen ion. The acidity constants of pyrophosphoric acid have been obtained in the absence of alkali metal ions and compared with those of ortho- and triphosphoric acid. The following complexes and their corresponding complexity constants were obtained at 25° using tetramethylammonium chloride to adjust the ionic strength to unity. $K(P_2O_7)^{3-}$, $K_{Kpy} = 10^{0.80 \pm 0.06}$; $Na(P_2O_7)^{3-}$, $K_{Napy} = 10^{1.00 \pm 0.06}$; $Li(P_2O_7)^{3-}$, $K_{Lipy} = 10^{2.39 \pm 0.06}$. Only lithium ions formed an acidic complex with the ligand ($HP_2O_7^{3-}$); $Li(HP_2O_7)^{2-}$, $K_{LiHpy} = 10^{1.03 \pm 0.06}$. The successive acidity constants of pyrophosphoric acid at 25° and unity ionic strength were $10^{0.82}$, $10^{1.81}$, $10^{6.13}$, $10^{8.93}$. No complexes of the alkali metal ions with orthophosphate ion were detected.

Introduction

This is the third paper of a series on the acidity and complexes of polyphosphates.[3,4]

The existence of alkali metal complexes with pyrophosphate ion was not considered before Monk,[5] during a conductance study of the acidity of pyrophosphoric acid, found evidence of complex formation with sodium ion and calculated a dissociation constant of $10^{-2.45}$ for the complex, $NaP_2O_7^{3-}$. Complex formation of pyrophosphate with alkali metal ion is of considerable importance since alkali metal ions usually are added to adjust ionic strength or as a source of pyrophosphates.

The classic conductivity measurements of Abbott and Bray[6] yielded reliable values for the acidity constants of pyrophosphoric acid, particularly the first and second constants, while Kolthoff and Bosch[7] obtained excellent values for the third and fourth ionization constants extrapolated to infinite dilution. The tendency of pyrophosphate to form complexes with many metals through chelate ring formation has been the subject of numerous studies.[8-16]

In the present study the acidity constants of pyrophosphoric acid were evaluated at various ionic strengths in the presence of tetramethylammonium chloride with alkali metal ions absent. As in the second paper of this series[4] on triphosphate complexes with alkali metal ions the lowering of the apparent acidity constants of pyrophosphoric acid in the presence of an excess of various alkali metal ions was used as a means of evaluating the extent of complex formation.

Theoretical

If an acid can be titrated in the presence of a relatively large excess of metal ion without precipitate formation, it is possible to investigate complex formation by the lowering of the *p*H. When the inflections at the various equivalence points persist for the stepwise addition or removal of hydrogen ions, the calculations are greatly simplified. In this case, it is evident that each ligand adds one hydrogen ion in a stepwise manner even though the ligand may also be bound to a metal ion. Under these conditions it is expedient to define a function which is called the apparent acidity constant,[11] K'_{4-n}, for this stepwise addition of hydrogen ion as

$$K'_{4-n} = \frac{[H^+]\Sigma q(M_m(H_nP_2O_7)_q^{(q(4-n)-m)-})}{\Sigma q(M_m(H_{n+1}P_2O_7)_q^{(q(3-n)-m)-})} \quad (1)$$

where m, n and q indicate the number of metal, hydrogen and pyrophosphate ions in any particular species. In this paper parentheses indicate concentrations and brackets indicate activities. The number of bound hydrogen ions, n, has a single value from zero to four if the addition of hydrogen ion is stepwise while m and q may have several values if several complex species, and the uncomplexed ligand, as well, are in equilibrium. The general equation for the stepwise addition of hydrogen ion to pyrophosphate ion and the corresponding acidity constant are

$$H^+ + H_nP_2O_7^{(4-n)-} \rightleftharpoons H_{n+1}P_2O_7^{(3-n)-}$$

$$K_{4-n} = \frac{[H^+](H_nP_2O_7^{(4-n)-})}{(H_{n+1}P_2O_7^{(3-n)-})} \quad (2)$$

The general equation for the formation of any complex ion and the corresponding complexity constant, $\beta_{M_mH_nL_q}$, are

$$mM^+ + qH_nP_2O_7^{q(4-n)-} \rightleftharpoons M_m(H_nP_2O_7)_q^{(q(4-n)-m)-}$$

$$\beta_{M_mH_nL_q} = \frac{(M_m(H_nP_2O_7)_q^{(q(4-n)-m)-})}{(M^+)^m(H_nP_2O_7^{(4-n)-})^q} \quad (3)$$

where the subscript L indicates the ligand $P_2O_7^{4-}$.

The equations used to calculate the complex formation constants were derived by substituting equations having the forms of (2) and (3) into (1) with m and q assumed to be equal to unity.

$$K_3' = \frac{[H^+][(HP_2O_7^{3-}) + (MHP_2O_7^{2-})]}{(H_2P_2O_7^{2-})} = K_3 + K_{MHL}K_3(M^+) \quad (4)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$$K_4' = \frac{[H^+][(P_2O_7^{4-}) + (MP_2O_7^{3-})]}{(HP_2O_7^{3-}) + (MHP_2O_7^{2-})} = \frac{K_4 + K_{ML}K_4(M^+)}{1 + K_{MHL}(M^+)} \quad (5)$$

K_3 and K_4 are the acidity constants of pyrophosphoric acid, while K_{ML} and K_{MHL} are the formation constants for the complexes $M(P_2O_7)^{3-}$ and $M(HP_2O_7)^{2-}$.

From these equations it follows that the apparent acidity constants are constants if the concentration of unbound metal ion is constant, provided precautions are taken to avoid changes in activity coefficients. A high concentration of an essentially non-complexing electrolyte and relatively low concentrations of metal ion and pyrophosphate ion were used for this purpose. For the titration of pyrophosphate ion with hydrogen ion in the absence of metal ions the acidity constants can be calculated by the following form of eq. 1. In the presence of metal ions K'_{4-n} is calculated by the same equation

$$K_{4-n} = \frac{[H^+][(n + 1 - a)C_p - K_w/[H^+]f + H^+/f]}{(a - n)C_p + K_w/[H^+]f - [H^+]/f} \quad (6)$$

where a is the number of moles of hydrogen ion per mole of pyrophosphate ion present in any form. The symbol f indicates the activity coefficient of a univalent ion. If the acid is not too dilute the constants have the same value as the pH at $a = n + 1/2$.

Experimental

The source of pyrophosphate ion for most of the experiments was $Na_4P_2O_7 \cdot 10H_2O$, Mallinckrodt analytical reagent grade. The pyrophosphoric acid was prepared from sodium pyrophosphate by the use of the acid form of the ion-exchange resin Dowex 50-X12, 100–200 mesh, low porosity in a manner exactly analogous to that described for the preparation of triphosphoric acid.[3] Potassium pyrophosphate was prepared by heating anhydrous dipotassium hydrogen phosphate at 500 to 700° for 3 hr.[8] Lithium pyrophosphate was prepared in the same manner as lithium triphosphate in the previous study using the exchange resin Dowex 50-X12 charged with lithium ions. All other reagents and the general experimental procedure are described in the previous paper.[4]

The titrations were performed in an aqueous thermostat adjusted to 25 ± 0.1° using the Beckman model G pH meter equipped with a "general purpose" glass electrode.

The $H_4P_2O_7$ or $((CH_3)_4N)_4P_2O_7$ solutions obtained from the columns were tested for removal of sodium ion.[3] The extent of hydrolysis of $((CH_3)_4N)_4P_2O_7$ was tested by titrations and found to be negligible after periods of one week if the solution was stored in a freezer at −15°. Crowther and his co-workers[17,18] studied the hydrolysis of pyrophosphoric acid and found it to be acid catalyzed but not base catalyzed. In the present study no appreciable hydrolysis was observed if the tetramethylammonium pyrophosphate solution was left at room temperature for one hour.

Results and Discussion

The Acidity of Pyrophosphoric Acid.—Since all previous studies of the acidity of pyrophosphoric acid at large ionic strength were made in the presence of alkali metal ions, the acidity constants were re-evaluated using tetramethylammonium chloride to adjust the ionic strength but with alkali metal ions absent.

Curve 1, Fig. 1, was obtained for the titration of 0.02968 $M((CH_3)_4N)_4P_2O_7$ with a solution containing 0.2805 M HCl and the same concentration of $H_4P_2O_7$ as the solution titrated. Curve 5, Fig. 1, was obtained for the titration of 0.04524 M $H_4P_2O_7$ with 0.08901 M $(CH_3)_4NOH$. All solutions contained sufficient $(CH_3)_4NCl$ to produce an ionic strength of unity. The ordinate "a" is the number of equivalents of acid or base added per mole of

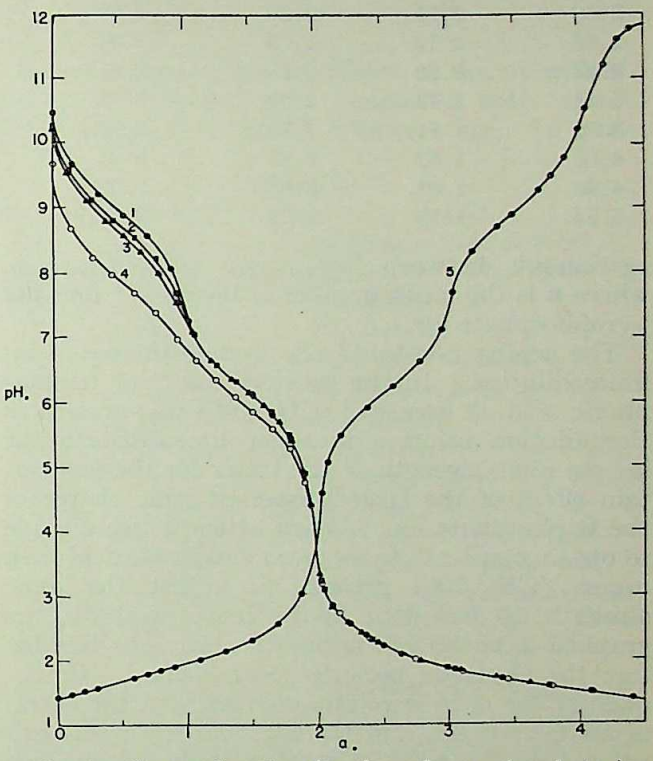

Fig. 1.—Curves for the titration of pyrophosphate ion with hydrochloric acid and the titration of pyrophosphoric acid with tetramethylammonium hydroxide. A comparison of the effects of potassium, sodium and lithium ion on the titration curve of pyrophosphate ion with hydrochloric acid. Curve 1, 0.02968 M $((CH_3)_4N)_4P_2O_7$ titrated with a solution 0.2805 N in HCl and 0.02968 M in $H_4P_2O_7$; curve 2, similar to curve 1, but 0.12 M in K^+; curve 3, 0.12 M in Na^+; curve 4, 0.12 M in Li^{++}; curve 5, 0.04524 M $H_4P_2O_7$ titrated with a solution 0.08901 M $(CH_3)_4NOH$. All solutions adjusted to $\mu = 1$ with $(CH_3)_4NCl$.

pyrophosphate present in any form. The titration curves for pyrophosphoric acid indicate that the first two hydrogen ions are highly dissociated and that the values for their ionization constants are not widely separated. Therefore, Bjerrum's method was used to evaluate these constants in the same manner as for triphosphoric acid.[3] The expression for the stepwise complexity constants is

$$\beta_n = \frac{(H_nP_2O_7^{(4-n)-})}{[H^+]^n(P_2O_7^{4-})}$$

where parentheses indicate concentrations and brackets indicate activities.

Due to the absence of appreciable concentrations of the species $P_2O_7^{4-}$ and $HP_2O_7^{3-}$ at pH values below 3 the simultaneous solution of Bjerrum's formation equation[3] for β_3 and β_4 in groups of two yielded the values of log $\beta_3 = 1.81 \pm 0.05$ and log $\beta_4 = 2.63 \pm 0.05$. Converting to the usual stepwise acidity constants the values are $pK_2 = 1.81 \pm 0.05$ and $pK_1 = 0.82 \pm 0.05$. Table I shows the

agreement between $\bar{n}_{experimental}$ and $\bar{n}_{theoretical}$, where $\bar{n}$ is the mean number of bound H^+ ions per pyrophosphate ion.

The acidity constants also were evaluated at infinite dilution. In the previous study of triphosphoric acid an excess of $(CH_3)_4NCl$ was present in the dilution solution in order to substitute the known ionic strength of the latter for the less certain effect of the larger dispersed ionic charge of the triphosphate ion. When attempts were made to obtain similar data for pyrophosphoric acid with excess $(CH_3)_4NCl$ present to adjust the ionic strength, as was done in the previous study, the graphed data did not approach a straight line before the electrode became poorly poised. Consequently the data were obtained without the extraneous electrolyte, and the ionic strength was calculated on the basis of total pyrophosphate ionic charge.

The values of K_2, K_3 and K_4 at concentrations approaching infinite dilution were calculated using eq. 6 which contains terms for the degree of hydrolysis and dissociation. The activity coefficients of Harned and Ehlers[19] were used. The p values of K_3 and K_4 at an ionic strength of unity were $pK_3 = 6.13$ and pK_4 8.93. At an ionic strength of 0.1, the value of pK_2, pK_3 and pK_4 were 2.22, 6.36 and 9.11, respectively. The graphic extrapolation to infinite dilution yielded $pK_2 = 2.64$, $pK_3 = 6.76$ and $pK_4 = 9.42$. It is of interest to observe that the last two constants for K_3 and K_4 are quite close to the values $pK_3 = 6.679$ and $pK_4 = 9.391$ obtained by Kolthoff and Bosch using a hydrogen electrode with sodium ion added as the pyrophosphate salt. It is evident from the magnitude of the sodium complexes constant that the latter should not affect their result at infinite dilution.

On the basis of these results the dilution experiments for triphosphoric acid were repeated using the same conditions. These revised constants are included in Table II. The agreement of our data for pyrophosphoric acid using the glass electrode with Kolthoff and Bosch's value using the hydrogen electrode supports these values.

pK_1 was determined by Bates,[20] pK_2 by Bates and Acree[21] and pK_3 by Abbott and Bray.[6] Constants

having pK values indicated by $-\infty$ were too large to measure.

The Complexes of the Alkali Metals with Pyrophosphate.—Curves 2, 3 and 4, Fig. 1, illustrate the pH lowering effect due to the presence of approximately 0.10 M potassium, sodium and lithium ions in the titration of approximately 0.03 M $((CH_3)_4N)_4P_2O_7$ with a solution containing approximately 0.28 M HCl and the same concentration of $H_4P_2O_7$ as the solution titrated. Since curves 1 to 4 coincide at "a" values beyond 2, it is evident that no complex formation occurs between any of the alkali metal ions and $H_2P_2O_7^{2-}$ or $H_3P_2O_7^{1-}$. Furthermore the reactants are sufficiently dilute so there is no measurable effect on the activity coefficients. Consequently the pH lowering at "a" values below 2 must be due to complex formation.

Comparing curve 2 obtained in the presence of potassium with curve 1, a lowering of the pH occurred only for "a" values less than unity proving the absence of detectable concentrations of potassium hydrogen pyrophosphate complexes, so eq. 5 reduced to the form

$$K_4' = K_4 + K_{KL}K_4(K^+)$$

Using the acidity constants of pyrophosphoric acid taken from the previous section and estimating the concentration of the free potassium ion to be the total concentration less the concentration of pyrophosphate ion one obtains a temporary complexity constant. More accurate values of (K^+) were then obtained on the basis of the temporary constant.

$$K^+ + P_2O_7^{4-} \rightleftharpoons KP_2O_7^{3-}$$

$$K_{KL} = \frac{(KP_2O_7^{3-})}{(K^+)(P_2O_7^{4-})} = 10^{0.80 \pm 0.06}$$

As shown in curve 3 obtained in the presence of sodium ion the pH was lowered only for "a" values less than unity proving the absence of detectable concentrations of acidic sodium complexes. Substituting the values of K_4 and the free sodium ion into eq. 7 as before, one obtains

$$Na^+ + P_2O_7^{4-} \rightleftharpoons NaP_2O_7^{3-}$$

$$K_{NaL} = \frac{(NaP_2O_7^{3-})}{(Na^+)(P_2O_7^{4-})} = 10^{1.00 \pm 0.06}$$

As shown in curve 4, Fig. 1, obtained in the presence of lithium ions, pH lowering occurred for n or "a" values less than 2 proving the presence of complexes of lithium ion with both $P_2O_7^{4-}$ and $HP_2O_7^{3-}$. Substituting the individual values for the apparent constant, K_3, and (Li^+) into eq. 5 yields the values of K_{LiHL} given in Table III for the reaction

$$Li^+ + HP_2O_7^{3-} \rightleftharpoons LiHP_2O_7^{2-}$$

$$K_{LiHL} = \frac{(LiHP_2O_7^{2-})}{(Li^+)(HP_2O_7^{3-})} = 10^{1.03 \pm 0.06}$$

	1.50	5.91	3.667	50.41	1.06
				Av.	1.03 ± 0.06

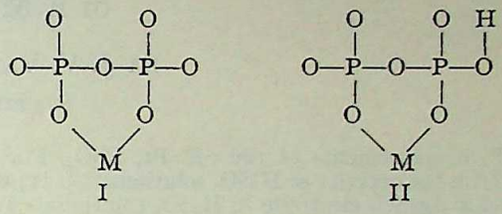
[a] C_L is the total ligand, $P_2O_7^{4-}$, concentration while C_M is the total metal ion concentration. [b] Ionic strength adjusted to unity with $(CH_3)_4NCl$, 25°.

Substituting the values for the apparent acidity constant, K_4', the acidity constant, K_4, the metal concentration, (Li^+), and the above acid complex formation constants into eq. 4 yields the values of the formation constant given in the last column of Table III for the reaction

$$Li^+ + P_2O_7^{4-} \rightleftharpoons LiP_2O_7^{3-}$$

$$K_{LiL} = \frac{(LiP_2O_7^{3-})}{(Li^+)(P_2O_7^{4-})} = 10^{2.39 \pm 0.06}$$

Regarding the structure of the complex, $MP_2O_7^{3-}$, the most pertinent information is the fact that no alkali metal complexes were obtained with orthophosphate ion even though the latter has a greater affinity than pyrophosphate ion for the first associated hydrogen ion. This eliminates the possibility that the metal ion is associated with one or two oxygen atoms of a single phosphorus atom in the pyrophosphate ion. It is possible that the metal ion is a member of a six-membered ring, structure I, which can be formed without strain. However, the bonding with the alkali metal ions is probably essentially electrostatic rather than covalent in nature so the exact position of the metal ion as a part of a chelate ring may be more a function of field strength than of bond direction. If this structure persists for the acidic complex $MHP_2O_7^{2-}$ which forms with lithium ion it seems probable that the hydrogen ion is bonded to one oxygen atom, structure II, possibly with some hydrogen bonding to the other available oxygen atom bonded with the same phosphorus atom, since two six-membered rings involving both phosphorus atoms cannot be formed without some strain. The possibility of strong bonding of a hydrogen ion to one or two oxygen atoms of a single phosphorus atom is evident from the small second and third acidic dissociation constants of orthophosphoric acid.



A comparison of the stabilities of the pyrophosphate and triphosphate complexes with alkali metals shown in Table IV is interesting. In general, the constants of the triphosphate complexes are $10^{0.56 \pm 0.1}$ larger than those of pyrophosphate. As suggested by Martell and Schwarzenbach[11] for the calcium complex this may be due to a tridentate structure involving two six-membered rings containing oxygens bound to all three phosphorus atoms. However, the following factors also may be responsible. The statistical probability of complex formation with triphosphate ion with one metal ion is greater by a factor of 2 if the metal ion enters at a chelating position or by a factor of 8/6 if the metal enters the complex at a single oxygen. Thus the statistical factor may account for $10^{0.3}$ or about half of the difference. Furthermore, the triphosphate ion has a total negative charge of 5 while pyrophosphate has a total negative charge of 4 which may be partially localized in the vicinity of the metal ion. Consequently there is a possibility that the structure of triphosphate complexes with alkali metals may be similar to those of pyrophosphate complexes.

TABLE IV

Metal ion	Ligand	log K^a
K^+	$P_2O_7^{4-}$	log K_{KPy} = 0.80 ± 0.06
K^+	$P_3O_{10}^{1-}$	log K_{KTp} = 1.37 ± 0.06
K^+	$HP_2O_7^{3-}$	Not detected
K^+	$HP_3O_{10}^{4-}$	Not detected
Na^+	$P_2O_7^{4-}$	log K_{NaPy} = 1.00 ± 0.06
Na^+	$P_3O_{10}^{5-}$	log K_{NaTp} = 1.64 ± .06
Na^+	$HP_2O_7^{3-}$	Not detected
Na^+	$HP_3O_{10}^{4-}$	log K_{NaHTp} = 0.77 ± 0.06
Li^+	$P_2O_7^{4-}$	log K_{LiPy} = 2.39 ± 0.06
Li^+	$P_3O_{10}^{5-}$	log K_{LTp} = 2.87 ± .06
Li^+	$HP_2O_7^{3-}$	log K_{LHPy} = 1.03 ± 0.06
Li^+	$HP_3O_{10}^{4-}$	log K_{LHTp} = 1.88 ± .06

[a] Complex formation constants were obtained at an ionic strength adjusted to unity with $(CH_3)_4NCl$, 25°. Pyrophosphate is designated by Py and triphosphate by Tp.

The formation constants of the acidic complexes with either $HP_2O_7^{3-}$ or $HP_3O_{10}^{4-}$ are about $10^{1.2 \pm 0.2}$ smaller than those with hydrogen ion absent. This is consistent with our finding no detectable concentrations of the acid complexes of potassium with either $HP_2O_7^{3-}$ or $HP_3O_{10}^{4-}$ and sodium with $HP_2O_7^{3-}$ since their constants would probably be of the order of unity or smaller.

A Study of the Effect of Dissolved Ag_2SO_4 on the Activity of H_2SO_4 Solutions by Means of E.M.F. Measurements[1]

BY J. V. VAUGHAN AND M. H. LIETZKE

RECEIVED DECEMBER 17, 1956

E.M.F. measurements of the cell Pt, PbO_2, $PbSO_4$, $H_2SO_{4(m)}$, Ag_2SO_4, Ag have been used to demonstrate the effect of Ag_2SO_4 on the activity of H_2SO_4 solutions. It is pointed out that care must be used in the interpretation of data involving the use of a Ag_2SO_4 electrode in H_2SO_4 solutions. It is necessary to refer the thermodynamic functions of the H_2SO_4 to a Ag_2SO_4 solution, the concentration of which may be by no means inappreciable.

Introduction

In a previous paper[2] the solubility of Ag_2SO_4 in H_2SO_4 solutions was described as a function of H_2SO_4 concentration and temperature. It was shown that the solubility increased with H_2SO_4 concentration and that this effect became very pronounced at higher temperatures. Hence when the Ag, Ag_2SO_4 electrode is used in H_2SO_4 solutions account must be taken of the solubility of the Ag_2SO_4 in these solutions. For example, the thermodynamic functions of H_2SO_4 are not those of H_2SO_4 in pure aqueous solution but are referred to a Ag_2SO_4 solution, the concentration of which may be by no means inappreciable. In the present paper it will be shown how e.m.f. measurements of the cell Pt, PbO_2, $PbSO_4$, $H_2SO_{4(m)}$, Ag_2SO_4, Ag can be used to determine the effect of dissolved Ag_2SO_4 on the activity of H_2SO_4 solutions.

Experimental

Two types of Pt, PbO_2, $PbSO_4$ electrodes were used in the present work.

(1) Electrodes were prepared according to the method suggested by Vosburgh and Craig[3] and used by Hamer.[4] Essentially, this type of electrode consisted of a platinum wire covered with a slurry of PbO_2 and $PbSO_4$. The PbO_2 was prepared by electrolysis of a solution of $Pb(NO_3)_2$ in HNO_3. After being treated in hot H_2SO_4 the PbO_2 was mixed with $PbSO_4$ and slurried in H_2SO_4 of the concentration to be studied.

(2) Electrodes were also prepared by plating onto platinum a hard, tightly adhering deposit of PbO_2 from a 35% HNO_3 solution saturated with $Pb(NO_3)_2$. The electrodeposition was carried out at reflux temperature (*ca.* 111°). In the course of the investigation the time of deposition was varied from a few seconds to several hours and the current from 10 milliamperes to one ampere. In all cases the electrode base consisted of a spatula of platinum made by flattening a 25 mm. length of 18 gage wire on one end. The platinum was sealed in a soft glass tube for support so that the average dimensions of the exposed part were 15 × 2 × 0.25 mm. Connection to the platinum was accomplished by soldering stranded insulated copper wire to the end within the glass tube. In the first experiments the electrode was surrounded with $PbSO_4$ slurried in H_2SO_4 of the concentration to be studied. The slurry was held in place with a loose sleeve of Fiberglas or a wad of glass wool. In the later experiments this practice was abandoned and the hot, freshly plated electrode was placed directly in the sulfuric acid cell-medium. Solid $PbSO_4$ was added to the excess Ag_2SO_4 in the cell to maintain a saturated solution with respect to both components.

The Ag, Ag_2SO_4 electrode consisted of a spiral of silver wire spotted to a platinum wire which was sealed into a soft glass tube. Connection with the silver electrode was accomplished in the same fashion as with PbO_2, $PbSO_4$ electrode. The silver spiral was surrounded with crystals of Ag_2SO_4 prepared by the method described by Archibald.[5] A sufficient amount of Ag_2SO_4 was used so that the H_2SO_4 solution was saturated with Ag_2SO_4 at all temperatures. The electrodes and solution were sealed into a Fischer and Porter tube provided with the necessary flanges to hold the Teflon ends in place. This type of apparatus was suitable for use to about 140°.

The electrode assembly was heated in an electric oven provided with a circulating fan. The temperature was controlled to ±1° and was measured by means of an iron–constantan thermocouple.

Electrode and thermocouple e.m.f.'s were measured by means of a Rubicon Portable Precision Potentiometer.

Results and Discussion

In the course of the work an attempt was first made to use the type of Pt, PbO_2, $PbSO_4$ electrode described by Hamer (type 1 above). It was observed, however, that different e.m.f. values were obtained from two different platinum wires immersed in the same PbO_2, $PbSO_4$ slurry when measured against a Ag, Ag_2SO_4 electrode. Although new platinum wires were used which showed no difference in potential between each other in H_2SO_4 solutions, they sometimes showed a difference of at least 100 mv. when immersed in the PbO_2, $PbSO_4$ slurry. The same phenomenon was observed with old platinum wires that had been in contact with lead solutions. No explanation for this behavior is available, although it may be due in some way to adsorption of lead or a lead compound on the platinum.

It was possible to bring two platinum electrodes in PbO_2, $PbSO_4$ slurry to the same e.m.f. *vs.* a Ag, Ag_2SO_4 electrode by connecting them together for a short time. The agreement was temporary, however, and an e.m.f. between them returned on standing. A pair of platinum wires sealed in glass and left for several weeks in a PbO_2, $PbSO_4$ slurry still showed a difference in potential of 1.5 mv. Even annealing the wires in a muffle furnace did not significantly reduce the potential difference. Because of the difficulty of obtaining reproducible results with this type of PbO_2, $PbSO_4$ electrode, attention was directed to a study of the electrode made by plating PbO_2 on platinum (type 2 above).

Hard, mechanically resistant PbO_2 for electrode purposes has been prepared by others.[6] While not all these modifications have been investigated in the present work, the method of preparation described as type 2 seemed to offer the most promise. Merely plating PbO_2 onto platinum by electrolysis of $Pb(NO_3)_2$–HNO_3 solutions without regard to

the concentrations and temperature given did not produce a satisfactory electrode. Besides variability in initial potential from sample to sample the electrodes tended to suffer a decrease in potential with age. This and other possible sources of error in work involving the use of the PbO_2, $PbSO_4$ electrode have been considered by Brown and Zimmer.[7]

Figure 1 shows the e.m.f. values obtained with the cell Pt, PbO_2, $PbSO_4$ (type 2), $H_2SO_{4(m)}$, Ag_2SO_4-(sat.), Ag as a function of temperature and concentration. The various points on the graph were obtained in the course of several different runs at each concentration (6 in the case of 1 m H_2SO_4). A new Pt, PbO_2, $PbSO_4$ electrode was used in each run. The mean values of the e.m.f. (in millivolts) for the system at each concentration of H_2SO_4 as a function of temperature are given by the equations 1a to 1d obtained by the method of least squares.

$$E_{(0.3\ m\ H_2SO_4)} = 838.8 + 0.1041t \quad (1a)$$

$$E_{(0.5\ m\ H_2SO_4)} = 850.8 + 0.2723t \quad (1b)$$

$$E_{(1.0\ m\ H_2SO_4)} = 891.9 + 0.3406t \quad (1c)$$

$$E_{(2.0\ m\ H_2SO_4)} = 928.7 + 0.6126t \quad (1d)$$

Equations 1a to 1d were solved to give mean e.m.f. values at 25° intervals from 0 to 125°.

When the Ag, Ag_2SO_4 electrode is measured against the Pt, PbO_2, $PbSO_4$ electrode in H_2SO_4 the cell reaction is

$$2Ag + PbO_2 + 2H_2SO_4 = Ag_2SO_4 + PbSO_4 + 2H_2O \quad (2)$$

Hence the e.m.f. of the cell can be expressed by the Nernst equation in the form

$$E = E^0 - \frac{RT}{2F} \ln \frac{a_w^2}{a^2 H_2SO_4} \quad (3)$$

Therefore

$$E = E^0 - \frac{RT}{F} \ln a_w + \frac{RT}{F} \ln a_{H_2SO_4} \quad (4)$$

where $a_{H_2SO_4}$ represents the activity of H_2SO_4 in a solution saturated with Ag_2SO_4. In the present work it was not possible to obtain reproducible e.m.f. values over the entire temperature range at H_2SO_4 concentrations much below 0.3 m. If all e.m.f. measurements are referred to the values at 0.3 m and substituted into equation 4, it *follows that*

$$E_m - E_{(0.3)} = \frac{RT}{F} \ln \frac{a_{w(0.3)}}{a_{wm}} + \frac{RT}{F} \ln \frac{a_{H_2SO_4m}}{a_{H_2SO_4(0.3)}} \quad (5)$$

Equation 5 can be rearranged to give

$$\log \frac{a_{H_2SO_4m}}{a_{H_2SO_4(0.3)}} = \frac{F}{2.303RT}(E_m - E_{(0.3)}) - \log \frac{a_{w(0.3)}}{a_{wm}} \quad (6)$$

Values of $a_{H_2SO_4(m)}/a_{H_2SO_4(0.3)}$ were then calculated at 25° intervals from 0 to 125°. For convenience in representing the data and in order to facilitate comparison of $a_{H_2SO_4(m)}/a_{H_2SO_4(0.3)}$ ratios at different molalities values of the ratios were multiplied at each concentration by a constant k_m^{-1}, where $k_m = [a_{H_2SO_4(m)}/a_{H_2SO_4(0.3)}]_0$. This process normalized all the plots to unity at 0°. Values of k_m as a function of concentration both for pure H_2SO_4 solutions and for H_2SO_4 solutions saturated with Ag_2SO_4 are shown in Table I.

The a_w's in equation 6 represent the activity of water in H_2SO_4 solutions saturated with Ag_2SO_4. Since these data were not available a_w's in pure aqueous H_2SO_4 solutions were used in the calculations.[8] Since the terms $\log a_{w(0.3)}/a_{wm}$ are small compared to the $F/2.303$ $(E_m - E_{(0.3)})$ terms this introduces no very large error in the calculations. Values of a_w above 60° were derived by a linear extrapolation of the values measured between 0 and 60°.

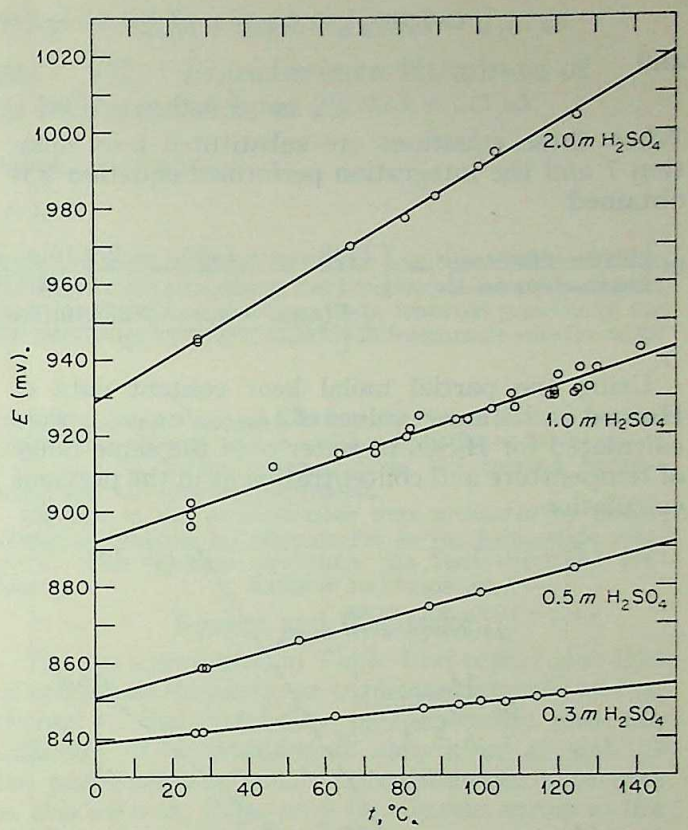

Fig. 1.—E.m.f. of the cell Pt, PbO_2, $PbSO_4$, $H_2SO_4(m)$, Ag_2SO_4, Ag as a function of temperature and H_2SO_4 concentration.

TABLE I

VALUES OF $k_m = [a_{H_2SO_4(m)}/a_{H_2SO_4(0.3)}]_0$ AS A FUNCTION OF CONCENTRATION

$m_{H_2SO_4}$	0.5	1.0	2.0
$k_{H_2SO_4}$	2.8690	14.423	109.48
$k_{H_2SO_4 + Ag_2SO_4}$	1.652	9.270	41.93

In order to compare the values of $a_{H_2SO_4}/a_{H_2SO_4(0.3)}$ measured in H_2SO_4 solutions saturated with Ag_2SO_4 with values of the same ratio measured in H_2SO_4 solutions containing no Ag_2SO_4 equation 7 was integrated over the desired temperature range.

$$\frac{\partial \ln a_m/a_{(0.3)}}{\partial T} = \frac{\bar{L}_2(T)_{(0.3)} - \bar{L}_2(T)_m}{RT^2} \quad (7)$$

In this equation a_m and $a_{(0.3)}$ refer to activities of H_2SO_4 in water and $\bar{L}_2(T)_m$ and $\bar{L}_2(T)_{(0.3)}$ to the corresponding partial molal heat content values of the H_2SO_4 which are functions of the temperature. The $\bar{L}_2(T)$ values have been determined by Hamer and can be expressed as quadratic functions of the temperature as shown in equations 8 and 8a.

$$\bar{L}_2(T)_{(.3)} = \bar{L}_2(0)_{(0.3)} + \alpha_{(0.3)}t + \beta_{(0.3)}t^2 \quad (8)$$

and

$$\bar{L}_2(T)_m = \bar{L}_2(0)_m + \alpha_m t + \beta_m t^2 \quad (8a)$$

When these equations are substituted into equation 7 and the integration performed equation 9 is obtained

$$\ln \frac{[a_{H_2SO_4m}/a_{H_2SO_4(0.3)}]_t}{[a_{H_2SO_4m}/a_{H_2SO_4(0.3)}]_0} = \left[\frac{\bar{L}_2(0)_{(0.3)} - \bar{L}_2(0)_m - 273.16(\alpha_{(0.3)} - \alpha_m) + 273.16^2(\beta_{(0.3)} - \beta_m)}{273.16RT}\right](T - 273.16) + \left[\frac{(\alpha_{(0.3)} - \alpha_m) - 2(273.16)(\beta_{(0.3)} - \beta_m)}{R}\right]\ln T/273.16 + \left[\frac{(\beta_{(0.3)} - \beta_m)(T - 273.16)}{R}\right] \quad (9)$$

Using the partial molal heat content data of Harned and Hamer[9] values of $a_{H_2SO_4m}/a_{H_2SO_4(0.3)}$ were calculated for H_2SO_4 in water over the same range of temperature and concentration as in the previous calculation.

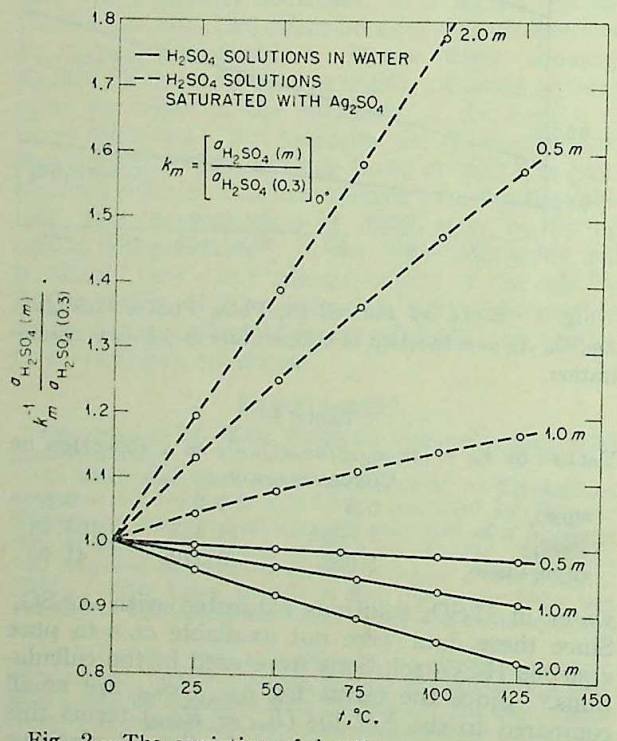

Fig. 2.—The variation of $k_m^{-1}(a_{H_2SO_4(m)}/a_{H_2SO_4(0.3)})$ as a function of temperature and H_2SO_4 concentration both in the presence and absence of Ag_2SO_4.

(9) H. S. Harned and W. J. Hamer, This Journal, **57**, 27 (1935).

Figure 2 shows the variation of k_m^{-1} $(a_{H_2SO_4(m)}/a_{H_2SO_4(0.3)})$ as a function of temperature and H_2SO_4 concentration both in the presence and absence of Ag_2SO_4. It is seen that in the absence of Ag_2SO_4 the values of the normalized ratios decrease as the temperature is raised and that values of the ratios at higher concentrations of H_2SO_4 decrease more than those at lower concentrations. In the presence of Ag_2SO_4 values of the activity ratio function increase with temperature at all the concentrations studied. However, when the H_2SO_4 is saturated with Ag_2SO_4 the plot of the $2.0m/0.3m$ ratios lies above the other two plots, while the $1.0m/0.3m$ plot lies below that for $0.5m/0.3m$. Although the activity ratios vary almost linearly with temperature in the presence of Ag_2SO_4, no simple relationship between activity and molality could be found based only on the assumption that H_2SO_4 acts like a 1–1 electrolyte and that the only important ionic species in solution are H^+, HSO_4^-, $SO_4^=$ and Ag^+. This is not surprising, however, since HSO_4^- is slightly dissociated in the concentration range studied, the dissociation being larger at the lower concentrations of H_2SO_4. Moreover, the enhanced solubility of Ag_2SO_4 in the H_2SO_4 means a further change of species in solution, while the effect of ionic strength on the second dissociation constant of H_2SO_4 provides an additional complication. No completely satisfactory explanation of the inversion in order of the plot of k_m^{-1} $(a_{H_2SO_4(2m)}/a_{H_2SO_4(0.3)})$ in the presence of Ag_2SO_4 could be obtained, although it may be tied in with the fact that the change of solubility of Ag_2SO_4 with H_2SO_4 concentration goes through a maximum in this range.[10]

Acknowledgment.—The authors wish to express their appreciation to Dr. R. W. Stoughton of the ORNL Chemistry Division for helpful discussions on the work and to M. P. Lietzke for help in performing the calculations.

Solvents Having High Dielectric Constants. VII. Transference Numbers of Potassium and Chloride Ions in Formamide at 25°[1]

BY LYLE R. DAWSON AND CARL BERGER

RECEIVED APRIL 4, 1957

Approximate transference numbers of potassium and chloride ions in formamide at 25° have been determined by the Hittorf method within the concentration range of 0.2 to 0.6 *N*. Extrapolation of a plot of the Longsworth function yielded a limiting cation transference number of 0.406. From the present results and conductance data reported previously the calculated limiting transference number of the solvated proton in a solution of hydrogen chloride in formamide was found to be 0.37 at 25°.

The electrical conductances of solutions of potassium chloride in formamide have been reported in an earlier paper[2] from this Laboratory. It was shown that the slope of the plot of Λ *vs.* $\sqrt{C}$ corresponds closely to the theoretical slope below 0.01 *N* and that potassium chloride is completely dissociated in formamide even at concentrations considerably above 0.1 *N*.

Transference data have been obtained by the moving boundary method in ethanol and in methanol[3] but numerous experimental difficulties prevented using this method for formamide solutions. The present investigation was designed to apply the Hittorf method in an attempt to obtain information concerning the relative solvent–solute interaction in this medium and in other more familiar solvents for which reliable data are available in the literature.

Experimental

Apparatus.—Use was made of the familiar type of Hittorf cell[4] which was constructed from large Pyrex glass tubing. The cell was held in a thermostated water-bath. Care was exercised to avoid exposure of the solution to the atmosphere and to prevent its contamination in any other way.

Silver and silver–silver chloride electrodes were constructed from No. 24 B. and S. gage silver wire. A device employing a 6F6 pentode tube on a power line with relatively small voltage fluctuation maintained a constant current.

A Richards silver coulometer was used in the circuit. Specially constructed weight burets were used for the transfer of larger amounts of solutions.

Salt.—Potassium chloride which had been purified especially for accurate *p*H work was purchased. The salt was dried at 110° for ten hours and used without further treatment.

Solvent.—Commercial grade formamide was distilled three times at reduced pressure over calcium oxide. The middle portion retained from the third distillation was carried through several fractional freezing cycles using the procedure described by the present authors in an earlier paper.[5] Physical properties at 25° of the solvent used were as follows: density = 1.129 g./ml.; viscosity = 0.0331 poise; dielectric constant = 109.5 at 10 mc.; conductivity = $1\text{–}5 \times 10^{-5}$ ohm^{-1} cm.$^{-1}$.

The solvent was used as promptly as possible after final purification and was protected from light while in storage.

Procedure.—Dissolution of the salt required several hours with frequent agitation of the solution. All solutions were prepared out of contact with air and dry nitrogen was bubbled through a solution for one hour before it was transferred to the cell. Lubriseal was used on the stopcocks and the usual precautions were observed to ensure tight seals and the absence of air bubbles in the cell.

After the cell had been in the thermostat long enough to establish temperature equilibrium the circuit was closed and electrolysis allowed to proceed for from 24 to 30 hours at 1–3 ma. At higher concentrations the current became larger and the time was decreased.

Changes in salt concentration were measured by potentiometric titration for chloride ion in the formamide solutions. This titration procedure has been described previously.[5]

Results and Discussion

The data presented in Table I represent averages of consistent duplicate or triplicate determinations. Owing to the instability of formamide and the difficulty of maintaining it anhydrous as well as the problems involved in potentiometric titrations in this solvent, there may be inherent errors in the results amounting to 2 or 3%.

TABLE I

POTASSIUM CHLORIDE IN FORMAMIDE

Concn. × 10^3	I (ma.)	G. of Ag$^+$ deposited	t_+
20.04	1.0	0.1247	0.40
20.80	1.0	.1214	.40
24.37	1.2	.1337	.40
28.98	1.4	.1612	.39
57.28	2.0	.1871	.38
58.91	2.2	.1917	.38

Although experimental difficulties prevented extension of the study to dilute solutions, an attempt was made to obtain an approximate value for the limiting transference number by extrapolating a plot of the Longsworth function.[6]

$$t_+^{0\prime} = (t_+\Lambda^1 + {}^1/_2\beta C^{1/2})/(\Lambda^1 + \beta C^{1/2})$$

In this expression, $\Lambda^1 = \Lambda_t - (\alpha\Lambda_0 + \beta)C^{1/2}$, $\beta = 82.42/(DT)^{1/2}\eta$ and $\alpha = 8.204 \times 10^5/(DT)^{3/2}$. D is the dielectric constant, η is the viscosity and C is the concentration in equivalents per liter. The entries in Table I correspond to the plot in Fig. 1. A value of 0.406 for the limiting transference number of the potassium ion was obtained by extrapolation of the plot; therefore, the limiting transference number of the chloride ion is 0.594. Above 3×10^{-2} *N* the plot deviates sharply from a straight line. Conductance data from another study in progress in this Laboratory, which support the general validity of these values, will be reported in a subsequent paper.

Using data from the work of Dawson, Newell and McCreary[2] with a value of approximately 29.7 ohms^{-1} cm.^{2} equiv.$^{-1}$ for the limiting equivalent conductance of potassium chloride at 25° and our value for t_{K^+}, the limiting equivalent ionic con-

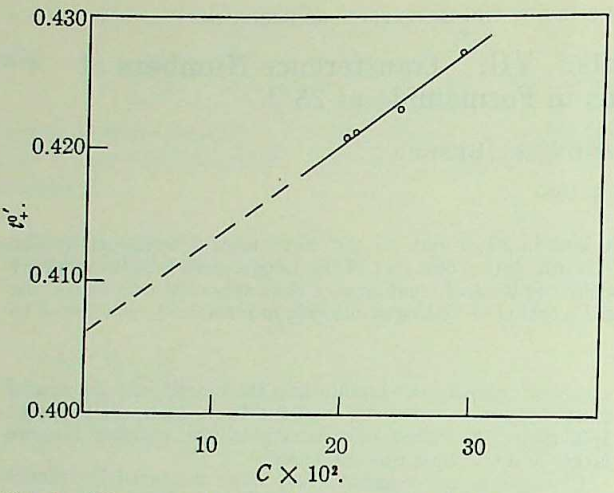

Fig. 1.—The concentration dependence of the Longsworth function for potassium chloride in formamide.

ductances become $\lambda^0_{K^+} = 12.1$, and $\lambda^0_{Cl^-} = 17.6$. Similarly from a value of 27.9 ohms^{-1} cm.$^{-2}$ equiv.$^{-1}$ for the limiting equivalent conductance of hydrogen chloride in formamide at 25°, and $\lambda^0_{Cl^-} = 17.6$, the calculated λ^0 value for the solvated hydrogen ion is 10.3 and its transference number is 0.37.

In passing from water ($t^0_{K^+}$ in KCl = 0.49) to formamide solutions the limiting transference number of the potassium ion in potassium chloride is decreased 17%. The relatively larger solute–solvent interaction with the potassium ion in the latter solvent probably is an ion–dipole effect resulting from the greater dipole moment of the formamide.[7] Evidence that the large dipole moment of formamide produces strong ion–dipole forces appears also in the decrease in transference numbers of the solvated proton from 0.82 in water to 0.37 in formamide. In formamide dissociated protons are held by the solvent molecules with sufficient force to prevent easy transfer from molecule to molecule as occurs in aqueous solutions.

The limiting equivalent ionic conductance–viscosity products for the potassium ion at 25°, in ohm^{-1} cm.^{2} equiv.$^{-1}$ poise, in methanol, ethanol, formamide and water are 0.283, 0.255, 0.400 and 0.656. A complete explanation of the relative magnitudes of these values would involve not only direct ion–solvent interactions but also short-range viscosity effects resulting from the influence of the ions in modifying the normal solvent structure.

The Copper(II)–Pyridine Complexes and their Reaction with Hydroxide Ions

BY D. L. LEUSSING AND R. C. HANSEN[1]

RECEIVED FEBRUARY 21, 1957

The formation constants have been evaluated at an ionic strength of 1.0 and 25.0° for the reactions: $Cu^{++} + py \rightleftarrows Cupy^{++}$, $Cu^{++} + 2py \rightleftarrows Cupy_2^{++}$, . . ., $Cu^{++} + 5py \rightleftarrows Cupy_5^{++}$. The values found are 3.92×10^2, 2.14×10^4, 8.5×10^5, 3.5×10^6 and $1.0_6 \times 10^7$, respectively. Mixtures of these complexes react with hydroxide to form a dimer: $py_2Cu(OH)_2Cupy_2^{++}$. The constant for the reaction $2Cu^{++} + 2OH^- + 4py \rightleftarrows py_2Cu(OH)_2Cupy_2^{++}$ is $5.1 \times 10^{+24}$. The absorption spectra of each of the complexes were determined and the spectral behavior of the solutions was found to be in accordance with the interpretation based upon equilibrium concentration measurements.

Recent publications have described the formation of mixed hydroxy complexes of copper(II) with ethylenediaminetetraacetate,[2] ethylenediamine,[3] 1,10-phenanthroline,[4] α,α'-dipyridyl[5] and ammonia.[6] The hydroxide was shown to occupy a fifth or sixth coördination position on the copper in the case with bis-ethylenediamine and ethylenediaminetetraacetate. However, with 1,10-phenanthroline and α,α'-dipyridyl the coördination of copper is lower (excluding water) as only one molecule of the bidentate ligand per copper was observed in the mixed complexes. The existence of the hydroxy ammonia complex[6] was inferred from spectral evidence and its composition was assumed to be $Cu(NH_3)_3OH^+$. Only in the case of ethylenediaminetetraacetate was the constant for the formation of the mixed complex evaluated. This was found to have a pK of 11.3 for the reaction

$$CuY^- + OH^- \rightleftarrows CuYOH^=$$

The reactions of the copper–pyridine complexes were investigated in order to throw more light on the nature of the reactions of the copper ammines with hydroxide. Pyridine was chosen because it is a monodentate ligand and its activity in aqueous solutions can be determined very easily by measuring the distribution into toluene. The conventional pH method of Bjerrum[7] cannot be used in the present case to determine the nature and stability of the mixed complexes because the pyridinium ion does not exist in appreciable quantities at the pH values optimum for the reaction with hydroxide. In Bjerrum's method the concentration of

the pyridinium ions in the solution must be known so that the concentration of free pyridine can be determined using the measured pH.

It is necessary to know the stabilities of the copper–pyridine complexes before their reaction with hydroxide can be assessed. Bruehlman and Verhoek[8] report values of 2.52, 1.86, 1.31 and 0.85 for the logarithms of the successive stepwise formation constant in 0.50 M potassium nitrate, 0.100 M nitric acid and 0.0300 M cupric nitrate at 25°. Bjerrum and Nielsen[9] report corresponding values of 2.41, 1.88, 1.14 and 0.60 in 0.50 M pyridinium nitrate at 25°. However, because of a change in the experimental conditions in the present work it was deemed necessary to redetermine these constants. Distribution and pH measurements both were used to evaluate the formation constants in 0.99 M potassium nitrate, 0.030 M cupric nitrate and 0.0110 M pyridinium nitrate at 25°. The small amount of pyridinium nitrate was used so that the formation of any hydroxy complexes through reactions such as

$$Cupy_n^{++} + H_2O \rightleftharpoons Cupy_mOH^+ + (n - m - 1)py + pyH^+$$

could be detected by a discrepancy in the value of the free pyridine concentration as measured by the pH and distribution methods.

Experimental

Pyridine, Baker Analyzed Reagent was refluxed over barium oxide for 6 hours and then distilled. The fraction boiling over the range 113–114° at 743 mm. was collected. The redistilled pyridine was stored and transferred under a blanket of nitrogen. Solutions of known concentration were prepared by weight from the reagent.

Copper nitrate, 0.1565 M, was prepared from the Mallinckrodt, Reagent Grade, product and standardized electrolytically. The stock solution was made up 0.005 M in nitric acid to prevent hydrolysis. The amount of acid present was checked by the method of Blaedel and Panos.[10]

Perchloric acid, anhydrous, 0.500 M in glacial acetic acid, was prepared and standardized according to the directions of Kolthoff and Bruckenstein.[11]

Potassium nitrate, 3.05 M, was prepared from the Baker and Adamson reagent grade product.

Nitric acid, 0.504 M and sodium hydroxide, 0.1025 M, were prepared and standardized according to the usual procedures.

The pH measurements were made with a Beckman model G pH meter using a 1190-80 glass electrode. The instrument was standardized before and checked after a measurement with Beckman buffer at pH 7.00.

All solutions were prepared with air-free redistilled water and were equilibrated at 25.0 ± 0.1°.

Absorption spectra were determined using a Cary Model 14 and a Beckman DU spectrophotometer. The Beckman instrument was equipped with a cell compartment thermostated at 25.0 ± 0.2 and the Cary was in a room thermostated at 25°.

The distribution measurements were made by shaking an aqueous phase containing an initially known amount of pyridine with 15.0 ml. of toluene. The rate of equilibration was rapid. The equilibrium concentration of pyridine in the toluene phase was determined by titrating an aliquot introduced into acetic acid with the standard solution of perchloric acid. The experiments were designed so that the equilibrium volume of the aqueous phase was 30.0 ml. A preliminary run was made for each experiment to determine approximately the amount of pyridine transferred and in the final run the volume of the aqueous phase was adjusted appropriately. Also, it was necessary to know the final volume of the toluene phase to compute the results. The volume changes of the two phases accompanying pyridine transfer were calculated using values of the apparent molar volume of pyridine which were determined to be 80 ml. per mole in the aqueous phase and 76 ml. per mole in the toluene phase.

The equilibrium distribution of free pyridine between the two phases was determined in experiments in which the copper(II) nitrate was replaced by an equivalent amount of barium nitrate. At a constant ionic strength of 1.0 the distribution of free pyridine was the same within experimental error regardless of whether the solution contained 0.030 M barium nitrate or only pyridinium and potassium nitrates. It was found that the equilibrium concentration of free pyridine in the aqueous phase is given by the equation

$$(py)_w = 0.373\ (py)_{tol} + 0.064\ (py)_{tol}^2$$

The standard deviation in $(py)_w$ was found to be ±0.002 M from the results of 14 experiments throughout the range of $(py)_{tol}$ from 0.028 M to 1.130 M.

The value of pK_a for the pyridinium ion was found to be 5.51 for solutions in which barium ions replaced copper(II). As above this value was found to be independent of the type of the electrolyte as long as the ionic strength remained constant.

The Copper(II)–Pyridine Complexes.—In solutions containing copper(II) the values of $\bar{n}$, the average number of molecules of pyridine combined with a copper(II) ion, were calculated from the results of the pH and distribution measurements using the method outlined by Bjerrum.[7] The conventional pH method was used on 13 solutions in which the free pyridine concentration covered the range 1.5×10^{-4} to 0.0694 M (values of $\bar{n}$ from 0.057 to 2.82) and the distribution measurements were made on 17 solutions covering the range 0.018 to 0.388 M free pyridine ($\bar{n}$ 1.87 to 4.11).[12]

The pH of the aqueous phase was also determined in each of the distribution experiments. To determine whether or not significant hydrolysis of the copper(II) occurred in these solutions the values of pH calculated assuming no hydrolysis were compared with those observed. If significant formation of hydroxy complexes occurred this would result in an increase in the pyridinium ion concentration and the observed pH would be lower than that calculated. The agreement between the calculated and observed values of pH was found to be within 0.02–0.03 unit. Positive and negative deviations were scattered randomly. This shows that in 0.030 M copper(II) solutions the presence of 0.0110 M pyridinium nitrate is sufficient to repress the formation of appreciable amounts of the hydroxy complexes.

The values of $\bar{n}$ could then be calculated directly from the data. These values showed no tendency to level off to a value of $\bar{n}$ equal to four as the pyridine concentration was increased. Plots of the data according to the method of Rossotti and Rossotti[13] indicated the existence of complexes up to $Cupy_5^{++}$. Letting the symbol β_n represent the overall formation constant for the reaction: $Cu^{++} + npy \rightleftarrows Cupy_n^{++}$, values of β_1 and β_2 were evaluated from the plots using the method of least squares to effect the extrapolation. Values of β_3, β_4 and β_5 were obtained by using the method of least squares to obtain three simultaneous equations. The values so calculated are 392, $2.14 \times 10^{+4}$, 8.5×10^5, 3.5×10^6 and $1.0_6 \times 10^7$ for $\beta_1, \ldots \beta_5$, respectively. Values of $\bar{n}$ calculated using these constants agree with those observed with an average deviation of ±2% in the range of $\bar{n}$ from 4.11 to 2.9, ±1.8% in the range 2.6 to 1.0 and ±3% in the range 0.86 to 0.056.

Absorption spectra were determined for solutions of the aquo copper(II) ion and eleven solutions covering values of $\bar{n}$ from 0.34 to 4.1. These spectra were resolved into those

(8) R. J. Bruehlman and F. H. Verhoek, THIS JOURNAL, **70**, 1401 (1948).

(11) I. M. Kolthoff and S. Bruckenstein, THIS JOURNAL, **78**, 1 (1956).

(12) At the higher values of $\bar{n}$, the distribution method was found to be more precise. At a value of $\bar{n}$ equal to four, the error of about 1% in the determination of the free pyridine concentration introduces an error of about 3% into the calculated value of $\bar{n}$. At this same value of $\bar{n}$, an error of 0.02 pH unit in determining the pH introduces an error of 13% into $\bar{n}$. On the other hand, at the low values of $\bar{n}$ the pH measurements are better because the titration errors in the distribution experiments assume relatively large importance.

of the complexes. To do this a plot was made at each chosen wave length of the absorbance *vs.* $-\log (py)_w$. A smooth curve was drawn through the points and values from this curve together with the equilibrium constants reported above were used to obtain five simultaneous equations which were solved for the extinction coefficients of the complexes. The resolved spectra are shown in Fig. 1. Values of the absorbance of mixtures of the complexes calculated from the equilibrium constants and the values in Fig. 1 agree with those observed within 1–2%.

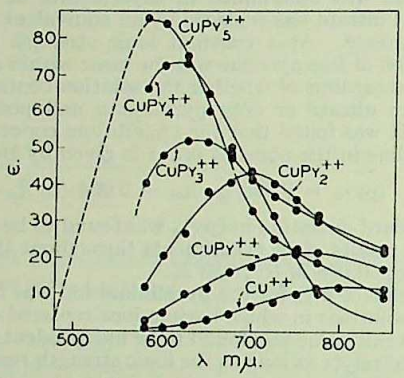

Fig. 1.—The absorption spectra of the copper(II)–pyridine complexes.

The Reaction with Hydroxide.—Most of the solutions for the study of the reaction with hydroxide were prepared in the same manner as those described above except the nitric acid was omitted, varying amounts of standard sodium hydroxide were added and the final solutions were made 1.00 *M* in potassium nitrate. Several additional distribution measurements were made on solutions which were 0.060 *M* in copper nitrate and 0.91 *M* in potassium nitrate.

It was found that the amount of sodium hydroxide taken up by the solution before the appearance of a precipitate (cupric hydroxide or basic nitrates) depends greatly on the concentration of free pyridine in the solution. Only in those solutions in which the concentration of free pyridine was 0.13 *M* or greater was it possible to add sufficient hydroxide without precipitation to obtain interpretable results. The amount of hydroxide that is held in dilute pyridine solutions was found to be less than one mole per mole of copper. However, in 10 *M* pyridine, 0.030 *M* copper nitrate it was found possible to titrate the copper with a solution of sodium hydroxide and obtain no precipitate until the molar ratio of hydroxide to copper reached 1:1.

The details for the experiments carried out in dilute pyridine solutions are given in Table I.

$Cupy_{\bar{m}}OH^+$. The value of $\bar{m}$ can be obtained using the equations

$$(Cupy_{\bar{m}}OH^+) = [OH^-] - [HNO_3] + (pyH^+)$$

$$(Cupy_{\bar{n}}^{++}) = [Cu^{++}] - (Cupy_{\bar{m}}OH^+)$$

$$\bar{m} = \frac{[py]_w - \bar{n}(Cupy_{\bar{n}}^{++}) - (py)_w - (pyH^+)}{(Cupy_{\bar{m}}OH^+)}$$

where the quantities in brackets refer to total concentrations and the quantities in parentheses refer to equilibrium concentrations. The pyridinium ion arises from hydrolysis and its concentration was calculated from pK_a and the measured values of *p*H and concentration of pyridine, $(py)_w$. The nitric acid is from the copper nitrate stock solution. The value of $\bar{n}$ was calculated using the experimental values of $(py)_w$ and the formation constants determined above.

The results of the calculations of $\bar{m}$ are presented in Table I. The deviation is calculated on the basis of an error of ±2% in the value of $\bar{n}$.

In solutions 0.030 *M* in copper(II) the value of $\bar{m}$ comes close to 2 within the experimental error.[14] Also, the values of $\bar{m}$ show no trend with increasing concentration of pyridine. Therefore, only one mixed complex of the general formula $Cupy_2OH^+$ appears to be formed under the present experimental conditions.

Apparent equilibrium constants, K_m and K_d, were calculated assuming monomer and dimer formation for the equilibria

$$Cupy_3^{++} + OH^- \rightleftarrows Cupy_2OH^+ + py$$

and

$$Cupy_3^{++} + OH^- \rightleftarrows {}^1/_2py_2Cu(OH)_2Cupy_2^{++} + py$$

These "constants" are also reported in Table I. Concentration units were used except for the hydroxide ion which is in terms of activity. The values of K_d show less relative deviation than do those of K_m. Also, better agreement is observed with the K_d values when comparing the 0.030 and 0.060 *M* copper(II) solutions. The most convincing evidence favoring the dimer formulation lies in the agreement discussed above between the calculated and observed values of *p*H in the distribution determination of $\bar{n}$. The magnitude of K_m is such that the experimental values of *p*H should have been appreciably lower than those calculated. The value of K_d is of the correct order to agree with the observations. The difference lies in the fact that the dimer concentration varies inversely as the square of the hydrogen ion concentration and, therefore, the change of about one *p*H unit in the experimental conditions exerts considerable effect on the dimer concentration.

Absorption spectra were determined for solutions 5, 6 and 10 of Table I and for a solution containing 0.0313 *M* copper nitrate, 0.496 *M* pyridine and 0.0205 *M* NaOH in 1.0 *M* KNO_3. For each solution the absorbance due to py_2Cu-

Calculations.—The results of the titration in 10 *M* pyridine show that copper and hydroxide react in the molar ratio of 1:1 to form a soluble complex. This stoichiometry is that most likely to be maintained in the experiments described in Table I as in these solutions there was always an excess of copper over hydroxide. Then analogous to the definition of $\bar{n}$, the average composition of the hydroxy complexes present in a solution can be represented by the formula,

(14) In the solutions containing 0.060 *M* copper(II) the values of $\bar{m}$ are slightly higher. These latter values are not as reliable because only slight changes in the distribution coefficient of pyridine or in the equilibrium constants with the slightly different conditions would bring about appreciable changes in $\bar{m}$. The equilibrium constants calculated from the results in 0.060 *M* solutions reflect these slight changes much less and can be compared directly with those calculated for the 0.030 *M* copper(II) solutions.

$(OH)_2Cupy_2^{++}$ was obtained by subtracting the calculated absorbance of the aquopyridino complexes from the observed absorbance. On a molar basis the resulting spectra are identical within the experimental error. In the visible, the curve consists of a single broad peak with a maximum at 625 mμ having an extinction coefficient of 57 ± 2 (mole copper)$^{-1}$ l. cm.$^{-1}$ (the extinction coefficient based on the dimer concentration is twice this value). The resolved absorption spectrum agreed very closely with that obtained directly for a 0.014 *M* solution of the dimer in 10 *M* pyridine. This latter spectrum exhibits a maximum at 625 mμ with an extinction coefficient of 61 (mole copper)$^{-1}$ l. cm.$^{-1}$. Considering the fact that in the former experiments all errors are lumped into the calculated extinction coefficients, the agreement is very good and lends support to the interpretation of the equilibrium data.

In addition, the absorption spectrum of the dimer has a very intense maximum at about 320 mμ. This was not investigated in greater detail, however.

Discussion

It is not surprising that the earlier workers[8,9] did not report the existence of $Cupy_5^{++}$ as this is formed in a region where not much reliance would be placed on the results of ordinary *p*H measurements with the glass electrode. The pyridine system is not unique as the ammonia and ethylenediamine–copper(II) systems also take up a fifth nitrogen[6,7,9,15] but with less ease. For example the value of the stepwise constant, K_5, for the formation of the pentammine from the tetrammine is 0.33 with ammonia[15] but is 30 with pyridine.

The spectral changes accompanying the uptake of the fifth ligand are also different with pyridine than with ammonia and ethylenediamine. These latter systems show a progressive shift of the absorption maximum to the blue with the uptake of successive ligand but with the addition of the fifth group a shift back toward the red is noted.[6,9] With pyridine the shift continues toward the blue with the uptake of the fifth group.

Qualitatively, the difference in the values of K_5 can be correlated with the positions of the absorption maxima of the pentammine on the basis of arguments taken from the crystal field theory.[16,17] The position of the absorption maximum reflects the contribution to the stability of the molecule caused by the splitting of the 3d orbitals of the metal ion by the field of the ligands. This energy is seen to be more favorable with pyridine than ammonia, resulting in a larger value of K_5. On this basis the copper–pyridine system is similar to the copper–dipyridyl and 1,10-phenanthroline systems which have been classified by Bjerrum and Jorgensen[17] as normal octahedral systems of coördination number 6. For the reaction

$$2Cu^{++} + 4py + 2OH^- \rightleftharpoons py_2Cu(OH)_2Cupy_2^{++}$$

the concentration constant is calculated to be $5.1 \times 10^{+24}$. This value was calculated using the values of K_d and β_3 reported herein and a value of 0.59 for the square of the hydroxide ion activity coefficient assuming this to be equal to the quantity $\gamma_H\gamma_{OH}/a_{H_2O}$ as reported by Harned and Owen.[18]

The aquo copper(II) ion also hydrolyzes to form a dimer,[19] the value of *pK* being 10.6 for the reaction

$$2Cu^{++} + 2H_2O \rightleftharpoons Cu(OH)_2Cu^{++} + 2H^+$$

The analogous reaction in the copper–pyridine system is

$$2Cupy_2^{++} + 2H_2O \rightleftharpoons py_2Cu(OH)_2Cupy_2^{++} + 2H^+$$

with a value of *pK* equal to 11.5 calculated using 1.7×10^{-14} as the value of the concentration product of water.[18] Thus, as might be expected the acidity of the dipyridinocopper(II) ion is less than that of the aquo ion.

The spectral changes occurring in the visible region with the formation of the hydroxy complex are similar with pyridine to those reported for 1,10-phenanthroline[4] and ethylenediaminetetraacetate.[2] No great change occurs in the position of the absorption maximum but the height of the maximum decreases with the uptake of the hydroxide ion. The position of the absorption maximum is not different in 10 *M* pyridine. This does not necessarily mean that the hydroxy complex does not take up more pyridine but may indicate that the binding is not strong as is the case with $Cu(NH_3)_6^{++}$.[6] The results with ethylenediamine[3] and ethylenediaminetetraacetate[2] lead one to expect higher complexes with higher pyridine concentration.

The very intense absorption maximum at about 320 mμ exhibited by the hydroxypyridine complex is more likely due to charge transfer.[20] The hydroxy ammonia complex exhibits an intense absorption in this same region. Very likely, the composition of this complex is similar to that of the pyridine complex.

Acknowledgments.—The authors wish to express their appreciation to Professor E. L. King for his valuable suggestions regarding this work.

Activity Coefficients of Electrolytes of High Charge: Tris-(ethylenediamine)-platinum-(IV) Perchlorate and Tris-(ethylenediamine)-cobalt (III) Chloride

BY C. H. BRUBAKER, JR.

RECEIVED APRIL 15, 1957

Activity and osmotic coefficients of aqueous solutions of $Pt(en)_3(ClO_4)_4$ and $Co(en)_3Cl_3$ have been determined at 25° by isopiestic comparison with KCl solutions. Measurements have been made on solutions varying from about 0.05 m to saturation. The solubilities of $Pt(en)_3(ClO_4)_4$ and $Co(en)_3Cl_3$ were found to be 0.2229 and 1.110 m, respectively. The platinum complex appears to be a strong 4-1 electrolyte, but the cobalt compound does not behave as a typical 3-1 salt.

As part of a program of investigation of the properties of solutions of electrolytes of high charge,[1,2] two additional compounds, tris-(ethylenediamine)-platinum(IV) perchlorate and tris-(ethylenediamine)-cobalt(III) chloride, which showed some promise of serving as representative electrolytes of high charge and large size, have been prepared and studied. The first seems to qualify as a 4–1 electrolyte, perhaps stronger than potassium octacyanomolybdate(IV),[2] but the cobalt complex is very different in behavior from other 3–1 chlorides.[3] Osmotic coefficients of these salts were determined by isopiestic comparison with potassium chloride solutions at 25° and activity coefficients have been derived from the osmotic coefficients.[4]

Experimental

The experimental procedure and apparatus were the same as in the previous work,[2] with the exception that the gold plated sample containers have been replaced with platinum ones. The temperature was 24.953 ± 0.005°.

Tris-(ethylenediamine)-platinum(IV) perchlorate was prepared by a quantitative metathesis reaction between $Pt(en)_3Cl_4$[2] and $AgClO_4$ in aqueous solution. An excess of freshly prepared, nitrate free, Ag_2O was treated with 0.1 M $HClO_4$ and the resulting 0.1 M $AgClO_4$ solution was separated from the excess Ag_2O by filtration. From this a 0.0580 M solution was prepared.

2.1127 g. of $Pt(en)_3Cl_4$ in 25 ml. of water was titrated with the $AgClO_4$ solution and care was taken that only a drop or two excess $AgClO_4$ was used. The silver chloride was filtered off after being digested on a steam-bath for one hour and the $Pt(en)_3(ClO_4)_4$ was recovered by evaporation. This product was dried in an oven at 70° and was weighed. 3.1532 g. of $Pt(en)_3(ClO_4)_4$ was obtained; the theoretical yield would be 3.159 g.

The $Pt(en)_3(ClO_4)_4$ was then recrystallized from water three times and was dried at 70° and stored over barium oxide. This salt occurs as a hydrate in equilibrium with water at room temperature, but much water is lost on standing in air and the compound can be completely dehydrated at 70° or by drying over barium oxide. The exact degree of hydration was not determined, but there are probably $2H_2O$ or $2.5H_2O$ (compare $Pt(en)_3(NO_3)_4 \cdot 2H_2O$[5] and $Pt(en)_3Cl_4 \cdot 2.5H_2O$).[6] The anhydrous material does not absorb moisture from the air readily and was the form weighed in these experiments.

$Co(en)_3Cl_3$ was prepared according to the method in "Inorganic Syntheses"[7] and the product was purified by recrystallizing three times from water. The trihydrate is prepared by this process, but the water is removed by drying in an oven at 100° and the anhydrous salt can be weighed conveniently.

Results and Discussion

The notation employed in this section is that used in reference 4. In Table I are given the experimental molalities and osmotic coefficients for $Pt(en)_3(ClO_4)_4$ and $Co(en)_3Cl_3$. The concentrations of the saturated solutions were found to be 0.2229 and 1.110 m, respectively. Of course the hydrated forms of the two salts are in equilibrium with these solutions, although the samples were prepared from the anhydrous compounds.

			1.110[a]	.4833	

[a] Saturated solutions.

It was found that the osmotic coefficients of both salts, up to about 0.25 m could be calculated (Table I) very well from

$$(1 - \phi)_{calc} = 0.7676 S_m(f) \sigma_m \sqrt{m} + {}^1/_2 Bm - (\Delta\phi)_{smoothed} \quad (1)$$

where

$$\Delta\phi = 0.7676 S_m(f) \sigma_m \sqrt{m} + {}^1/_2 Bm - (1 - \phi)_{obs}$$

The smoothed values are obtained by the method discussed by Scatchard and Prentiss[8] in treating freezing point data. The $\Delta\phi$ are smallest (*ca.* 1% or less) when, for $Pt(en)_3(ClO_4)_4$, $\mathring{a} = 11.5$ and $B = 2.06$ and for $Co(en)_3Cl_3$, $\mathring{a} = 3.42$ and $B = 0.610$. We notice that the sign of the linear term is positive and that the $\mathring{a}$ for $Co(en)_3Cl_3$ is much too small. This only serves to emphasize the empirical nature of equation 1. The chief virtues of this equation are that, besides giving good agreement with observed osmotic coefficients, it approaches the limiting value with the theoretical limiting slope. In the case of $Co(en)_3Cl_3$, above 0.25 m the $\Delta\phi$ become large and so calculated values are not

given at higher concentrations (it appears that a negative term in m^2 would have to be added to equation 1 to keep $\Delta\phi$ small at the higher concentrations).

We notice that $\mathring{a}$ for the platinum compound (11.5) is somewhat greater than the 8–10 Å. we might expect, if we consider the crystal radii[5] of $Pt(en)_3^{+4}$ and ClO_4^-, but perhaps it is not unreasonably large. Thus, this compound may represent a strong 4–1 electrolyte.

If equation 1 is used in treating the data for $K_4Mo(CN)_8$ instead of the simple form previously employed,[2] $\mathring{a}$ can be increased only from 4.33 to about 4.85 and the activity coefficients are changed by less than 1%. It appears, then, that the much larger $\mathring{a}$ for the platinum salt is not wholly a result of using a different extrapolation than was used for $K_4Mo(CN)_8$.

It is certain that $Co(en)_3Cl_3$ is not strong and perhaps should not even be considered a 3–1 electrolyte. The osmotic coefficients do not resemble those of other 3–1 chlorides at similar concentrations.[3] It is not surprising that this is not a strong electrolyte for conductance measurements[9] also suggest incomplete dissociation.

In view of the manner of calculating the osmotic coefficients and of the smallness of $\Delta\phi$, the activity coefficients of $Pt(en)_3(ClO_4)_4$ and of $Co(en)_3Cl_3$ (up to $m = 0.25$) were calculated by the method Smith[10] employed for sodium chloride solutions at the boiling points.

$$\ln \gamma\pm = -\frac{2.303 S_m(f)\sqrt{m}}{1 + A'_m\sqrt{m}} - Bm + \int_0^m \frac{\Delta\phi}{m}\,dm + \Delta\phi \qquad (2)$$

(9) R. Lorenz and I. Posen, *Z. anorg. allgem. Chem.*, **96**, 81 (1916).
(10) R. P. Smith, THIS JOURNAL, 61, 500 (1939).

Since $\Delta\phi$ becomes large for $Co(en)_3Cl_3$ at concentrations above 0.25 m, the values of ln $\gamma\pm$ from $m = 0.25$ to $m = 1.110$ were determined by graphical integration of

$$\ln \gamma\pm = -(1 - \phi) - 2\int_{0.25}^m \frac{(1 - \phi)}{\sqrt{m}}\,d\sqrt{m} - 1.4862 \qquad (3)$$

where 1.4862 is twice the calculated (from 2) value of the integral from $m = 0$ to $m = 0.25$.

In Table II are given the smoothed values of the osmotic and activity coefficients for solutions of $Pt(en)_3(ClO_4)_4$ and $Co(en)_3Cl_3$. Those for $Pt(en)_3(ClO_4)_4$ differ considerably from those for $K_4Fe(CN)_6$[3] and $K_4Mo(CN)_8$,[2] but that may be due to its being a stronger electrolyte. Not only is $\mathring{a}$ large, but isopiestic molalities of KCl and $Pt(en)_3(ClO_4)_4$ are nearly in a ratio of 5:2 (*i.e.*, at equilibrium, $\nu_1 m_1 \cong \nu_2 m_2$). This is not true in the case of $K_4Mo(CN)_8$.

TABLE II

Inorganic Complex Compounds Containing Polydentate Groups. XIV. The Stability of the Complexes Formed between the Nickel(II) Ion and Tetraethylenepentamine

BY HANS B. JONASSEN AND LOWELL WESTERMAN

RECEIVED APRIL 1, 1957

The basicity constants of tetraethylenepentamine and the formation constants of the complex ions formed between nickel (II) and tetraethylenepentamine were measured by the method of Schwarzenbach. The formation constant of the complex was also measured by the method of Bjerrum. The complex ions NiHtetren^{+3} and Nitetren^{+2} were found to be present in aqueous solution having log K values of 12.6 ± 0.1 and 17.6 ± 0.1, respectively, at 25°.

Introduction

The stability of complexes of various metal ions of the transition series with members of the polyethyleneamine series has been the subject of considerable investigation. Bjerrum[1] developed a method for determining the stability constants for the formation of metal amine complexes in aqueous solution which is based upon the stepwise formation of the complex ion. Jonassen, *et al.*,[2–4] extending the equations derived by Bjerrum measured the dissociation constants of diethylenetriamine and triethylenetetramine and also the formation constants of the complexes formed between these ligands and the nickel(II) ion.

Schwarzenbach[5] has pointed out that "hydrogen complexes" (complexes formed by adding one or more protons to the polyamine(s) coördinated to the metal ion) also must be considered in addition to the simple MZ_x type, where Z is the polyamine and x equals 1,2,3,. . .n. Schwarzenbach developed a method for determining these complexes from a study of neutralization curves, and studied the complexes of nickel(II) with all of the members of

the polyethyleneamine series below tetraethylenepentamine and measured their stabilities.[6-8]

Previous work in these laboratories[9] has indicated the presence of complexes of nickel(II) with tetraethylenepentamine other than the simple MZ_x type. The purpose of this investigation was to utilize the methods of Schwarzenbach and Bjerrum to identify and measure the stabilities of the complexes formed in aqueous solution.

Experimental

A. Reagents and Instruments.—Carbide and Carbon Chemicals Corporation technical grade tetraethylenepentamine (abbreviated tetren) was purified as the pentahydrochloride salt by methods developed in these laboratories.[10]

Freshly boiled distilled water was used in the preparation of all solutions. Solutions 0.00200 M in respect to tetren·5HCl and 0.15 M in respect to $KClO_4$ were prepared from the purified tetren·5HCl and Baker C.P. $KClO_4$.

G. Frederick Smith and Company reagent grade $Ni(ClO_4)_2$ and Baker C.P. potassium hydroxide were used in the preparation of the nickel perchlorate and carbonate-free base solutions. The KOH solutions were standardized by titration against primary standard potassium acid phthalate using phenolphthalein as an indicator. Nickel perchlorate solutions were standardized by quantitatively precipitating nickel as nickel dimethylglyoxime. The tetren·5HCl solutions were standardized potentiometrically by titration with standard KOH solution.

All pH determinations were made with a Beckman, model G pH meter using a glass electrode with a saturated calomel electrode as the reference electrode. The instrument was standardized against Beckman standard buffer solutions pH 4, 7 and 10.

B. "Metal-free" Curve.—The "metal-free" curve was obtained as follows. Fifty milliliters of 0.00200 M tetren·5HCl in 0.15 M $KClO_4$ was measured into a four-necked flask immersed in a constant temperature bath regulated to ±0.1°. This was diluted with 50 ml. of distilled water resulting in a solution which was 0.00100 M with respect to tetren·5HCl and 0.075 M with respect to $KClO_4$. The four-necked flask was equipped with a stirrer, glass and calomel electrodes, and nitrogen bubbler. Nitrogen was passed through the solution for at least 15 min. prior to the titration. The titration was carried out by the addition of 0.100 N KOH solution from a 5-ml. buret.

C. "Excess-metal Ion" Curve.—The "excess-metal ion" curve was obtained in the same fashion as the "metal free" curve by titrating a solution 0.00100 M in respect to tetren·5HCl, 0.075 M in $KClO_4$, and 0.0100 M in respect to nickel(II) perchlorate with 0.100 N KOH.

D. "Equivalent" Curve.—The "equivalent" curve was obtained by measuring 25 ml. of 0.00200 M tetren·5HCl in 0.15 M $KClO_4$ and 25 ml. of 0.00200 M $Ni(ClO_4)_2$ solution into 60-ml. glass-stoppered bottles. To each bottle was added various volumes of 0.0500 N KOH solution, after nitrogen had been passed through the solution for at least 15 min. The bottles were suspended in a constant temperature bath for a period of one week, after which pH measurements were made on each solution.

All the above measurements were made at 15, 25 and 35 ± 0.1°, numerous curves being taken of each type and the best curves picked for calculations. The neutralization curves obtained at 25° are shown in Fig. 1.

E. Bjerrum's Method.—For determination of the stability constant of the nickel(II)–tetren complex by the method of Bjerrum, a titration of a solution 0.000500 M in tetren·5HCl and 0.000500 M in $Ni(ClO_4)_2$ with 0.0125 N KOH was conducted in the same fashion as described above for the "equivalent" curve. This titration was only conducted at 25 ± 0.1°.

Method of Calculation and Results

A. Basicity Constants for Tetraethylenepentamine by the Method of Schwarzenbach.

—Using the general method derived by Schwarzenbach[5] the basicity constants for tetren may be calculated from the neutralization curve obtained from the titration of tetren·5HCl with KOH ("metal-free" curve). The following equilibria and equations apply to the case of tetren (abbreviated T in the following equations)

$$T + H^+ \rightleftharpoons TH^+;\ K^H_{TH} = [TH^+]/[H^+][T]$$

$$TH^+ + H^+ \rightleftharpoons TH_2^{2+};\ K^H_{TH_2} = [TH_2^{2+}]/[H^+][TH^+]$$

$$TH_2^{2+} + H^+ \rightleftharpoons TH_3^{3+};\ K^H_{TH_3} = [TH_3^{3+}]/[H^+][TH_2^{2+}]$$

$$TH_3^{3+} + H^+ \rightleftharpoons TH_4^{4+};\ K^H_{TH_4} = [TH_4^{4+}]/[H^+][TH_3^{3+}]$$

$$TH_4^{4+} + H^+ \rightleftharpoons TH_5^{5+};\ K^H_{TH_5} = [TH_5^{5+}]/[H^+][TH_4^{4+}]$$

total concn. of tetren present in soln. =

$$[T]_t = [T] + [TH^+] + [TH_2^{2+}] + [TH_3^{3+}] + [TH_4^{4+}] + [TH_5^{5+}] \quad (1)$$

If a = apparent degree of neutn. of cation acid, TH_5^{5+} = (ml. base added) (N base)/(concn. of tetren)(ml. soln.) and g = number of protons which appear on the average to be bound to tetren· = true degree of neutn., then

$$[H^+]_t = [T]_t(5 - a) = [H^+] - [OH^-] + [TH^+] + 2[TH_2^{2+}] + 3[TH_3^{3+}] + 4[TH_4^{4+}] + 5[TH_5^{5+}]$$

and

$$[T]_t \times g = [TH^+] + 2[TH_2^{2+}] + 3[TH_3^{3+}] + 4[TH_4^{4+}] + 5[TH_5^{5+}] \quad (2)$$

but

$$g = m - a + ([OH^-] - [H^+])/[T]_t \quad (3)$$

where m = maximum number of protons which may be associated with tetren = 5.

Combining equations 1, 2 and 3 the following equation is obtained

$$g + (g-1)[H^+]K^H_{TH} + (g-2)[H^+]^2\bar{K}^H_{TH_2} + (g-3)[H^+]^3\bar{K}^H_{TH_3} + (g-4)[H^+]^4\bar{K}^H_{TH_4} + (g-5)[H^+]^5\bar{K}^H_{TH_5} = 0 \quad (4)$$

where $\bar{K}^H_{TH_n}$ = product of the constants from K^H_{TH} to $K^H_{TH_n}$. The first two constants may be considered in the first approximation, allowing equation 4 to be reduced to

$$g + (g-1)[H^+]K^H_{TH} + (g-2)[H^+]^2\bar{K}^H_{TH_2} = 0 \quad (5)$$

Dividing equation 5 through by $\bar{K}^H_T$ the following equation results

$$g(1/K^H_{TH}) + (g-1)[H^+] + (g-2)[H^+]^2K^H_{TH} = 0 \quad (6)$$

if we let $x = 1/K^H_{TH}$, and $y = K^H_{TH_2}$ then

$$gx + (g-1)[H^+] + (g-2)[H^+]^2y = 0 \quad (7)$$

solving for y

$$y = -\{gx/(g-2)[H^+]^2\} - \{(g-1)[H^+]/(g-2)[H^+]^2\}$$

If $A = -g/(g-2)\ [H^+]^2$, and $B = -(g-1)\ [H^+]/(g-2)\ [H^+]^2$ then equation 7 becomes

$$y = Ax + B \quad (8)$$

which is the slope intercept form of the linear equation.

A and B may be found for a number of points on the curve where the first two constants are important (a = 3–5) and equation 8 may be solved graphically or algebraically for x and y thus yielding approximate values for K^H_{TH} and $K^H_{TH_2}$.

Using these approximate values it is now possible

(6) G. Schwarzenbach, *Helv. Chim. Acta*, **33**, 963 (1950).
(7) G. Schwarzenbach, *ibid.*, **33**, 974 (1950).

to solve for $K^{H}_{TH_3}$ by using equation 4 omitting the last two terms. $K^{H}_{TH_3}$ is thus obtained in the first approximation from

$$K^{H}_{TH_3} = \frac{-g-(g-1)[H^+]K^{H}_{TH}-(g-2)[H^+]^2\bar{K}^{H}_{TH_2}}{(g-3)[H^+]^3\bar{K}^{H}_{TH_2}} \quad (9)$$

Having found $K^{H}_{TH_3}$ to the first approximation the fourth term of equation 4 may be used to redetermine K^{H}_{TH} and $K^{H}_{TH_2}$ in the same manner as described above. By recourse to equation 9, a better value for $K^{H}_{TH_3}$ may be obtained. This process of successive approximations is repeated as many times as necessary to get consistent values for K^{H}_{TH}, $K^{H}_{TH_2}$ and $K^{H}_{TH_3}$.

The best values for these first three constants may then be used to calculate $K^{H}_{TH_4}$ and $K^{H}_{TH_5}$ using equation 4, and solving sets of simultaneous equations in two unknowns from the points on the curve between $a = 0$ and 2.

The results of these calculations are given in Table I.

TABLE I
BASICITY CONSTANTS FOR TETREN

	Temp., °C. 15	25	35
log K^{H}_{TH}	9.90	9.78	9.60
log $K^{H}_{TH_2}$	9.51	9.38	9.23
log $K^{H}_{TH_3}$	8.22	8.14	8.09
log $K^{H}_{TH_4}$	4.94	4.83	4.73
log $K^{H}_{TH_5}$	3.17	3.15	3.12

B. Apparent Basicity Constants for Tetren in the Presence of Excess Nickel(II) Ion and Formation Constants for the Nickel–Tetren Complexes by the Method of Schwarzenbach.—The apparent basicity constants of tetren in the presence of excess nickel(II) ion may be calculated from the neutralization curve obtained by titrating tetren·5HCl in the presence of a tenfold excess of the nickel(II) ion, with KOH. Since only a small fraction of the nickel(II) ion is removed from the solution due to complex formation the concentration $[Ni^{2+}]$ may be considered to be practically constant.

This "excess-metal ion" curve then follows equation 10 where $'K^{H}$ refers to the apparent basicity constants. This equation has the same form as equation 4.

$$g+(g-1)[H^+]\,'K^{H}_{TH}+(g-2)[H^+]^2\,'\bar{K}^{H}_{TH_2}+(g-3)[H^+]^3\,'\bar{K}^{H}_{TH_3}+(g-4)[H^+]^4\,'\bar{K}^{H}_{TH_4}+(g-5)[H^+]^5\,'\bar{K}^{H}_{TH_5}=0 \quad (10)$$

From this equation may be calculated the apparent basicity constants in a manner similar to that described above for the basicity constants. In the case of the nickel(II) ion with tetren, however, a buffer zone ($a = 1$ to $a = 4$) characteristic of a "three-proton in one step" process is indicated as shown in Fig. 1, so that the terms $(g-2)[H^+]^2\,'\bar{K}^{H}_{TH_2}$ and $(g-3)[H^+]^3\,'\bar{K}^{H}_{TH_3}$ are smaller in comparison to the preceding and following terms in equation 10. Equation 10 may then be reduced to

$$g+(g-1)[H^+]\,'K^{H}_{TH}+(g-4)[H^+]^4\,'\bar{K}^{H}_{TH_4}+(g-5)[H^+]^5\,'\bar{K}^{H}_{TH_5}=0 \quad (11)$$

The constants $'K^{H}_{TH}$, $'\bar{K}^{H}_{TH_4}$ and $'\bar{K}^{H}_{TH_5}$ may be obtained by solving sets of simultaneous equations in three unknowns using successive points on the "excess-metal ion" curve. By appropriate division, $'K^{H}_{TH}$, $'K^{H}_{TH_2}$, $'\bar{K}^{H}_{TH_3}$, $'K^{H}_{TH_4}$ and $'K^{H}_{TH_5}$ may be obtained. The results of these calculations are given in Table II.

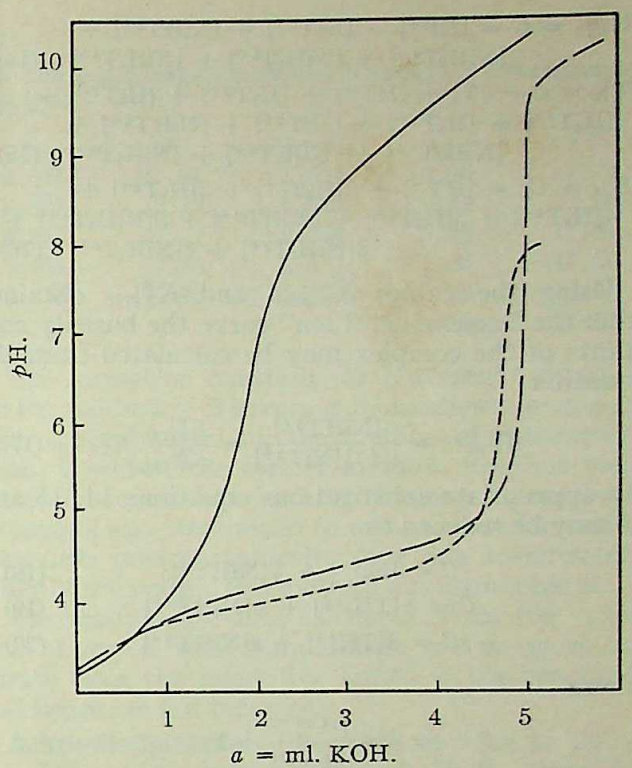

Fig. 1.—Neutralization curves at 25°: ———, "metal free" curve; — — —, "equivalent" curve; – – – – –, "excess metal ion" curve.

TABLE II
APPARENT BASICITY CONSTANTS OF TETREN IN PRESENCE OF TENFOLD EXCESS OF NICKEL(II) ION

	Temp., °C. 15	25	35
log $'K^{H}_{TH}$	5.08	5.11	5.09
log $'K^{H}_{TH_2}$ $'K^{H}_{TH_3}$ $'K^{H}_{TH_4}$	12.87	12.46	12.13
log $'K^{H}_{TH_5}$	3.18	3.15	3.13

From consideration of the equilibria of the nickel(II) ion with tetren the following equations may be derived to determine the formation constants $K^{Ni}_{NiHT^{+3}}$ and $K^{Ni}_{NiT^{+2}}$

$$K^{Ni}_{NiHT^{3+}} = \frac{1}{[Ni^{2+}]}\left[\frac{\bar{K}^{H}_{TH_2}K^{H}_{TH_3}K^{H}_{TH_4}K^{H}_{TH_5}}{'K^{H}_{TH_2}\,'K^{H}_{TH_3}\,'K^{H}_{TH_4}\,'K^{H}_{TH_5}}-1\right] \quad (12)$$

$$K^{Ni}_{NiT^{2+}} = \frac{1}{[Ni^{2+}]}\left[\frac{\bar{K}^{H}_{TH_5}}{'\bar{K}^{H}_{TH_5}}-1\right] \quad (13)$$

These equations are derived on the assumption that no polynuclear complexes are formed. The proof of the absence of polynuclear complexes is obtained if the value of $K^{Ni}_{NiT^{2+}}$ obtained from the "excess-metal ion" curve agrees with that calculated, as follows, from the "equivalent" curve.

The "equivalent" curve is obtained through the neutralization of tetren·5HCl in the presence of an equal molar quantity of the nickel(II) ion. Since the concentration $[Ni^{2+}]$ of the free nickel(II) ion is not constant, equation 10 is not applicable. If the assumption is made that no complexes with more than one T per complex species is formed then the equations may be written

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$$[Ni^{2}]_t = C = [Ni^{2+}] + [NiT^{2+}] + [NiHT^{3+}] + [NiH_2T^{4+}] + [NiH_3T^{5+}] + [NiH_4T^{6+}] \quad (14)$$

$$[T]_t = C = [T] + [HT^{+}] + [H_2T^{2+}] + [H_3T^{3+}] + [H_4T^{4+}] + [H_5T^{5+}] + [NiT^{2+}] + [NiHT^{3+}] + [NiH_2T^{4+}] + [NiH_3T^{5+}] + [NiH_4T^{6+}] \quad (15)$$

$$[H]_t = Cg = [HT^{+}] + 2[H_2T^{2+}] + 3[H_3T^{3+}] + 4[H_4T^{4+}] + 5[H_5T^{5+}] + [NiHT^{3+}] + 2[NiH_2T^{4+}] + 3[NiH_3T^{5+}] + 4[NiH_4T^{6+}] \quad (16)$$

Using the values $K^{Ni}_{NiHT^{3+}}$ and $K^{Ni}_{NiT^{2+}}$ obtained from the "excess metal ion" curve the basicity constants of the complex may be calculated from the equation

$$K^{H}_{NiHT^{3+}} = \frac{[NiHT^{3+}]}{[H^{+}][NiT^{2+}]} = \frac{K^{Ni}_{NiHT^{3+}}}{K^{Ni}_{NiT^{2+}}} K^{H}_{TH} \quad (17)$$

By appropriate substitutions equations 14, 15 and 16 may be reduced to

$$C = [Ni^{2+}] + \gamma[NiHT^{3+}] \quad (18)$$

$$C = \alpha[TH_4^{4+}] + \gamma[NiHT^{3+}] \quad (19)$$

$$gC = \beta[TH_4^{4+}] + \delta[NiHT^{3+}] \quad (20)$$

where

$$\gamma = \frac{[H^{+}]^{-1}}{K^{N}_{HNiHT^{3+}}} + 1$$

$$\alpha = \frac{[H^{+}]^{-4} + [H^{+}]^{-3}\bar{K}^{H}_{TH} + [H^{+}]^{-2}\bar{K}^{H}_{TH_2} + [H^{+}]^{-1}\bar{K}^{H}_{TH_3} + \bar{K}^{H}_{TH_4}}{\bar{K}^{H}_{TH_4}}$$

$$\beta = \frac{[H^{+}]^{-3}\bar{K}^{H}_{TH} + 2[H^{+}]^{-2}\bar{K}^{H}_{TH_2} + 3[H^{+}]^{-1}\bar{K}^{H}_{TH_3} + 4\bar{K}^{H}_{TH_4}}{\bar{K}^{H}_{TH_4}}$$

$$\delta = \frac{K^{H}_{NiHT^{3+}}[H^{+}]}{K^{H}_{NiHT^{3+}}[H^{+}]} = 1$$

For the reaction

$$Ni^{2} + TH_4^{4+} \rightleftharpoons NiHT^{3+} + 3H^{+}; \quad K_I = \frac{[NiHT^{3+}][H^{+}]^3}{[Ni^{2+}][TH_4^{4+}]} \quad (I)$$

The concentrations $[NiHT^{3+}]$, $[H^{+}]$, $[Ni^{2+}]$ and $[TH_4^{4+}]$ thus can be obtained easily and K_I may be calculated.

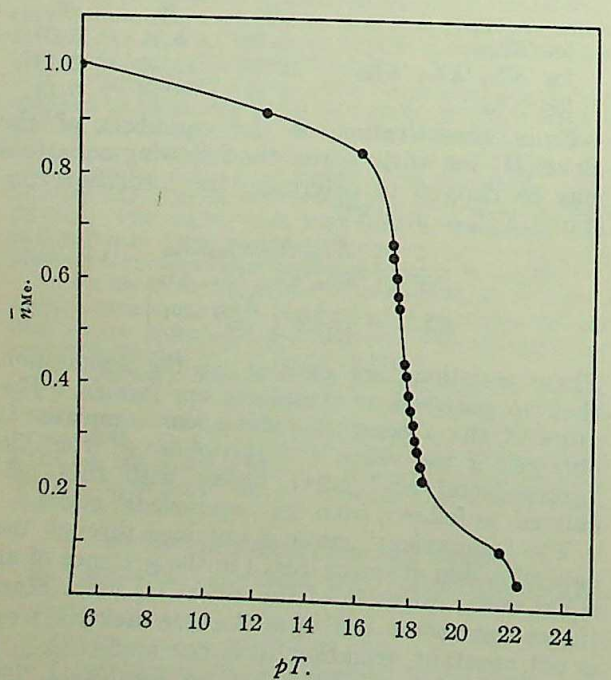

Fig. 2.—Formation curve for the complex species formed between $Ni(ClO_4)_2$ and tetren at 25°.

Having found K_I the formation constants of any of the metal complexes are easily obtained, thus for $K^{Ni}_{NiT^{2+}}$ and $K^{Ni}_{NiHT^{3+}}$ the following equations are used to calculate the constants.

$$K^{Ni}_{NiT^{2+}} = \frac{K_I\bar{K}^{H}_{TH_4}}{K^{H}_{NiHT}} \quad (21)$$

$$K^{Ni}_{NiHT^{3+}} = \frac{K^{H}_{TH_5^{5+}}}{K_I} \quad (22)$$

The results of the calculations for these constants are given in Table III.

TABLE III

FORMATION CONSTANTS FOR NICKEL(II)–TETREN COMPLEXES

C. Formation Constants by the Method of Bjerrum.—The calculation of the formation constants for metal ions with amines has been described by Bjerrum[1] and the extension of his equations has been given by Jonassen, *et al.*,[2,3] for the formation constants of metal ions with polyamines. The acid constants used in the calculations were those measured by Jonassen, Frey and Schaafsma.[11] The formation curve obtained is shown in Fig. 2, and the results of the calculations are given in Table IV, where

C_{Me} = total concn. of metal ion
C_{HCl} = total concn. of HCl
C_T = total tetren concn. in the soln.
C_A = concn. of hydrogen ions bound to uncomplexed tetren
$\bar{n}_T$ = av. no. of hydrogen ions bound to tetren = C'_A/C'_T
C'_T = total concn. of tetren not bound to the metal ion

$$\bar{n}_{Me} = \frac{(C_T - C_A)/\bar{n}_T}{C_{Me}}$$

$$\log K = pT + \log \bar{n}_{Me}/(1 - \bar{n}_{Me})$$

Discussion

The basicity constants of tetren given in Table I are slightly higher than those reported by Jonassen, Frey and Schaafsma.[11] This is as would be expected due to the higher ionic strength at which they were determined.

Comparison of the apparent basicity constant $'K^{H}_{TH_5}$ with the basicity constant $K^{H}_{TH_5}$ shows equality of the two constants. This indicates that no complex formation takes place in the region $a = 0$ to $a = 1$, which is in agreement with conclusions drawn previously.[9] Only the product of the apparent basicity constants, $'K^{H}_{TH_2}$ $'K^{H}_{TH_3}$ $'K^{H}_{TH_4}$ could be calculated in the buffered region of the "Excess-metal ion" curve, $a = 1$ to $a = 4$, indicating a "three-proton in one step" neutralization and complex formation process is taking place. This

TABLE IV

FORMATION CONSTANT CALCULATED BY METHOD OF BJERRUM FOR THE EQUILIBRIUM BETWEEN NICKEL(II) PERCHLORATE AND TETREN AT 25°

pH	$C_{Mo} \times 10^4$	$C_{HCl} \times 10^3$	C_T	C_A	$\bar{n}_T$	pT	$C_T - C'_T$	$\bar{n}_{Mo}$	log K
4.26	4.505	1.014	4.505	0.9590	3.547	17.91	1.801	0.40	17.73
4.29	4.484	0.9524	4.484	.9011	3.527	17.83	1.929	.43	17.70
4.33	4.464	.8929	4.464	.8461	3.502	17.71	2.048	.46	17.69
4.39	4.405	.7154	4.405	.6747	3.464	17.59	2.457	.56	17.69
4.44	4.386	.6579	4.386	.6216	3.433	17.45	2.570	.59	17.60
								Av. log K	17.68

may be illustrated by the equation

$$Ni^{2+} + tetrenH_4^{4+} \rightleftharpoons [Ni\ Htetren]^{3+} + 3H^+$$

The formation constant for the "hydrogen" complex formed in this process was calculated, the results being given in Table III.

The agreement of the formation constants calculated from the "Excess-metal ion" curve and the "Equivalent" curve indicates that no polynuclear complexes are formed. Thus for the over-all neutralization process and complex formation the following equations are descriptive.

$$tetrenH_5^{5+} \xrightarrow[-H^+]{} tetrenH_4^{4+} \xrightarrow[-3H^+]{Ni^{2+}} NiHtetren^{3+} \xrightarrow[-H^+]{} Nitetren^{2+}$$

The formation constant for Nitetren^{2+} obtained by the method of Bjerrum is in excellent agreement with that obtained by the method of Schwarzenbach; however, the former method does not yield formation constants for the "hydrogen complex." Attempts also were made to measure the formation constants polarographically, but due to irreversibility of the system this method was unsuccessful.

Thermodynamic data calculated from the variation of log K with temperature are no more accurate than the reliability limits of the constants and hence are not reported.

Inorganic Complex Compounds Containing Polydentate Groups. XVI. A Study of the Complex Ions Formed by the Copper(II) Ion with Triethylenetetramine, Tetraethylenepentamine and Pentaethylenehexamine[1]

BY HANS B. JONASSEN, J. AARON BERTRAND, FRANK R. GROVES, JR., AND ROBERT I. STEARNS

RECEIVED APRIL 6, 1957

The complexes of the copper(II) ion with triethylenetetramine, tetraethylenepentamine and pentaethylenehexamine have been studied polarographically. It has been shown that the copper(II) ion exhibits an amine coördination number of five with these compounds and that hydrogen complexes are formed.

Introduction

The polarographic study of complex ions is a well established method[2] provided that the complex ion to be investigated is reduced reversibly at the dropping mercury electrode. If a plot of $E_{d.e.}$ *versus* the corresponding values of log $(i_d - i)/i$ from equation I is a straight line with slope 2.303 (RT/nF) the reduction process is reversible.

$$E_{d.e.} = E_{1/2} + 2.303\ RT/nF \log (i_d - i)/i \qquad (I)$$

Where

$E_{d.e.}$ = voltage at the dropping mercury electrode
$E_{1/2}$ = half-wave potential of the complex
i_d = diffusion current
i = current at any $E_{d.e.}$
n = number of electrons transferred

The composition of the complex can be determined from the equation

$$(E_{1/2})_c - (E_{1/2})_a = 2.303\ RT/nF \log K_c - 2.303\ RT/nFp \log C_x \qquad (II)$$

Where

$(E_{1/2})_c$ = half-wave potential of the complex
$(E_{1/2})_a$ = half wave potential of the simple aquo metal ion
K_c = dissociation constant of the complex
p = no. of moles of ligand per mole of metal ion in the complex
C_x = concn. of ligand in moles/l. (C_x must be in considerable excess over the concn. of the metal ion in order that the concn. of the simple aquo metal ion will be negligible.)

A plot of $(E_{1/2})_c$'s of several solutions of varying C_x *versus* log C_x will yield a straight line of slope 2.303 RT/nFp from which p can be calculated.

Using the value of p established in equation II pK_c can be calculated.

The polyamines which become protonated to varying degrees depending upon the pH of the solution become a special case. Their dissociation occurs as shown in the reaction

$$H_z(H_qX)_a^{+(z+q)} \rightleftharpoons zH^+ + pHqX^{+q}$$

(1) Abstracted in part from the Master's Theses submitted to Tulane University, New Orleans, Louisana, by J. Aaron Bertrand, 1956, Frank R. Groves, Jr., 1951, and Robert I. Stearns, 1955.

Where

z = no. of protons dissociated from the acid amine
q = no. of protons associated with the amine in the complexes formed

The equilibrium constant of this dissociation is

$$K_a = \frac{[H^+]^z[H_qX^{+q}]^p}{[H_z(H_qX)_p]} \quad \text{(III)}$$

According to this notation the ligand is H_qX^{+q} and the term C_x of equation II is given by $[H_qX^{+q}]$. Also

$$[H_z(H_qX)_p] = \Sigma[(HX_p)^+] + [(H_2X)_p^{+2}] + \ldots + [H_{z+q}(X)_p] \quad \text{(IV)}$$

Solving (III) for $p \log [H_qX^{+q}]$

$$p \log [H_qX^{+q}] = zp\mathrm{H} + \log K_a + \log [H_z(H_qX)_p] \quad \text{(V)}$$

Substituting (V) into (II)

$$(E_{1/2})_c - (E_{1/2})_a = 2.303 \frac{RT}{nF} \log K_c - 2.303 \frac{RT}{nF} (zpH - \log K_a + \log [H_z(H_qX)_p] \quad \text{(VI)}$$

The reduction of a complex ion of a protonated polyamine occurs then as

$$M(H_qX)_p^{+(v+q)} + ve^- \longrightarrow M^0 + pH_qX^{+q}$$

M denotes the metal and v its oxidation state.

Combining this with the dissociation of the protonated amine the over-all reaction occurs

$$M(H_qX)^{+(v+q)} + zH^+ + ve^- \longrightarrow M^0 + H_z(H_qX)p^{+(z+q)}$$

A series of solutions may be prepared in which all the factors are constant except the pH and the $(E_{1/2})_c$'s which are measured and plotted *versus* each other. By equation VI such a plot will be a straight line of slope $2.303(RT/nF)z$ from which the value of z may be calculated.

Approximate thermodynamic values can be calculated by the usual equations.[3]

Experimental

The technical grades of triethylenetetramine (trien), tetraethylenepentamine (tetren) and the mixture of amines designated "Polyamine H" were obtained from Carbide and Carbon Chemicals.

I. **Purification of Triethylenetetramine.**—Stock solutions of trien were made by weighing out accurately proper amounts of trien which had been purified previously.[4] More dilute solutions were prepared by diluting aliquot portions of this stock solution.

II. **Purification of Tetraethylenepentamine.**—Tetren pentahydrochloride was obtained in the pure state by adding 100 g. of technical grade tetren to 100 ml. of benzaldehyde slowly and with vigorous stirring so as to avoid overheating. After the addition of the benzaldehyde the mixture was allowed to cool to room temperature with occasional stirring. At this point the mixture became quite viscous. The Schiff base separated when about 15 to 20 times its volume of water was added.

The water layer containing some unreacted tetren and other water-soluble impurities was separated from the oily Schiff base at the bottom of the beaker. About 200 ml. of concentrated HCl was then added slowly to the Schiff base. The mixture was heated after dilution with 100 ml. of water until it dissolved.

After cooling the solution in an ice-bath the tetren pentahydrochloride was precipitated with methanol. This recrystallization was repeated several times until a pure white product was obtained. The product was then washed with acetone and finally with ether, and then dried in the oven at about 80°.

Tetren pentahydronitrate was prepared similarly by using nitric acid.

The products were analyzed for primary amine nitrogen content by the Van Slyke method[5]; calcd. for tetren·5HCl, 7.54%; observed, 7.48%. Calcd. for tetren·5HNO_3, 5.56; observed, 5.65.

III. **Purification of Pentaethylenehexamine.**—About 1.5 l. of "Polyamine H" was distilled under a pressure of 10 to 20 mm. with about 1 l. of distillate being collected. Four hundred ml. of this distillate was redistilled and the fraction boiling at 220–250° (10–20 mm. pressure) was collected.

Forty milliliters of this fraction was dissolved in 250 ml. of methanol and cooled in an ice-bath. Concentrated HCl was added dropwise while stirring and a precipitate formed after the addition of about 50 ml. This was filtered, washed with acetone and ether and dried in a vacuum desiccator.

By the method of Van Slyke[5] the primary amine nitrogen content was determined; calcd. N, 6.21%; observed, 6.26%. By means of a potentiometric determination against NaOH the equivalent weight was determined; calcd., 75.19; observed, 75.13.

Aqueous stock solutions using boiled distilled water of tetren pentahydrochloride, tetren pentahydronitrate and hexen hexahydrochloride were prepared and standardized potentiometrically against NaOH. Other solutions of these amines were prepared by dilution of these stock solutions.

Stock solutions of cupric perchlorate (G. Frederick Smith Chemical Co.) and cupric nitrate were prepared using boiled distilled water and standardized electrolytically.

A carbonate-free solution of NaOH was obtained by first preparing a saturated solution of NaOH and letting it stand about a week. This was then filtered and diluted with distilled water and standardized against potassium acid phthalate.

Concentrated HCl and HNO_3 were diluted with distilled water and the stock solution standardized against NaOH.

The solutions used in the polarographic determinations of the trien and hexen complexes were prepared with the stock acid amine solutions to which a calculated amount of NaOH was added to neutralize the acid. By the addition of HNO_3 the pH for the trien complexes was varied.

The pH determinations were made with a Beckman Model G pH meter, standardized with Beckman buffer solutions (pH's of 4, 7 and 10).

The polarograph was one assembled according to the Leeds and Northrup technical manual 77-12-0-8, using Leeds and Northrup parts.

Results and Discussion

Stability Studies.—Polarograms were determined in the usual way. The $E_{1/2}$ (S.C.E.)'s for the various solutions are listed in Table I.

The polarographic data which showed reversible reduction were then used to determine the constitution of the complexes, the dissociation constants, and other thermodynamic functions. It was also shown that the reduction occurs in one step involving the transfer of two electrons.

A plot of the values of $(E_{1/2})_c$ *versus* the corresponding values of log C_{trien}, C_{tetren} and C_{hexen} resulted in a straight line whose slope indicated a value of 1 for p in the formation equation

$$Cu^{2+} + p\begin{pmatrix}\text{trien,}\\ \text{tetren}\\ \text{or}\\ \text{hexen}\end{pmatrix} \longrightarrow \left[Cu\begin{pmatrix}\text{trien,}\\ \text{tetren}\\ \text{or}\\ \text{hexen}\end{pmatrix}_p\right]^{2+}$$

where $p = 1$

Using equation II and the $E_{1/2}$ values listed in Table I, the dissociation constants of the complex ions $[Cutrien]^{2+}$, $[Cutetren]^{2+}$ and $[Cuhexen]^{2+}$ were calculated. In these calculations the value of $(E_{1/2})$s was taken to be +0.04.[6] The results of these calculations are shown in Table II.

(c) $[Cu^{2+}] = 4.0 \times 10^{-4}$ M; maximum suppressor was gelatin

TABLE II

AVERAGE pK_c VALUES

	25°	30°	35°	45°
$[Cutrien]^{2+}$		20.7		
$[Cutetren]^{2+}$	24.25		23.58	22.64
$[Cuhexen]^{2+}$	25.13		24.74	24.22

The approximate thermodynamic data of these complexes are listed in Table III. The data for the $[Cutrien]^{2+}$ complex are added for comparison.[7]

TABLE III

APPROXIMATE THERMODYNAMIC VALUES IN KCAL./MOLE

	25°	30°	35°	45°
$[Cutrien]^{2+}$				
ΔH^0		22.0		
ΔF^0		28.6		
$[Cutetren]^{2+}$				
ΔH^0	32.69		32.69	32.69
ΔF^0	33.07		33.24	32.95
$[Cuhexen]^{2+}$				
ΔH^0	19.62		19.62	19.62
ΔF^0	34.28		34.86	35.26

It has been shown that for most polyamines the amine coördination number of the copper(II) ion is less than six.[7,8]

Since a relatively large increase of the stability of the $[Cutetren]^{2+}$ ion over that of the $[Cutrien]^{2+}$ ion occurs, it is indicated that the coördination number of the copper(II) ion is greater than four, possibly five.

The pK_c of the $[Cuhexen]^{2+}$ ion is about the same as that of the $[Cutetren]^{2+}$ which seems to indicate that in both cases five copper to nitrogen bonds exist. The ΔH^0 values, however, indicate that the $[Cuhexen]^{2+}$ ion is less thermally stable than the $[Cutetren]^{2+}$ ion since its dissociation is accompanied by endothermic ΔH^0 of 19.62 kcal./mole, whereas the ΔH^0 of $[Cutetren]^{2+}$ is 32.69 kcal./mole. This would be expected since an additional amine group is present which does not seem to be bound to the copper(II) ion.

pH Studies.—Plots of $(E_{1/2})_c$ *versus* pH (Figs. 1, 2, 3) give the value of z of equation VI. For all

three complexes the maximum slope found in the *p*H regions of about 3 to 6 corresponded to a value of 3 for *z*.

Considering the species of the protonated amines existing in the *p*H regions of the study the following reactions are indicated:

For the Cu(II)–trien complexes with decreasing *p*H two reactions may occur

$$\text{Complex}_1 + 3H^+ + 2e \longrightarrow Cu^0 + \text{trien } 4H^{4+}$$
$$\text{Complex}_2 + 3H^+ + 2e \longrightarrow Cu^0 + \text{trien } 3H^{3+}$$

decreasing *p*H

This would fit the data if $\text{Complex}_1 = [\text{CuH-trien}]^{3+}$ and $\text{Complex}_2 = [\text{Cutrien}]^{2+}$

For the Cu(II)–tetren complex these three reactions fit the data.

$$\text{Complex}_1 + 3H^+ + 2e \longrightarrow Cu^0 + \text{tetren } 5H^{5+}$$
$$\text{Complex}_2 + 3H^+ + 2e \longrightarrow Cu^0 + \text{tetren } 4H^{4+}$$
$$\text{Complex}_3 + 3H^+ + 2e \longrightarrow Cu^0 + \text{tetren } 3H^{3+}$$

decreasing *p*H

if

$\text{Complex}_1 = CuH_2\text{tetren}^{4+}$
$\text{Complex}_2 = \text{CuHtetren}^{3+}$
$\text{Complex}_3 = \text{Cutetren}^{2+}$

For the Cu(II)–hexen system four reactions would explain the data

$$\text{Complex}_1 + 3H^+ + 2e \longrightarrow Cu^0 + \text{hexen } 6H^{6+}$$
$$\text{Complex}_2 + 3H^+ + 2e \longrightarrow Cu^0 + \text{hexen } 5H^{5+}$$
$$\text{Complex}_3 + 3H^+ + 2e \longrightarrow Cu^0 + \text{hexen } 4H^{4+}$$
$$\text{Complex}_4 + 3H^+ + 2e \longrightarrow Cu^0 + \text{hexen } 3H^{3+}$$

decreasing *p*H

If

$\text{Complex}_1 = CuH_3\text{hexen}^{5+}$
$\text{Complex}_2 = CuH_2\text{hexen}^{4+}$
$\text{Complex}_3 = \text{CuHhexen}^{3+}$
$\text{Complex}_4 = \text{Cuhexen}^{2+}$

This also seems to indicate that three of the copper to amine bonds in the copper(II) polyethyleneamine complexes are of about the same order of strength, far greater than the strength of the proton to amine bond. The other copper to amine bonds are of about the same order of strength as the proton to amine bond and an equilibrium is set up between them. At least three of the amine groups are bound to the copper(II) ion, the rest are protonated depending upon the *p*H of the medium.

Studies of Metallated Dye Complexes. III. Copper(II)–*o*-Azophenol Complexes

BY HANS B. JONASSEN AND ELWOOD J. GONZALES[1]

RECEIVED APRIL 22, 1957

Spectrophotometric and conductometric evidence indicates that the copper(II)–*o*-azophenol complex forms a copper(II) complex with propylene glycol in alkali in which the glycol and copper(II)–dye react in a 1:1 mole ratio. The complexes K[Cu–*o*-azophenol–OH] and Cu(II)–*o*-azophenol–H_2O were isolated from ethanolic solution.

Introduction

o-Azophenol, a dye containing hydroxy groups *ortho* to the azo group, readily forms a dye complex with transition metal ions in which the metal ion is bound to the two oxygen atoms and to the azo linkage as shown by investigations of Morgan and co-workers,[2–8] Drew and Landquist,[9] Wilson,[10] and Oliver.[11] In the present investigation dihydroxy compounds, propylene glycol (pngl) and *l*-2,3-butanediol, having free rotation of the hydroxy groups, are used to show their effect on the unsaturation of the copper(II) complex coördination sphere.

Experimental

A. Reagents.—Pngl (99+% pure), white label, Eastman Kodak Company was used without further purification.

A sample of dye prepared according to Willstätter and Benz[12] was kindly furnished by Mr. Gayle Strickland. The melting point was found to be 172–173° (lit. value 172°).

l-2,3-Butanediol, kindly furnished by Dr. R. E. Reeves, was used in polarimetric studies, $[\alpha]_D$ −12.8°.

Formamide, C.P. grade, Fisher Scientific Company, was distilled at 8 mm. pressure and the fraction boiling at 89–90° collected. The refractive index at 23° was 1.4468.

Molar solutions of pngl, *l*-2,3-butanediol, and the dye were prepared by direct weighing and dilution to volume with oxygen-free 95% ethanol prepared by bubbling nitrogen deoxygenated by alkaline pyrogallol into ethanol for at least one hour.

Aqueous molar solutions of copper(II) chloride were prepared by weighing directly reagent grade $CuCl_2 \cdot 2H_2O$, dried over partially dehydrated $CuSO_4 \cdot 5H_2O$, and diluting to volume.

A molar solution of copper(II) nitrate was prepared by dissolving reagent grade $Cu(NO_3)_2 \cdot 3H_2O$ in one liter of distilled water. A drop of C.P. concd. nitric acid was added to suppress hydrolysis. The copper(II) ion concentration was determined by electrolysis.

Aqueous molar potassium hydroxide solutions were prepared by weighing the appropriate quantities of potassium hydroxide. Standardization was against potassium acid phthalate using phenolphthalein as indicator.

B. Spectrophotometric Studies.—Absorption measurements in the visible spectral region were made with a Beckman Model B spectrophotometer using 1-cm. matched Corex cells. All solutions were diluted to 100 milliliters with oxygen-free 95% ethanol prepared by bubbling nitrogen deoxygenated by alkaline pyrogallol into ethanol for at least

one hour. Absorbancy values were determined at the wave lengths noted in the figures at 25–26°.

C. **Conductometric Studies.**—An Heath oscilloscope and a signal generator were used as a null point indicator in connection with a Leeds and Northrup slide wire potentiometer and decade resistance box. The conductance cell used was a vertical dipping type with platinized platinum electrodes. All conductometric work was carried out at 30°, under nitrogen in a constant temperature bath. In all cases the volume of the solution at the start of the titration was 100 ml. and conductances were corrected for dilution effects.

D. **Preparation of Complexes.**—Attempts to isolate the pngl complex of the Cu(II)–dye compound were unsuccessful. Instead the complexes listed below were obtained.

(1) K(Cu–dye–OH).—A compound K(Cu–dye–OH) was prepared by mixing 84 ml. (0.008 mole) of KOH, 0.002 mole of $Cu(OH)_2$, made by Segal,[13] 0.002 mole of pngl and 0.002 mole of dye. The solution turned from blue to deep red on adding the pngl and dye. A dark brown precipitate resulted. This was filtered, washed with distilled water and 150 ml. of ether until the filtrate was colorless. The residue was dried in a 120° oven overnight.

Anal. Calcd. for K(Cu–dye–OH): C, 43.44; H, 2.73; N, 8.44; ash, 38.17 (based on CuO and K_2O). Found: C, 43.39; H, 2.88; N, 8.51; ash, > 36.14 (sample popped slightly on combustion due to the —N=N— linkage).

(2) [Cu(II)–dye–H_2O].—A second compound was isolated by mixing 50 ml. of the pure pngl and 0.6 g. of the dye. The whole was stirred until some of the dye dissolved in the pngl. Then 1 g. of $Cu(NO_3)_2$ in 20 ml. of distilled water and 40 ml. of 95% ethanol was added. The solution immediately turned deep red. The whole was stirred and dissolved on the hot plate for 15 minutes. Filtration and dilution to 300 ml. with distilled water with subsequent slow evaporation to 100 ml. gave a brownish-red solution. Dilution to 200 ml. with distilled water and cooling in an ice–salt bath gave a brownish-black precipitate. The filtered and washed precipitate was dried in a 110° oven for 2 hours.

Anal. Calcd. for [Cu(II)–dye–H_2O]: C, 49.06; H, 3.43; N, 9.54; ash, 27.08 (as CuO). Found: C, 49.18; H, 3.15; N, 9.54; ash, 27.00 (as CuO).

Discussion and Results

A. **Spectrophotometric Studies.**—The spectrophotometric titration in Fig. 1 indicates that no change in absorption occurs until the two hydrogen ions liberated in the copper(II)–*o*-azophenol interaction have been neutralized. No sharp break is noted after two equivalents of KOH have been added such as was observed in the Jonassen, Cook and Wilson investigation.[14] Hence seemingly no Cu(II)–dye–hydroxy complex forms in the presence of pngl.

The change in slope occurring near 2.5 equivalents KOH is similar to a weak acid–strong base type interaction which the pngl–KOH reaction is. The pngl thus seems capable of coördinating with the Cu(II)–dye complex.

Nine equivalents of KOH are necessary to produce maximum absorption without formation of a precipitate. In Wilson's studies,[14] in the absence of pngl, seven equivalents of KOH are needed to give the maximum absorption without precipitation. If the same reaction mechanism is assumed as in Wilson's investigation,[14] *i.e.*, addition of OH^- ions to give the hydroxy complex which then decomposes to $[Cu(OH)_5]^{3-}$, then the additional two hydroxide ions in this investigation must have reacted with the pngl giving first the [copper(II)–dye–pngl]$^{2-}$ complex which then decomposes at high OH^- ion concentration again to the $[Cu(OH)_5]^{3-}$ ion.

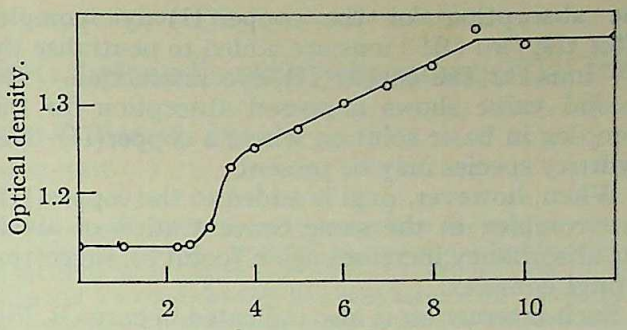

Fig. 1.—Spectrophotometric titration: 0.01 mmole copper(II)–*o*-azophenol + 0.01 mmole propylene glycol with 0.1119 *M* KOH; wave length, 525 mμ; temperature, 25–26°.

Although alcoholic hydrogens generally are not acidic, if the oxygen atoms coördinate, however, such as to a copper(II) ion in the dye complex, the resulting shift in electron density would weaken the oxygen–hydrogen bond giving enhanced acid characteristics such as reaction between tartrate and copper(II) ion in Fehling solution. If the other oxygen of the pngl behaves similarly, then two OH^- ions would be required if the pngl reacted as a bidentate ligand which would indicate a five coordinated [copper(II)–dye–pngl]$^{2-}$ complex proposed from the titration data. The sixth position of the copper(II) coördination sphere may be occupied by a solvent molecule.

The pngl and copper(II)–dye interaction with base may be shown as

$$\text{Cu(II)–dye} + \text{pngl} + 2OH^- \rightleftharpoons [\text{Cu(II)–dye–pngl}]^{2-} + 2H_2O \quad \text{(I)}$$

with decomposition of the pngl complex as further OH^- ion is added

$$[\text{Cu(II)–dye–pngl}]^{2-} + 5OH^- \rightleftharpoons [Cu(OH)_5]^{3-} + \text{dye ion} + \text{pngl ion} \quad \text{(II)}$$

Evidence for the presence of a copper(II)–dye–hydroxy complex in the absence of pngl is indicated by inspection of curve A, Fig. 2. The first value is

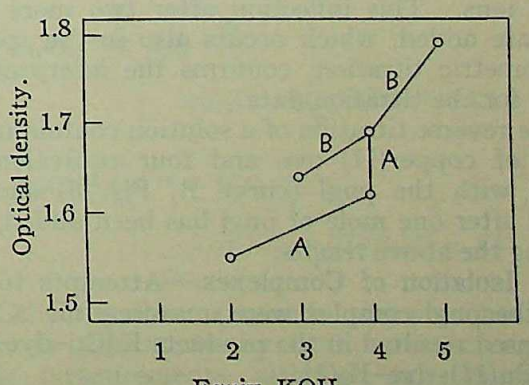

Fig. 2.—Effect of alkali on the copper(II)–*o*-azophenol and the copper(II)–*o*-azophenol + propylene glycol systems; wave length, 510 mμ; temperature, 25–26°. Curve A, points 1 and 2 contain 0.01 mmole copper(II)–*o*-azophenol; curve A, point 3 and curve B, points 1, 2, and 3 contain 0.01 mmole copper(II)–*o*-azophenol plus 0.01 mmole propylene glycol.

(13) L. Segal, Doctoral Dissertation, Tulane University, 1954.

Digitized by Arya Samaj Foundation Chennai and eGangotri

the absorption for the copper(II)–dye complex after the two OH^- ions are added to neutralize the H^+ ions for the copper(II)–dye interaction. The second value shows increased absorption for this complex in basic solution where a copper(II)–dye–hydroxy species may be present.

When, however, pngl is added to the copper(II)–dye complex in the same concentration of alkali, the absorbancy increases again (point 3), suggesting a pngl complex.

Such interaction is also indicated in curve B, Fig. 2 where, to equivalent quantities of copper(II)–dye and pngl, additions of the same 4 equivalents of OH^- ion cause increases in absorption to the same value. Addition of 5 equivalents of OH^- ion leads to point 3, curve B.

B. Conductometric Titration Studies.—Titration for a 1:1 molar ratio of the copper(II)–dye and pngl with KOH (curve A, Fig. 3) exhibits two

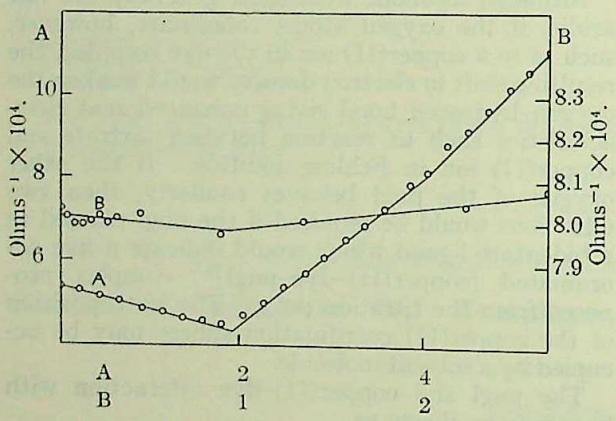

Fig. 3.—Conductometric titrations at 30°: curve A, 0.05 mmole copper(II)–*o*-azophenol in 0.05 mmole propylene glycol with 0.1119 *M* KOH; curve B, 0.05 mmole copper(II)–*o*-azophenol in 0.20 mmole KOH with 0.0236 *M* propylene glycol.

breaks: the first at the neutralization of the two hydrogen ions liberated in the copper(II)–dye reaction. The second break occurs at about four OH^- ions. This inflection after two more OH^- ions are added, which occurs also in the spectrophotometric titration, confirms the interpretation given for the titration data.

The reverse titration of a solution containing one mole of copper(II)–dye and four equivalents of KOH with the pngl (curve B, Fig. 3) shows a break after one mole of pngl has been added, confirming the above results.

C. Isolation of Complexes.—Attempts to prepare the pngl complex were unsuccessful. Conditions used resulted in the products K[Cu–dye–OH] and [Cu(II)–dye–H_2O].

In the preparation of K[Cu–dye–OH] small quantities of distilled water were used. High base concentration in the method results in the anionic complex having a coördinated OH group.

A second compound, [Cu(II)–dye–H_2O], isolated by using large amounts of water resulted in a coördinated H_2O molecule.

Depending on the method employed, the reactions may be

$$Cu(OH)_2 + \text{dye} + KOH \rightleftarrows K[\text{Cu–dye–OH}] + 2H_2O \quad \text{(III)}$$

and

$$Cu(NO_3)_2 + \text{dye} + H_2O \rightleftarrows [\text{Cu(II)–dye–}H_2O] + 2HNO_3 \quad \text{(IV)}$$

These compounds were found to be quite soluble in formamide and pngl. Determination of their absorption values at the wave length noted in Table I indicates the hydroxy complex in formamide has greater absorption than the aquo complex in the same solvent. This agrees with the data of curve A, Fig. 2, in which the dye complex in excess alkali also has greater absorption indicating a hydroxy complex.

TABLE I

System	mμ	Optical density
1×10^{-4} *M* K[Cu–dye–OH][a]	510	1.900
1×10^{-4} *M* [Cu(II)–dye–H_2O][a]	510	1.700
2×10^{-5} *M* K[Cu–dye–OH][a]	510	0.278
2×10^{-5} *M* K[Cu–dye–OH][b]	510	.382
2×10^{-5} *M* [Cu(II)–dye–H_2O][a]	510	.328
2×10^{-5} *M* [Cu(II)–dye–H_2O][b]	510	.337

[a] In formamide. [b] In pngl.

If the isolated compounds of same concentrations are dissolved in formamide and in pngl, the absorption values (Table I) are greater in both instances when pngl is added which might be another confirmation of pngl complexes. Furthermore, since the difference in optical densities in formamide and pngl for the hydroxy complex is at least tenfold over that of the aquo compound, this indicates the OH group is necessary in pngl ion formation.

It was also attempted to follow the complexing reaction polarimetrically by using *l*-2,3-butanediol, an optically active glycol. If the concentration of the glycol is kept constant, then the change in optical activity would be due to the optical activity of the [copper(II)–dye–glycol]$^{2-}$ complex. To facilitate visual observation solutions 1×10^{-5} *M* in copper(II)–dye and 3×10^{-4} *M* in glycol were used but the changes in activity were too small to be measured accurately.

The Kinetics of Aquation of *cis*-Dichloro-bis-(ethylenediamine)-chromium(III) Ion[1]

BY JOEL SELBIN[2] AND JOHN C. BAILAR, JR.

RECEIVED MARCH 30, 1957

The kinetics of acid hydrolysis of *cis*-$[Cr\ en_2Cl_2]^+$ has been studied at *p*H 1.0 at three temperatures and under various conditions of added electrolytes by a procedure which employs a chloride concentration cell to measure chloride release. The pseudo first-order rate constant for the loss of one chloride is given by $k_1 = 9.65 \times 10^{11} \exp(-21{,}100/RT)$ sec.$^{-1}$, and $\Delta S^{\ddagger} = -5.72$ e.u. A value for the specific rate constant for the loss of a second chloride has been estimated. Results of studies on the change in optical rotation of *l*-*cis*-$[Cr\ en_2Cl_2]^+$ are interpreted in terms of an initial aquation without loss of optical activity followed by racemization of the chloroaquo product. Analogies with the corresponding cobalt complexes suggest that complexes of the two metals follow similar mechanisms during acid hydrolysis. A suggestion is made as to why chromium(III) complexes resemble cobalt(III) complexes so closely.

Introduction

A large amount of kinetic data has accumulated in the literature on simple substitution reactions in octahedral complexes of the types: (I) $[MA_5X]^{+2\ or\ +1}$ and (II) $[MA_4YX]^{+1\ or\ +2}$ where M has been Co(III), Cr(III) or Ir(III) for type (I) and M has been Co(III) and, in a few cases, Cr(III) for type (II). The A represents a non-replaceable ligand and may be monodentate or polydentate, including N- and/or C-substituted polyamines. The X and Y, with X being the replaceable group, may be F^-, Cl^-, Br^-, I^-, NCS^-, NO_2^-, NO_3^-, N_3^-, $CO_3^=$, HCO_3^-, OCH_3^-, $C_2H_3O_2^-$, OH^- or H_2O.

The three types of substitution reactions which have been studied are: (1) aquation, or replacement by water in neutral or acid solution; (2) hydrolysis, or replacement by hydroxide ion in basic media; and (3) anation, or substitution of X by another anion.[3]

Although kinetic studies on complex ions were reported as early as 1911,[4] it has been only recently that the emphasis in the study of the kinetics has been on the elucidation of the mechanism by which substitution reactions occur.

Practically all of the recent work on complexes of types (I) and (II) has been concerned with the complexes of cobalt(III). These have been studied mainly by Basolo, Pearson and co-workers,[5] Taube and co-workers,[6] and by Ingold, Nyholm and Tobe[7] in aqueous solution, and by Brown, Ingold and Nyholm[8] in absolute methyl alcohol.

Relatively few kinetic experiments[9] have ever been carried out on chromium(III) complexes of type (I) and only three have concerned complexes of type (II).[9b,e,g]

Experiments by Adamson and Wilkins[9c] on the rates of aquation and exchange in the $[Cr(NH_3)_5NCS]^{+2}$ and $[Co(NH_3)_5NCS]^{+2}$ ions led them to suggest that different mechanisms for substitution may be operating for the two metals. Furthermore, the difference in electronic configuration existing between cobalt(III) and chromium(III),[10] coupled with the invariably greater rates of aquation found for chromium(III) complexes as compared with the analogous cobalt(III) complexes, might lead one to suspect a difference in mechanism. Therefore, the purpose of the work reported in this paper was to further compare the chemistry of cobalt(III) and chromium(III) complex ions. The compound chosen for study was *cis*-$[Cr\ en_2Cl_2]Cl \cdot H_2O$. The reasons for this choice are: (1) the complex is readily prepared and reasonably stable for long periods of time (months) if kept in a desiccator in the dark; (2) the corresponding cobalt(III) complex has been thoroughly studied[5,11]; (3) the complex undergoes aquation at a rate which can be followed conventionally; and (4) the complex is easily resolved into its optical isomers, allowing studies of racemization.

The aquation reaction, which has been studied, in 0.10 *N* acid solution, takes place in two steps which may be written

$$\underset{A}{cis\text{-}[Cr\ en_2Cl_2]^+} + H_2O \xrightarrow{k_1} \underset{B}{cis\text{-}[Cr\ en_2Cl(H_2O)]^{+2}} + Cl^- \quad (1)$$

$$\underset{B}{cis\text{-}[Cr\ en_2Cl(H_2O)]^{+2}} + H_2O \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \underset{C}{cis\text{-}[Cr\ en_2(H_2O)_2]^{+3}} + Cl^- \quad (2)$$

That the aquation proceeds stepwise has been shown in this study by both conductivity and kinetic measurements, although salts containing

ion B never have been isolated. As will be shown, reaction 1 proceeds at a rate approximately 10 times that of reaction 2, so that no serious interference is caused by reaction 2 in the study of reaction 1. The diaquo cation (C) is stable only in strongly acid solution and has been shown to retain the *cis* configuration.[12] It will revert to the *cis*-dichloro cation only on standing for several days in a concentrated hydrochloric acid solution or upon evaporation of a concentrated hydrochloric acid solution.[13] Therefore, under the conditions of the experiments reported here, it is reasonable to assume that equilibrium is not established either in reaction 1 or 2 and that in any case, an equilibrium in reaction 1 would lie far toward the right. Indeed, the experimental data allow an approximation of k_2 to be made.

Experimental

Preparation of Compounds.—*cis*-[Cr en_2Cl_2]Cl·H_2O was prepared according to the method described by Rollinson and Bailar.[14] The recrystallization procedure was modified as follows. The impure salt was dissolved quickly in water (4 ml. for each gram of salt) which had been acidified with several drops of concentrated hydrochloric acid and the solution was heated to about 65°. The solution was filtered rapidly into ice-cold concentrated hydrochloric acid (1.5 ml. for each gram of salt used) and the filtrate was cooled to −5° in an ice–salt mixture. The red-violet needles which came out were collected on a sintered glass funnel, washed well with alcohol and ether, and then dried in a vacuum desiccator. Equivalent conductance at zero time, Λ_{700} = 103, which is in the correct range for a uni-univalent salt containing a complex cation.[15] *Anal.* Calcd. for [Cr en_2Cl_2]Cl·H_2O: C, 16.19; H, 6.12; N, 18.88. Found: C, 16.14; H, 6.03; N, 18.40. The complex salt, *cis*-[Cr en_2Cl_2]Cl·H_2O, was resolved into its optical isomers by a modification of the method of Werner.[16] To a freshly prepared solution of [Cr en_2Cl_2]Cl·H_2O (12.0 g., 0.0404 mole) in 200 ml. water at 19° was added ammonium *d*-α-bromocamphor-π-sulfonate (22.5 g., 0.0687 mole) with vigorous stirring. The solution was kept at 19°. After several minutes the sulfonate salt separated. It was filtered and washed with alcohol and ether (10.0 g., 89.5% diastereoisomer), and was then dissolved in concentrated HCl in the ratio of 4 ml./g. To this solution was added two volumes of alcohol, which precipitated fine, dark-red crystals. These crystals were filtered, washed well with alcohol and ether, and dried in a vacuum desiccator. The yield was 3.85 g. or 71.8%. The observed rotation for a 0.075% solution was +0.235; $[\alpha]^{25}D$ +314. *Anal.* Calcd. for *l-cis*-[Cr en_2Cl_2]Cl·H_2O: C, 16.19; H, 6.12; N, 18.88; Cr, 17.28. Found: C, 16.44; H, 6.12; N, 18.50; Cr, 17.54. All other reagents were commercially available materials of reagent grade, and were used without further purification.

Kinetic Measurements.—Preliminary determinations of the rate of loss of chloride from *cis*-[Cr en_2Cl_2]$^+$ were made by titrating the ionic chloride potentiometrically with silver nitrate after the reaction had been quenched by running the aliquot being analyzed into an ice-cold 1:1 ethanol–water mixture. The results indicated that the reaction is too fast to follow conveniently by a titration technique. Therefore, a more rapid and, at the same time, a more accurate means of following the loss of chloride, was sought.

The method finally adopted was to employ a concentration cell composed of two Ag–AgCl electrodes. The cell design appears in Fig. 1. The Ag–AgCl electrodes were prepared by plating silver from a $KAg(CN)_2$ bath onto platinum plates having an area of 1 cm.^{2}, followed by anodization of the plates in a 1.0 *M* hydrochloric acid-bath at a current of 25 ma. for 10 min. Electrodes prepared in this way were stable for several months and never had an asymmetry potential greater than 0.2 mv. Between runs they were stored in 0.05 *M* hydrochloric acid in the dark. The cell was immersed in a constant temperature bath controlled to within ±0.05°. A Rubicon K-2 potentiometer and Leeds and Northrup galvanometer were employed for the potential measurements. A stock solution of standard chloride ion concentration of 0.0100 *M* was prepared from NaCl and either 0.100 *M* $HClO_4$ or 0.100 *M* HNO_3.

For runs not involving added electrolytes, the procedure was as follows: 50 ml. of standard chloride solution was placed in Vessel A. A weighed amount of complex was dissolved in 50.0 ml. of 0.100 *M* acid (either $HClO_4$ or HNO_3, but the same as was used to prepare the standard solution) which previously had been brought to the proper temperature. This solution of the complex was placed in Vessel B and the solutions from both A and B were allowed to flow into the corresponding cell compartments with the pinch clamps closed over the Tygon tubing (see Fig. 1). The clamps were released after the compartments were filled and junction was thereby made in the center bulb. All of this required just under one minute from the time the solution of the complex was prepared. The rate of chloride production in the compartment containing the complex was then continuously and readily followed by observing the change in cell potential.

The 0.100 *M* acid present in each solution served a twofold purpose. First, it prevented any reaction of hydroxyl ion from interfering with normal aquation of the complex, and second, it eliminated concern over a junction potential in the cell.

To be sure that no chloride ion transfer occurred from one cell compartment to the other during the time of a normal run, standard chloride solutions of differing concentrations were allowed to run into the cell compartments and the potential was measured periodically. No change in potential occurred over a period of time equal to that of a normal kinetic run.

The runs which involved added electrolytes were carried out in the same way except that a weighed amount of the material whose effect upon the rate of aquation was to be determined was added to 50.0 ml. of the standard solution and to 50.0 ml. of the solution of the complex to produce the desired concentration.

The run in "strong light" was made with a 60-watt bulb approximately one foot from the cell.

Racemization Measurements.—Measurements of change in optical rotation of *l-cis*-[Cr en_2Cl_2]Cl·H_2O were made in a 10 cm. jacketed polarimeter tube maintained at 21.9 ± 0.1°. The polarimeter used is a Schmidt and Haensch No. 9143. Measurements were made at the sodium-D line or approximately 5890 Å. Solutions were 0.005 *M* (0.148%) in complex and 0.100 *M* in $HClO_4$ or HNO_3. At this concentration, precision is initially poor due to the high absorbancy of yellow light by the solution. This absorbancy decreases fairly rapidly so that readings after about 20–25 minutes are more precise. The rotatory dispersion curve of this complex[17] indicates that the rotatory power is highest at a wave length of approximately 5490 Å. However, at this wave length practically all light is absorbed by the complex solution, which is red-violet in color. At the red end of the spectrum (about 6000 Å.) very little light is absorbed by the solution, but the rotatory power is small and the eye is not very sensitive to changes in light intensity. Hence, the sodium-D line was a compromise choice.

Results and Discussion

The measured potential of the concentration cell was converted to a chloride concentration by means of the relation

$$E = 2.303 \frac{RT}{nF} \log_{10} \frac{a}{x}$$

where E is the measured potential, a is the fixed standard chloride concentration, and x is the chloride concentration in the solution of the com-

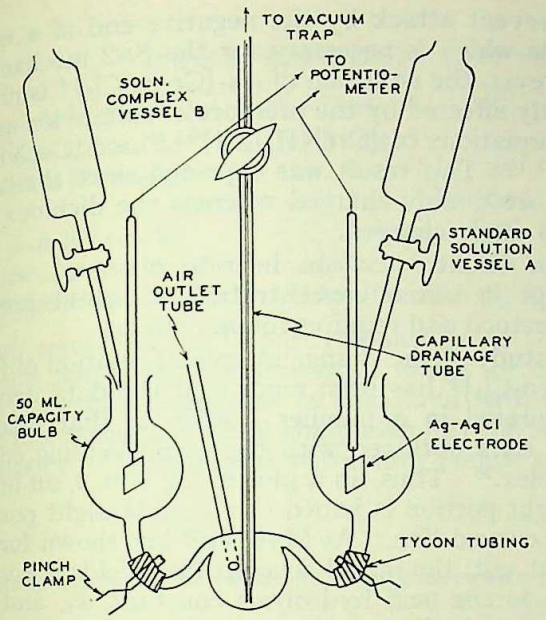

Fig. 1.—Concentration cell for measuring rate of chloride ion production.

plex at any time. The conditions at early reaction times may be represented as

$$\underset{(c - x_1)}{[Cr\ en_2Cl_2]^+} + \underset{c}{Cl_a^-} + H_2O \xrightarrow{k_1} \underset{x_1}{[Cr\ en_2ClH_2O]^{+2}} + \underset{c}{Cl_a^-} + \underset{x_1}{Cl_b^-} \quad (3)$$

At later times reaction (4) also must be considered

$$\underset{(x_1 - x_2)}{[Cr\ en_2ClH_2O]^{+2}} + \underset{c}{Cl_a^-} + \underset{x_1}{Cl_b^-} + H_2O \xrightarrow{k_2} \underset{x_2}{[Cr\ en_2(H_2O)_2]^{+3}} + \underset{c}{Cl_a^-} + \underset{x_1}{Cl_b^-} + \underset{x_2}{Cl_c^-} \quad (4)$$

The quantity measured experimentally is $(c + x_1 + x_2) = (Cl^-)$, but at early times $x_2 \sim 0$ and the value measured is $\sim (c + x_1)$. Hence, the concentration of $[Cr\ en_2Cl_2]^+$ left at any time is given by $(c - x_1)$ or $(2c - [Cl^-])$, where c is the initial concentration. Plots of log $(c - x_1)$ *vs.* time were found to be linear up to a time representing about 60% completion of reaction 3. A sample plot appears in Fig. 2. Thus, it is seen that reaction 3 is pseudo first order. The positive deviations from linearity were assumed to arise from the slower reaction indicated by eq. 4. Thus, at times greater than about 40 minutes x_2 begins to become significant and therefore account must be taken of the fact that what is really plotted is $(c - x_1 - x_2)$. By extrapolating the straight line to longer times and taking the difference between the value for the projected first-order decomposition and the actual value observed, a measure of x_2 is obtained, *i.e.*, $(c - x_1 - x_2) - (c - x_1) = -x_2$. Using the standard equation[18] for the series first-order reactions

$$\underset{(a - x_1)}{A} \xrightarrow{k_1} \underset{(x_1 - x_2)}{B} \quad ; \quad \underset{(x_1 - x_2)}{B} \xrightarrow{k_2} \underset{x_2}{C}$$

which is

$$(x_1 - x_2) = a \frac{k_1}{k_2 - k_1} (e^{-k_1 t} - e^{-k_2 t})$$

it was possible by the method of successive approximations to obtain a value for k_2 from known or measured values of a, k_1, x_1, x_2 and t.

The specific rate constant, k_1, for reaction 3 is given in Table I for the conditions specified. In most cases duplicate runs agreed within ± 2%, with ± 3% being the maximum discrepancy. The rate constant, k_2, for reaction 4 is also included, but its value should be considered less accurate due to the method by which it was obtained.

TABLE I

RATES OF ACID HYDROLYSIS OF *cis*-$[M\ en_2Cl_2]^+$ IN 0.10 *M* HNO_3

Complex	Temp., °C.	Ionic strength	k_1, sec.$^{-1}$ × 10^4	k_2, sec.$^{-1}$ × 10^5
cis-$[Cr\ en_2Cl_2]^+$	20.0	0.105	1.60	1.0
	20.0	.155[a]	1.57	..
	25.0	.105	3.30	2.8
	30.0	.105	5.88	..
cis-$[Co\ en_2Cl_2]^+$	25	.105	2.5[b]	
	25	.022[d]	1.2[c]	
	30	.022[d]	2.15[c]	
	25.0	.105	1.76[e]	

[a] 0.05 *M* $NaClO_4$. [b] Value obtained by Pearson, *et al.*[5d] [c] Values obtained by Mathieu.[11] [d] 0.012 *M* HNO_3 and 0.01 *M* complex used. [e] See Discussion.

Several rate constant values for the cobalt complex are included and, as is seen, agreement among the several values is poor. Conductivity measurements were used by Mathieu[11] in obtaining the low value; spectrophotometric measurements were used by Pearson, *et al.*,[5d] in obtaining the high value; the intermediate value was obtained in our

concentration cell. The latter measurements were not as precise as was expected, due to interaction between the cobalt complex and the Ag–AgCl electrode, preventing the rapid establishment of equilibrium conditions between solution and electrode. Thus, meaningful readings could not be taken for at least ten minutes after the solution of the complex was placed in the cell, and experimental scattering was increased. The chromium complex did not affect the electrodes in this manner. No further study of this phenomenon was made. However, as expected, the chromium complex aquates faster than the corresponding cobalt complex.

The thermodynamic data for reaction 3, which were obtained from a linear Arrhenius plot of log k *vs.* $1/T$ are: $\Delta E^{\ddagger} = 21.1$ kcal., $\Delta H^{\ddagger} = 20.5$ kcal., $\Delta F^{\ddagger}_{298^\circ} = 22.2$ kcal., $\Delta S^{\ddagger} = -5.72$ cal./deg. and log $Z = 11.98$. Corresponding values for the acid hydrolysis of the cobalt complex, *cis*-[Co en$_2$Cl$_2$]$^+$, are[11]: $\Delta E^{\ddagger} = 22.25$ kcal., $\Delta H^{\ddagger} = 21.6$ kcal., and log $Z = 14.02$. The energy required to form the activated complex is therefore similar for both metals, but is slightly lower in the case of chromium, as is expected.

Table II records the rate of acid hydrolysis at 25.0° and a pH = 1.0 (obtained with HClO$_4$) under various conditions of concentration and added electrolyte. Several conclusions can immediately be drawn. The presence or absence of light (no. 2) has no apparent effect on the reaction studied, as is apparently the case for some cobalt complexes.[7a] Variation in ionic strength (nos. 7, 8) appears to have no effect on the aquation reaction; this is in line with Mathieu's results with the cobalt complex.[11] However, chloride ion and sulfate ion (nos. 9–14) in concentrations 10-fold or greater over complex concentration appear to accelerate the aquation reaction. This can be accounted for by assuming ion-pair formation between anion and dichloro cation. If this is indeed the case, it constitutes additional support for an Sn1 or dissociation type mechanism. Thus, an ion pair [Cr en$_2$Cl$_2$]$^+$–SO$_4^=$ would induce an easier breaking of the Cr–Cl bond and at the same time would tend to prevent attack by the negative end of a water dipole which is necessary for the Sn2 mechanism. However, the aquation of *cis*-[Cr en$_2$Cl$_2$]$^+$ is not as greatly affected by the presence of sulfate ion as are the aquations of [Cr(NH$_3$)$_5$Cl]$^{+2}$ [9f] and [Co(NH$_3$)$_5$Cl]$^{+2}$.[19] This result was expected since the latter ions are doubly charged whereas the dichloro cation is singly charged.

Table II

Rates of Acid Hydrolysis of *cis*-[Cr en$_2$Cl$_2$]$^+$ under Various Conditions at 25.0° and pH 1.0 (HClO$_4$)

14	5.00	.100 M Na$_2$SO$_4$	.405	4.03

The slight variation in rate observed with a change in initial concentration is not at present understood and requires further study.

A study of the change in optical rotation of *l-cis*-[Cr en$_2$Cl$_2$]$^+$ has been made and the data may be interpreted in a manner similar to that used to treat data obtained with the corresponding cobalt complex.[20] Thus, in a plot of log α *vs.* t, an initial straight portion is joined to a final straight portion by a curved line. As Mathieu[20] has shown for the cobalt salt, the initial straight line yields a k value close to the acid hydrolysis constant, k_1, and the final straight line yields a specific rate constant for racemization of the species being formed by the first process, which in this case is *l-cis*-[Cr en$_2$Cl H$_2$O]$^{+2}$. If k_2 (Table I) is compared with k_r (Table III), it is seen that the optically active chloroaquo cation racemizes at a faster rate than it loses chloride. This is similar to what has been observed[20] in the case of the analogous cobalt complex and indicates that a different mechanism is operating to produce racemization than is operating to produce further aquation. A similar treatment has been given for the change in rotation of *d-cis*-[Co en$_2$ F$_2$]$^+$.[5f] Table III records the rates of acid hydrolysis, mutarotation and racemization for the above compounds. It appears that the initial change in rotation is due mainly to the formation of the optically active chloro-aquo compound, which then undergoes racemization.

It would seem from this work that the ions *cis*-[Co en$_2$Cl$_2$]$^+$ and *cis*-[Cr en$_2$Cl$_2$]$^+$ are not very different in their behavior, at least toward acid hydrolysis and optical change. This observation suggests that the two metal complexes follow a similar mechanism during the course of acid hydrolysis. Although the purpose of this work was not to attempt to decide upon a mechanism, the results would seem to favor for the chromium complex the Sn1 mechanism suggested by Basolo, Pearson, *et al.*,[5] for the acid hydrolysis of cobalt complexes.

If the assumption is true that both cobalt(III) and chromium(III) are using 3d^{2}4s4p^3 hybrid orbitals in their complex compounds, then the remaining three 3d orbitals are filled in cobalt and half-filled in chromium. It may well be that the strong similarity found between cobalt(III) and chromium(III) complexes is related to this fact. The similarity in reactivity between elements having the same orbital set either empty, half-filled, or filled has been noted before in both the transition and inner transition elements. Such orbital arrangements seem always to lead to greater stability than would otherwise be predicted. Thus it is suggested here that the filled orbitals in the cobalt complexes and the half-filled orbitals in the chro-

mium complexes are in part responsible for (1) the general non-labile characteristics found for cobalt and chromium complexes as compared with other first row transition metal complexes, (2) the strong similarity of cobalt and chromium complexes in ease of substitution-type reactions, and (3) the ease with which Cr(II) goes to Cr(III) in systems which can form d^2sp^3 hybrid-orbital complexes with Cr(III).

Pyridine: Experimental and Calculated Chemical Thermodynamic Properties between 0 and 1500°K.; a Revised Vibrational Assignment[1]

BY J. P. MCCULLOUGH, D. R. DOUSLIN, J. F. MESSERLY, I. A. HOSSENLOPP, T. C. KINCHELOE AND GUY WADDINGTON

RECEIVED APRIL 22, 1957

From studies by low temperature calorimetry, comparative ebulliometry, flow calorimetry and combustion calorimetry, values were obtained for the entropy, heat capacity and heat of formation of pyridine in the ideal gaseous state. The calorimetric values of entropy and heat capacity served as guides in revising the vibrational assignments for pyridine and several deuteropyridines. The revised assignment for pyridine and molecular structure data were used in computing values of the thermodynamic functions at selected temperatures between 0 and 1500°K. Values of the heat, free energy and equilibrium constant of formation were calculated at the same selected temperatures. The experimental investigations provided the following information: values of heat capacity for the solid (13–224°K.), the liquid [$C_{satd} = 33.633 - 9.1446 \times 10^{-2}T + 3.8478 \times 10^{-4}T^2 - 3.3430 \times 10^{-7}T^3$, cal. deg.$^{-1}$ mole^{-1} (240–347°K.)], and the vapor [$C_p^\circ = -8.262 + 10.608 \times 10^{-2}T - 5.4662 \times 10^{-5}T^2$, cal. deg.$^{-1}$ mole^{-1} (374–500°K.)]; the heat of fusion [1978.6 cal. mole^{-1}] at the triple point [231.49°K.]; the entropy of the liquid at 298.16°K. [42.52 cal. deg.$^{-1}$ mole^{-1}]; the vapor pressure [$\log_{10} p$(mm.) = 7.04162 − 1374.103/(t + 215.014), (67–153°)]; the heat of vaporization [$\Delta Hv = 13077 - 10.201\ T - 4.7941 \times 10^{-3}T^2$, cal. mole^{-1} (346–388°K.)]; the second virial coefficient in the equation of state, $PV = RT\ (1 + B/V)$, [$B = -15$–$84.5 \exp(950/T)$, cc. mole^{-1} (346–500°K.)]; and the standard heat of formation of the liquid at 298.16°K. [23.89 kcal. mole^{-1}].

Thermodynamic investigations of organic nitrogen compounds were begun recently in this Laboratory as part of American Petroleum Institute Research Project 52. The objective is to provide comprehensive thermodynamic data for nitrogen compounds that are important in petroleum technology. This paper is the first of a projected series on cyclic nitrogen compounds. Results are reported for pyridine, a compound important in theoretical considerations concerning molecular structure as well as in practical considerations as an industrial chemical. Some thermodynamic data for pyridine have been reported previously,[2] but many of the basic data are not of the accuracy that can be obtained by present-day methods.

The experimental part of this investigation consisted of measurements of thermodynamic properties by the methods of low temperature calorimetry, comparative ebulliometry, flow calorimetry and combustion calorimetry. Descriptions of the experiments and detailed results are given in the Experimental part of the paper. For convenience, the most important experimental results—values of the entropy, heat capacity and heat of formation for the ideal gaseous state—are collected in Table I. The entropy and heat capacity data served as guides in revising the vibrational assignment for pyridine and as checks on thermodynamic properties calculated by the methods of statistical

mechanics. The experimental value of the heat of formation and the calculated thermodynamic properties were used in computing values of the heat, free energy and equilibrium constant of formation at selected temperatures between 0 and 1500°K. These calculations are discussed in the following section.

Calculation of Thermodynamic Properties

The Vibrational Assignment.—The vibrational spectra of pyridine and several deuteropyridines have been studied by a number of investigators.[3] Corrsin, Fax and Lord (CFL) have given detailed vibrational assignments for pyridine and pyridine-d_5.[3a] Anderson, Bak, Brodersen and Rastrup-Andersen[3b] have given assignments for 4D-pyridine, 3D-pyridine and 2D-pyridine based on the assignments of CFL. When the published vibrational assignment for pyridine was used in calculating thermodynamic properties, the results disagreed with the experimental values of $C_p°$ and $S°$ listed in Table I (the discrepancies were about 2 and 0.3%, respectively). Because the accuracy uncertainty of the observed values of $C_p°$ is 0.2%, a revision of the vibrational assignment for pyridine was required for calculating accurate thermodynamic properties. The revised assignment for pyridine and its deuterated species is given in Table II.

The vibrational assignment of CFL is based on good spectroscopic evidence. It was considered likely that the choice of only one fundamental frequency was seriously in error. To obtain agreement between calculated and observed values of both $C_p°$ and $S°$, it was apparent that a frequency near 700 cm.$^{-1}$ had to be eliminated and replaced by one near 1000 cm.$^{-1}$. Corresponding changes in the assigments for the deuteropyridines had to be made to retain consistency with the product rule for isotopic substitution.

There are only three observed frequencies near 700 cm.$^{-1}$ in the spectrum of pyridine: 675 (infrared, weak); 703 (infrared, very strong; Raman, very weak); 749 (infrared, strong; Raman, very weak) cm.$^{-1}$. These frequencies had been assigned by CFL to ν_4, ν_{11} and ν_{10b},[4] respectively. The assignment of CFL was retained for the infrared band at 675 cm.$^{-1}$, which cannot be assigned as a likely overtone or combination. The other pair of frequencies was replaced by a single fundamental frequency by interpreting the 703–749 cm.$^{-1}$ doublet as the result of Fermi resonance between an a_1 mode near 720 cm.$^{-1}$, taken to be ν_{6a}, and the overtone of ν_{16a}, 2×374 (a_2) = 748-(A_1). This reinterpretation necessitated revised assignments for b_2 modes ν_{10b} and ν_{11}. The frequency previously assigned to ν_{6a}, 605 cm.$^{-1}$, was reassigned to ν_{11}. The assignment of the 605 cm.$^{-1}$ frequency to a b_2 rather than an a_1 mode is consistent with the reported depolarization of the Raman line.[5] The frequency at 981 cm.$^{-1}$, previously assigned to the a_2 mode ν_{17a} in violation of the strict selection rules of C_{2v} symmetry, was chosen for the other b_2 mode. However, this frequency was assigned to ν_5 and CFL's choice for ν_5, 940 cm.$^{-1}$, was assigned instead to ν_{10b}. (The latter change was made to obtain better over-all consistency among the assignments for pyridine, benzene and their deuterated species.[3b,6]

The result of the foregoing changes was to eliminate from the earlier assignment a frequency near 700 cm.$^{-1}$ and leave ν_{17a} available for assignment of a frequency near 1000 cm.$^{-1}$. The a_2 mode ν_{17a} may be unobserved, for it should appear with very low intensity in the Raman spectrum and is forbidden in the infrared. Although the weak Raman line at 1043 cm.$^{-1}$ could be due to ν_{17a}, it was interpreted as the sum-combination, 374 (a_2) + 675 (b_2) = 1049 (B_1). It was assumed that ν_{17a} is obscured in the Raman spectrum by the strong line of ν_{12} at 1030 cm.$^{-1}$, and that frequency was chosen for ν_{17a}. A value of 1030 cm.$^{-1}$ for ν_{17a} results in a slightly more satisfactory product-rule ratio, τ_{obsd}, for the a_2 frequencies of pyridine and pyridine-d_5.

Two additional minor changes have been made in the assignment for pyridine. Infrared bands at 1200 and 1085 cm.$^{-1}$ were observed recently by workers at the Chemical Research Laboratory[3c] and are assigned to ν_3 and ν_{18b}. These fundamentals were previously assigned (by CFL) the same values as ν_{9a} and ν_{18a}, 1218 and 1068 cm.$^{-1}$.

The revision of CFL's vibrational assignment for pyridine made necessary corresponding changes in the previous assignments for the deuterated pyridines.[3a,3b] The revised assignments for the deuterated species, given in Table II, were made concurrently with the revision of the assignment for pyridine.

The vibrational assignments in Table II are as consistent internally as those of refs. 3a and 3b. The comparisons of observed and calculated product rule ratios, τ_{obsd} and τ_{calcd}, in Table III show

Table III

Product-rule Ratios for Pyridine and Pyridine-d_5

Symmetry class	$\tau_{calcd.}$ from ref. 3a	Ref. 3a	$\tau_{obsd.}$ This work
a_1	5.49	5.38	5.45
b_1	5.07	4.89	4.90
a_2	1.84	1.80	1.82
b_2	2.56	2.55	2.54

that good agreement was retained. Also, all observed frequencies in the spectra of these compounds that were not chosen as fundamentals can be assigned readily as allowed overtones or combinations. For the most part, the intercomparison of assignments for pyridine, benzene and their deuterated species is slightly improved, although it is apparent that some of the fundamental frequencies of pyridine and benzene differ more than in the earlier assignment.[3a] Actually, spectroscopic evidence alone is not sufficient to choose between the assignment in Table II and that of CFL. The fact, discussed later, that excellent agreement between calculated and observed values of $C_p°$ and $S°$ was obtained by use of the revised assignment ensures that the set of fundamentals chosen is essentially correct. Uncertainties that may remain in the assigment of observed frequencies to particular modes of vibration can be removed only by additional spectroscopic evidence.

It should be noted that the net effect of these reassignments is merely the replacement of fundamentals at 703 and 749 cm.$^{-1}$ by fundamentals at 720 and 1030 cm.$^{-1}$—that is, the change that was found necessary to obtain agreement between calculated and experimental values of both $C_p°$ and $S°$.

Note added in proof. J. K. Wilmshurst and H. J. Bernstein of the Canadian National Research Council have recently made new spectroscopic studies of pyridine and some deuteropyridines. Dr. Bernstein courteously provided us with a copy of his manuscript, which is soon to be published. The data of Wilmshurst and Bernstein require further revision of the vibrational assignment for pyridine. In their forthcoming paper, Wilmshurst and Bernstein will present a new vibrational assignment that is consistent with the available spectroscopic and calorimetric data. Use of their assignment in calculating thermodynamic properties results in no significant changes in the calculated values listed in Tables I and III of this paper.

The Moments of Inertia and Anharmonicity Contributions.—The moments of inertia of the pyridine molecule have been determined in several recent microwave studies.[7-9] The difference between values of the product of principal moments of inertia calculated from the results of these studies is not significant, but the value actually used in calculation of thermodynamic properties, 5.691×10^{-113} g.^{3} cm.^{6}, was computed from the data of ref. 9. The symmetry number of over-all rotation is 2.

The contributions of anharmonicity to the thermodynamic functions were treated by the empirical

method described in an earlier paper from this Laboratory.[10] The parameters $Z = 0.340$ cal. deg.$^{-1}$ mole^{-1} and $\nu = 750$ cm.$^{-1}$ were selected to give agreement with the calorimetric values of $C_p°$. The contributions of anharmonicity to the thermodynamic properties are small at 400°K., 0.03 and 0.11 cal. deg.$^{-1}$ mole^{-1} in $S°$ and $C_p°$, but increase to 0.62 and 0.92 cal. deg.$^{-1}$ mole^{-1} in $S°$ and $C_p°$ at 1500°K.

The Chemical Thermodynamic Properties.—The vibrational assignment, product of principal moments of inertia and anharmonicity parameters given in preceding paragraphs were used in computing values of the following thermodynamic functions at selected temperatures between 0 and 1500°K.: $(F° - H°_0)/T$, $(H° - H°_0)/T$, $H° - H°_0$, $S°$ and $C_p°$. The results are listed in columns 2–6 of Table IV.[11]

The calculated and observed values of $C_p°$ and $S°$ are compared in Table I. Agreement within 0.1% was obtained over the entire range of temperature of the experimental data. Because the observed values of $S°$ and $C_p°$ are entirely independent, the excellent agreement obtained for $S°$ is another confirmation of the third law of thermodynamics.

The Heat, Free Energy and Equilibrium Constant of Formation.—The calculated values of the thermodynamic functions of pyridine, the experimental value of $\Delta Hf°_{298.16}$ (Table I) and values of the thermodynamic functions of C(graphite),[12] H_2(g)[12] and N_2(g)[12] were used in computing values of $\Delta Hf°$, $\Delta Ff°$ and $\log_{10}Kf$ at selected temperatures between 0 and 1500°K. These results are listed in columns 7–9 of Table IV.

Experimental

Physical Constants.—The 1951 International Atomic Weights[13] and the 1951 values of fundamental physical constants[14] were used. The results are based on a molecular weight of 79.098 for pyridine and the following relations: 0° = 273.16°K.; and 1 cal. = 4.1840 abs. j. = 4.1833 int. j. Measurements of temperature were made with platinum resistance thermometers calibrated in terms of the International Temperature Scale[15] between 90 and 500°K. and the provisional scale[16] of the National Bureau of Standards between 11 and 90°K. Measurements of mass, energy and resistance were made in terms of standard devices calibrated at the National Bureau of Standards.

The Material.—The sample of pyridine used in the low temperature thermal studies, vapor pressure measurements and heat of combustion experiments was part of the Standard Sample of Nitrogen Compound, API-USBM-52-1, prepared and purified by American Petroleum Institute Research Project 52b at the Laramie, Wyoming, Station of the Bureau of Mines. In a calorimetric study of the melting point to be discussed subsequently, the purity of this sample was found to be 99.92 mole %. A second sample of 99.8 mole % purity was used in studies of the heat of vaporization and vapor heat capacity.

The samples of pyridine were received in sealed ampoules and were dried in the liquid phase with CaH_2. Transfers of sample were made by distillation under vacuum.

The Heat Capacity in the Solid and Liquid States.—The low temperature thermal studies were made in an adiabatic calorimeter system similar to that described in previous publications.[17] The sample, 0.66591 mole, was sealed in a platinum calorimeter. About 27 mm. helium pressure, at room temperature, was left in the calorimeter to promote thermal equilibration at low temperatures.

The observed values of heat capacity at saturation pressure, C_{satd}, are recorded in Table V. No adjustment for the effect of premelting has been applied to these data. The temperature increments used in the measurements were small enough that corrections for non-linear variation of C_{satd} with temperature were unnecessary. Generally, the precision of the results is within ±0.1%; and it is estimated that above 30°K., the accuracy uncertainty is not greater than 0.2%.

The heat capacity curve, C_{satd} *vs.* T, for solid pyridine is smooth and regular from 13 to 200°K. A very small "bump" was observed in the curve between 200 and 215°K. (about 20° below the melting point). When the sample was cooled rapidly from a point above 215°K., the "bump" was not detected. It is believed that this anomaly was due to melting of the eutectic between pyridine and an impurity, and that rapid cooling caused the eutectic mixture to supercool. The excess energy associated with the "bump" was only 1.3 cal. mole^{-1}. This amount of energy corresponds to about 0.06 mole % impurity if the heat of fusion of the eutectic mixture is assumed to be about 2000 cal. mole^{-1}. In Table V, the values indicated by asterisks define the anomalous "bump." These points were disregarded in drawing the smoothed heat-capacity curve of pyridine.

An empirical equation that represents the observed heat capacity data for liquid pyridine between 240 and 347°K. with an average deviation of 0.01% is

$$C_{satd}(\text{liq.}) = 33.633 - 9.1446 \times 10^{-2}T + 3.8478 \times 10^{-4}T^2 - 3.3430 \times 10^{-7}T^3, \text{ cal. deg.}^{-1}\text{ mole}^{-1} \quad (1)$$

The Heat of Fusion.—Two determinations were made of the heat of fusion. Measurements were made of the enthalpy change over a finite temperature interval that included the melting point. Subtraction of the energy absorbed non-isothermally by the crystals and liquid gave the latent heat of fusion, 1978.6 ± 0.6 cal. mole^{-1}; the indicated uncertainty is the deviation of the two results from the mean. Corrections for premelting were applied in calculating the heat of fusion. The energy associated with the anomaly at about 210°K. is included in the value given.

The Triple Point Temperature, Cryoscopic Constants and Purity of Sample.—For determination of the triple point temperature and purity of sample, a study of the melting temperature, T_{obsd}, as a function of fraction of total sample melted, F, was made by the procedure outlined in an earlier publication.[18] The results are summarized in Table VI. Values of T_{obsd} were plotted as a function of $1/F$. The triple point temperature, $T_{T.P.} = 231.49 \pm 0.05$°K., was obtained by linear extrapolation to zero value of $1/F$. If the impurities present form ideal solutions in the liquid phase and are insoluble in the solid phase, the relation between mole fraction of total impurity, N^*_2, and melting point depression, $\Delta T = T_{T.P.} - T_{obsd}$, is[19]

$$-\ln(1 - N_2) = A\Delta T(1 + B\Delta T + \ldots..) \quad (2)$$

where $N_2 = N^*_2/F$. The cryoscopic constants, $A = \Delta H_{fusion}/RT^2_{T.P.} = 0.01858$ deg.$^{-1}$ and $B = 1/T_{T.P.} -$

$\Delta C_{fusion}/2\Delta H_{fusion}$ = 0.00255 deg.$^{-1}$ were evaluated from the values for $T_{T.P.}$ and ΔH_{fusion} and from ΔC_{fusion} = 6.99 cal. deg.$^{-1}$ mole^{-1} (Table VII). Application of eq. 2 in its simplified form (for $N^*_2 << 1$), $N^*_2 = AF\Delta T$, yielded a value of 0.08 mole % for the indicated concentration of impurity in the Standard Sample of pyridine.

[a] A straight line through these points was extrapolated to $1/F = 0$ to obtain the triple-point temperature, $T_{T.P.}$ [b] Temperatures read from the straight line of footnote *a*; deviations from T_{obsd} indicate slight departure from assumed conditions. [c] Triple-point temperature.

Biddescombe, Coulson, Handley and Herington[2c] report a value for t_f°, the freezing point in air at 1 atm., that is 0.12° higher than the triple-point temperature found in this investigation. However, recent unpublished studies by these authors[20] on a purer sample of pyridine gave a value of t_f° that is 0.10° lower than their reported value, in better consistency with the results of this work.

The Thermodynamic Properties in the Solid and Liquid States.—Values of the free energy function, heat content function, heat content, entropy and heat capacity at selected temperatures between 10 and 350°K. were computed from the low-temperature calorimetric data for pyridine. The values at 10°K. were calculated from a Debye function for 4 degrees of freedom with θ = 107.40°; these parameters were evaluated from the heat capacity data between 13 and 22°K. The thermodynamic properties above 10°K. were computed from the values of the heat of fusion and triple-point temperature, and from increments computed by numerical integration of values of C_{satd} read from a large scale plot of the data in Table V. The results are given in Table VII. Corrections for the effect of premelting have been applied to the "smoothed" data recorded in Table VII.

The results in Table VII agree with those of Parks, Todd and Moore[2d] within the 1% accuracy uncertainty of the earlier data. The results of Pearce and Bakke[2e] seem to be in error.

The Vapor Pressure.—The vapor pressure of pyridine at temperatures between 67 and 153° was measured with an improved version of the twin ebulliometer system described in an earlier publication.[21] Observations were made of the boiling and condensation temperatures of pyridine and water as the two compounds boiled simultaneously at a common pressure. The pressures corresponding to the observed boiling points of the water were obtained from the data of Osborne, Stimson and Ginnings.[22] The results are presented in Table VIII. The difference between the boiling and condensation temperatures of the sample was observed to be 0.004° or less; this observation indicates that the material was essentially free of impurities of different volatility. The constants in an Antoine equation

$$\log_{10} p \text{ (mm.)} = 7.04162 - 1374.103/(t + 215.014) \quad (3a)$$

were obtained from the data in Table VIII by a least squares treatment.[23] Also, to provide a more accurate means of

[a] The values tabulated are the free energy function, heat content function, heat content, entropy and heat capacity of the condensed phases at saturation pressure.

extrapolation to temperatures beyond the range of the experiments, the following Cox equation[24] was derived

$$\log_{10}P\ (\text{atm.}) = A(1 - 388.394/T) \qquad (3b)$$
$$\log_{10}A = 0.858631 - 6.7114 \times 10^{-4}T + 6.0722 \times 10^{-7}T^2$$

In these equations, t is in °C. and T is in °K. Comparisons of the observed and calculated vapor pressures for both the Antoine and Cox equations are given in Table VIII. The normal boiling point of pyridine, calculated from either equation, is 115.23° (388.39°K.).

The results in Table VIII are in good agreement with those of Herington and Martin.[20] In the range of temperature of the experimental data, values of the boiling point differ by 0.02° or less.

[a] From vapor pressure data for water given in ref. 22.

The Heat of Vaporization.—The heat of vaporization and vapor heat capacity of pyridine were measured in the flow calorimeter system described in previous publications.[25] The modified apparatus and procedure of ref. 25b were used. The results of measurements of the heat of vaporization at boiling points corresponding to 1/4, 1/2 and 1 atm. pressure are summarized in Table IX. The estimated accuracy uncertainty of the values of the heat of vaporization reported in Table IX is ±0.1%. The following empirical equation was derived for interpolation in the temperature range of the measurements (346 to 388°K.)

$$\Delta Hv = 13077 - 10.201T - 4.7941 \times 10^{-3}T^2, \text{ cal. mole}^{-1} \qquad (4)$$

The standard heat of vaporization at 298.16°K. was calculated by three methods: (1) from eq. 3b, 4 and 6 (given in the following section) and the relationship, $\Delta Hv° = \Delta Hv - BRT/V + (dB/dT)RT^2/V$; (2) from the Clapeyron equation with the aid of eq. 3b and 6; and (3) from a thermodynamic network that used the experimental value of S_{satd} (Table VII), the calculated value of $S°$ (Table IV) and eq. 3b. The results are 9612, 9599 and 9606 cal. mole^{-1}, respectively, and the average value, 9606 ± 7 cal. mole^{-1}, was selected as $\Delta Hv°_{298.16}$.

[a] Calculated by use of eq. 6. [b] Maximum deviation from the mean of 3 to 5 determinations.

The Vapor Heat Capacity and the Effect of Gas Imperfection.—The vapor heat capacity of pyridine was measured at two or more pressures at each of five temperatures between 374 and 500°K. The results are summarized in Table X.

To correlate the thermal data, an equation of state for pyridine was obtained from data for the vapor pressure, heat of vaporization and vapor heat capacity. "Observed" values of the second virial coefficient, B, in the equation of state, $PV = RT(1 + B/V)$, were computed by use of the exact Clapeyron equation. Values of d^2B/dT^2 were determined from the thermodynamic relationship, $(\partial^2 V/\partial T^2)_P = -(1/T)(\partial C_p/\partial P)_T$, in terms of which the variation

TABLE X

THE MOLAL VAPOR HEAT CAPACITY OF PYRIDINE IN CAL. DEG.$^{-1}$

T, °K.	374.20	397.20	420.20	450.20	500.20
C_p(1.00 atm.)		25.877	27.110	28.753	31.336
C_p(0.50 atm.)	24.199	25.540			
C_p(0.25 atm.)	23.991	25.390	26.761	28.512	31.170
C_p°(obsd.)	23.79	25.23	26.65	28.43	31.12
$-T(d^2B/dT^2)$,[a] obsd.	0.79	0.60	0.44	0.30	0.21
$-T(d^2B/dT^2)$,[a] calcd.[b]	.80	.59	.45	.33	.20

[a] $-T(d^2B/dT^2) = \lim_{p\to 0}(\partial C_p/\partial P)_T$; units are cal. deg.$^{-1}$ mole^{-1} atm.$^{-1}$. [b] Calculated by use of eqs. 5 and 6.

of vapor heat capacity with the pressure is represented, with slight approximations,[25b] by

$$C_p = C_p^\circ - T\left(\frac{d^2B}{dT^2}\right)P + 2\left(\frac{B}{R}\right)\left(\frac{d^2B}{dT^2}\right)\left(1 - \frac{3BP}{RT}\right)P^2 \quad (5)$$

The value of the last term in eq. 5 (0.04 cal. deg.$^{-1}$ mole^{-1} or less) was estimated for each experimental point and subtracted from C_p(obsd.). The adjusted values of C_p at each temperature were plotted against P. The intercept and slope of the resulting straight lines were taken as C_p°(obsd.) and $\lim_{p\to 0}(\partial C_p/\partial P)_T = -T(d^2B/dT^2)$(obsd.), respectively. Constants in the following empirical equation for B were evaluated from the values of B(obsd.) and (d^2B/dT^2)(obsd.).

$$B = -15 - 84.5\exp(950/T), \text{ cc. mole}^{-1} \text{ (346–500°K.)} \quad (6)$$

Iteration using eq. 6 with eq. 5 and the experimental data produced no change in the correlation. The values of C_p° (obsd.) so determined are given in Table X. Observed values of B and $T(d^2B/dT^2)$ are compared in Tables IX and X with values calculated by using eq. 6.

The accuracy uncertainty of the values of C_p° (obsd.) listed in Table X should not exceed 0.2%. The following empirical equation represents these data within ±0.07% from 374 to 500°K.

$$C_p^\circ = -8.262 + 10.608\times 10^{-2}T - 5.4662\times 10^{-5}T^2, \text{ cal. deg.}^{-1}\text{ mole}^{-1} \quad (7)$$

Gas density measurements on pyridine were recently made at the Chemical Research Laboratories, Teddington, England.[20] Values of B calculated from an equation representing these data are −1258, −1126 and −993 cc. mole^{-1} at 346.65, 366.11 and 388.40°K. (the temperatures at which data were obtained in this Laboratory). These values of B are in excellent agreement with those listed in Table IX.

The Entropy in the Ideal Gaseous State.—The experimental and derived data given in the foregoing sections were used in computing "observed" values of the entropy in the ideal gaseous state at one atmosphere pressure. These calculations are summarized in Table XI.

TABLE XI

THE MOLAL ENTROPY OF PYRIDINE IN CAL. DEG.$^{-1}$

0–10°K.	Debye extrapolation	0.166

S°(obsd.)[±0.15][a]	70.65	71.86	73.27

[a] Estimated accuracy uncertainty. [b] Interpolated in Table VII. [c] Extrapolation by use of eq. 1. [d] Entropy of vaporization; from data in Table IX. [e] Entropy of gas imperfection; calculated by use of eq. 6. [f] Entropy of compression; calculated with the aid of eq. 3b.

The Heat of Formation and Related Properties.—The heat of combustion of pyridine was determined by precise combustion calorimetric experiments, details of which will appear as part of another publication.[26] From this study, the heat of formation of liquid pyridine, $\Delta Hf°_{298.16}$ (liq.), was found to be 23.89 kcal. mole^{-1}. Addition of the standard heat of vaporization, 9.606 kcal. mole^{-1}, given in a preceding section, yields the heat of formation of pyridine in the ideal gaseous state, 33.50 kcal. mole^{-1}, as presented in Table I.

The value of S_{satd} (liq.) from Table VII and values of the entropy of C(graphite),[12] H_2(g)[12] and N_2(g)[12] were used in computing values of the entropy, free energy and logarithm of the equilibrium constant of formation of liquid pyridine according to the reaction

$$5C(\text{graphite}) + 5/2H_2(g) + 1/2N_2(g) \longrightarrow C_5H_5N(l)$$

$\Delta Hf°_{298.16}$ = 23.89 kcal. mole^{-1}; $\Delta Sf°_{298.16}$ = −65.20 cal. deg.$^{-1}$ mole^{-1}*; $\Delta Ff°_{298.16}$ = 43.33 kcal. mole^{-1}; $\log_{10}Kf$ = −31.76

NOTE ADDED IN PROOF.—Dr. Kun Li of Jones and Laughlin Steel Corporation, Pittsburgh, Pa., recently has published a paper [*J. Phys. Chem.*, **61**, 782 (1957)] in which the earlier thermodynamic data for pyridine are correlated and extended. With the exception of the heat of formation and vapor pressure data (refs. 2b and 2c of this paper), the accuracy of the experimental data used by Li is significantly lower than that of the data given in this paper. Those thermodynamic properties derived from the less accurate experimental data are also subject to greater uncertainty than the corresponding values listed in this paper.

Spectrophotometric Studies of Uranyl-Urea, -Thiourea and -Guanidine Systems in Absolute Ethyl Alcohol[1]

BY PHILIP S. GENTILE AND LAWRENCE H. TALLEY

RECEIVED APRIL 26, 1957

Analysis of absorption spectra and continuous variation studies have been employed to determine the stoichiometry of complexes present in uranyl-urea, -thiourea and -guanidine systems in absolute ethyl alcohol. Evidence is presented to show that only one complex is formed with each of the ligands. The urea and thiourea complexes were found to exist in a 1:2 (uranium/organic base) mole ratio. However, the guanidine complex exhibited a stoichiometry of 1:1. In addition, isolation of the compound $UO_2(NO_3)_2 \cdot [CO(NH_2)_2]_2$ from alcoholic solution supports the interpretation of the spectral measurements made with the urea system.

It had previously been reported[2] that no evidence of compound formation was observed at room temperature when attempts were made to prepare coordination compounds of uranyl nitrate with various organic ligands in alcoholic solutions. The complexing agents cited were urea, thiourea, guanidine, nitrilotriacetic acid and ethylenediaminetetraacetic acid. In the course of some studies conducted in our laboratories, evidence was obtained for uranyl compound formation with urea, thiourea and guanidine, a summary of which is presented in this paper.

Experimental

Materials.—Uranyl nitrate dihydrate was obtained by vacuum drying the hexahydrate (Baker and Adamson, A.C.S.) over sulfuric acid. The urea (American Cyanamid Company), thiourea (Eastman Kodak Company), guanidine (Eastman Kodak Company) and the absolute alcohol (U. S. Industrial Chemical Company, Reagent Grade, U. S. P.) were used without further purification.

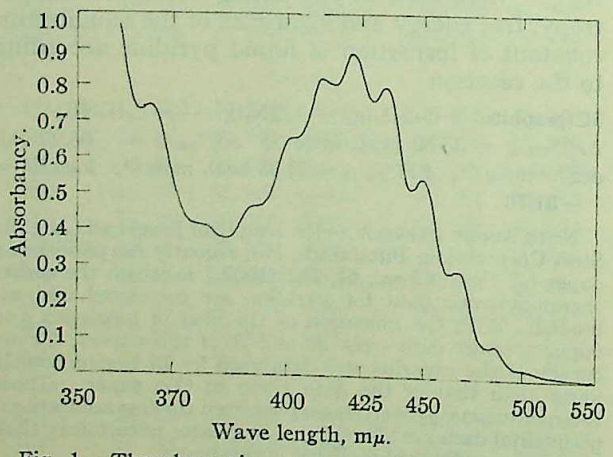

Fig. 1.—The absorption spectrum of a 0.076 *M* uranyl nitrate dihydrate solution in absolute ethyl alcohol. The absorption curves for 0.076 *M* solutions of uranyl-urea and thiourea are so similar that major differences are not detectable throughout the range of 420–600 mμ. Except for minor shifts in some spectral bands, the uranyl-guanidine curve was similar to that shown above.

Analysis.—Urea was determined according to the method of Gertner and Inkovik.[3] The uranium was assayed by ignition to uranouranic oxide (U_3O_8).

Procedure.—In applying Job's[4] technique of continuous variation, 0.076 *M* solutions of uranyl nitrate dihydrate, urea, thiourea and guanidine were prepared and arbitrarily allowed to stand 24 hours in the dark prior to making measurements. The instability of the solutions toward light necessitated this precaution.

Initial spectral transmission curves were obtained with a model DK-2 Beckman spectrophotometer while subsequent studies were made with a model DU Beckman spectrophotometer using Corex cells of 10 mm. light path.

Diureadioxouranium(VI) Nitrate.—To 60 ml. of a 4 *M* alcoholic solution of uranyl nitrate dihydrate, urea (19.7 g.) was added in small increments. A finely divided yellow precipitate was obtained which was filtered and air-dried. This compound melted at 203–205° and was extremely water-soluble.

Anal. Calcd. for $UO_2(NO_3)_2 \cdot [CO(NH_2)_2]_2$: U, 46.30; N, 16.34; urea, 23.36. Found: U, 46.07; N, 15.83; urea, 22.51.

In an analogous manner, the addition of thiourea to an alcoholic solution of uranyl nitrate dihydrate resulted in the formation of a deep red-colored solution showing a reaction had taken place. However, all efforts to isolate a uranyl–thiourea complex were unsuccessful.

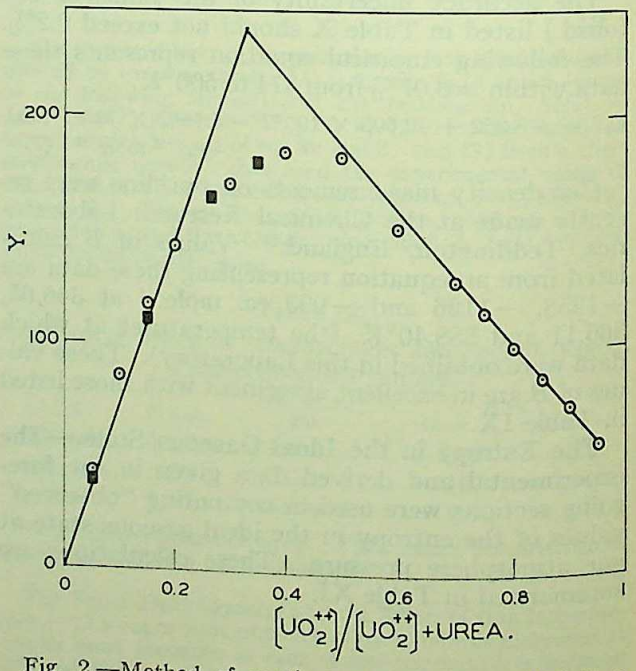

Fig. 2.—Method of continuous variation applied to a uranyl nitrate–urea system. The concentrations (UO_2^{++} + urea) were 0.076 *M* for each solution. The value *Y* represents the difference between the absorbancy of the complex mixture and that of uranium if no reaction had occurred. The solid squares represent solutions of diureadioxouranium(VI) nitrate in molarities equivalent to that of the corresponding uranium concentration used for continuous variation studies. Since these points are coincident with the curve obtained, it provides further supporting evidence for the existence of an MR_2 complex in alcoholic solutions.

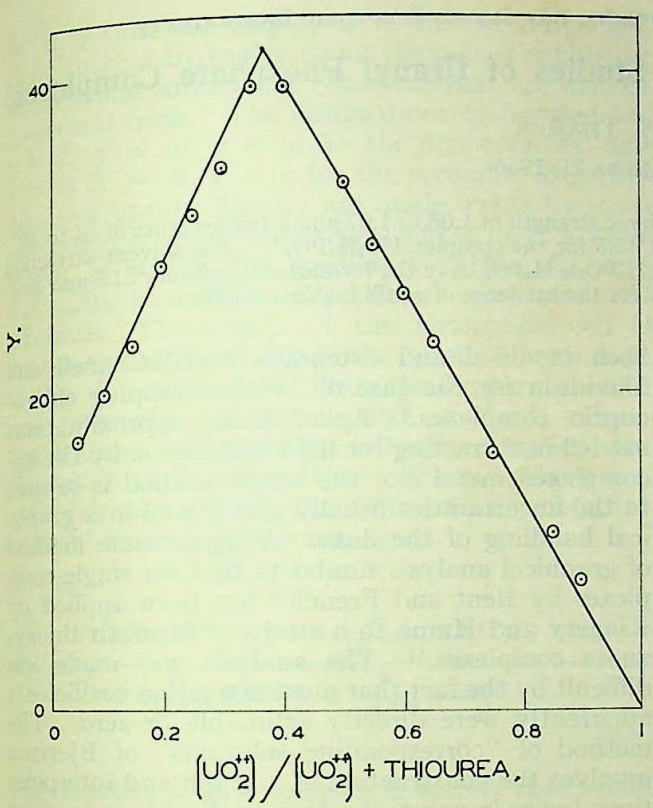

Fig. 3.—Uranyl complex with thiourea.

Solutions of guanidine and uranyl nitrate retained the characteristic yellow color of uranyl compounds and the isolation of a complex was not realized.

Results and Discussion

For the low concentration employed (0.076 *M*) at maximum absorbancy, all the solutions displayed the typical yellow coloration of uranyl compounds. The absorption curves were so similar that *major* differences in the spectral bands were not detectable throughout the range of 420–600 mμ (Fig. 1). It is not surprising, therefore, that Watt and Machel,[2] employing 0.057 *M* solutions, reported no evidence for compound formation in these systems. However, at high concentrations, unlike the urea and guanidine systems, the uranyl-thiourea solution is deep red in color indicating major changes in the spectral curves. Unfortunately, these curves could not be obtained readily with available facilities due to high absorbancy in this concentration region.

For the urea and thiourea system, the differences in spectral bands as compared to uranyl nitrate are so slight as to be virtually undetectable. The presence of new chemical species was indicated by abnormal increases in the absorbancy which were unattributable to the uranyl ion concentration present.

For the guanidine system, the 356 mμ band vanished and the 366, 368 and 488 mμ bands of uranyl nitrate shifted slightly to 364, 464 and 480 mμ. The 480 mμ band also was characterized by a relatively large increase in extinction coefficient. In the region of 370–465 mμ, there was virtually no change in the spectral bands.

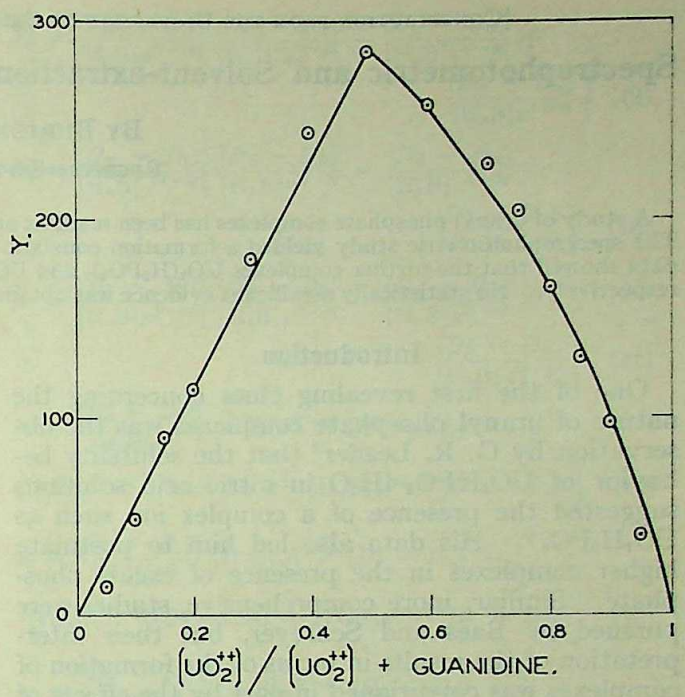

Fig. 4.—Uranyl complex with guanidine.

Continuous variation data for uranyl-urea mixtures were examined at 423, 435 and 467 mμ. As seen in Fig. 2, the experimental data show the presence of a uranyl-urea complex with a 1:2 mole ratio as indicated by a maximum at 0.33. The broad maxima are characteristic of compounds that display appreciable dissociation. Isolation of the compound $UO_2(NO_3)_2 \cdot [CO(NH_2)_2]_2$ and subsequent absorption studies in solution (Fig. 2) provides supporting evidence for the interpretation of the spectral measurements.

Uranyl-thiourea mixtures examined at 412, 423 and 435 mμ (Fig. 3) indicate the presence of a complex with a uranyl/thiourea mole ratio of 1:2. As in the case of urea, it is very unlikely that other complexes exist in solution. The absence of major differences in the spectral bands, as compared to uranyl nitrate, indicates that if other complexes are present, it would be difficult to detect them in the concentration range utilized (0.076 *M*).

For the uranyl-guanidine system (Fig. 4), there is evidence to support the presence of only one complex, namely, a coördination compound with a 1:1 mole ratio. Spectral measurements were made at 402, 423 and 450 mμ.

Spectrophotometric and Solvent-extraction Studies of Uranyl Phosphate Complexes[1]

BY BURTON J. THAMER

RECEIVED SEPTEMBER 21, 1956

A study of uranyl phosphate complexes has been made at an ionic strength of 1.06 to 1.07 and a temperature of 24 to 25°. The spectrophotometric study yielded a formation constant of 15.5 for the complex $UO_2H_2PO_4^+$. The solvent-extraction data showed that the further complexes $UO_2(H_2PO_4)_2$ and $UO_2(H_2PO_4)_2 \cdot H_3PO_4$ have the formation constants 21.8 and 10.2, respectively. No statistically significant evidence was obtained for the existence of a still higher complex.

Introduction

One of the first revealing clues concerning the nature of uranyl phosphate complexes was the observation by G. R. Leader[2] that the solubility behavior of $UO_2HPO_4 \cdot 4H_2O$ in nitric acid solutions suggested the presence of a complex ion such as $UO_2H_2PO_4^+$. His data also led him to postulate higher complexes in the presence of excess phosphate. Similar, more comprehensive, studies were pursued by Baes and Schreyer, but their interpretation of the results in terms of the formation of complexes was conditioned in part by the effects of inconstant ionic strength.[3,4] Findings from the original spectrophotometric study of the first complex,[5] which they and J. M. Lesser had made, recently have been revised to take into account the effect of the second complex.[6] These results as well as those of this article will be discussed in some detail later.

1. Spectrophotometric Studies.—Spectrophotometry is one of the more experimentally suitable techniques with which to study complex ions of uranium. The ease and rigor with which spectrophotometric data on complex ions have been interpreted have depended largely upon the complexity of the system and the degree of overlap of the ranges of stability of the complex ions. In his study of chromate–phosphate complexes, Holloway was able to separate largely the two operative equilibria, and thus simplify the problem, by altering the *p*H.[7] The method was based on successive approximations. The slope-intercept method of Benesi and Hildebrand[8] for a single complex has been modified and extended by McConnell and Davidson for the case of two overlapping chlorocupric complexes.[9] Apart from approximations needed in correcting for light absorption by the uncomplexed metal ion, the latter method is subject to the uncertainties usually introduced in a graphical handling of the data. A logarithmic method of graphical analysis similar to that for single complexes by Bent and French[10] has been applied by Kingery and Hume to a study of bismuth thiocyanate complexes.[11] The analysis was made less difficult by the fact that most extinction coefficients apparently were directly estimable or zero. The method of "corresponding solutions" of Bjerrum involves the construction of a graph and interpolations between points.[12] It is applicable to systems of strong complexes. All but the last of the above methods that are applicable in the formation of two complex ions become appreciably less accurate or more time consuming if the two complexes have overlapping ranges of stability. The following algebraic treatment is rigorously applicable to the case of two complexes no matter what their degree of overlap. (Even if appreciable amounts of other complexes are present, a proper use of the data will yield better information concerning one of the two principal complexes than would be obtained otherwise.) A minimum amount of data is required. No extinction coefficients need be directly estimated. The method is most suitable for systems of other than strong complexes. As in all of the above methods except that of Bjerrum, the concentration of unbound complexing agent must be calculated with corrections for its equilibrium as an acid or base and for what is bound in complexes, the latter possibly requiring a few successive approximations. In the present application no more than 20% of the complexing agent was bound to the uranium in any solution.

This treatment is designed for the case of a light-absorbing species A (UO_2^{++}) forming two complexes with a non-light-absorbing, *s*-basic acid H_sB (H_3PO_4).

$$A + XH_sB = AH_{sX-x}B_X + xH^+ \qquad (1)$$

$$k_y = \frac{[AH_{sX-x}B_X][H^+]^x}{[A][H_sB]^X} \qquad (2)$$

The equilibria are expressed in terms of undissociated acid as the complexing agent because this is its predominant form at the acidities (0.5 and 1.0

M H^+) that are employed in this investigation. Ionic charges are neglected for the sake of simplicity in these and subsequent equations that are written in general form. The designations to be used are $y = 1$, $X = M$, $x = m$ for the first complex, and $y = 2$, $X = N$, $x = n$ for the second. Measurements of optical density are made *versus* the concentration of the complexing agent H_sB at a wave length at which the species A, $AH_{sM-m}B_M$ and $AH_{sN-n}B_N$ have markedly different absorption coefficients. The length of the absorption cell is kept constant, as is also c, the total concentration of A in all forms. In addition the temperature and ionic strength are maintained at fixed values. Under these conditions the following equation, analogous to that derived by Holloway,[7] relates the optical density D to D_1, the optical density obtained in the absence of complexing agent.

$$D - D_1 = \frac{\frac{k_1}{[H^+]^m}[H_sB]^M (LcE_2 - D_1) + \frac{k_2}{[H^+]^n}[H_sB]^N(D_3 - D_1)}{1 + \frac{k_1}{[H^+]^m}[H_sB]^M + \frac{k_2}{[H^+]^n}[H_sB]^N} \quad (3)$$

The quantity LcE_2 is the optical density that would be obtained if $AH_{sM-m}B_M = c$, and D_3 is that corresponding to $AH_{sN-n}B_N = c$. Neither LcE_2 nor D_3 need be directly measured.

A rearrangement of equation 3 gives the following for each i-th solution

$$\Phi_i(D_i - D_1)[k_1] + (D_i - D_1)[k_2] - [k_2(D_3 - D_1)] - \Phi_i[k_1(LcE_2 - D_1)] = -\theta_i\Phi_i(D_i - D_1) \quad (4)$$

where

$$\theta_i = \frac{[H^+]_i^m}{[H_sB]_i^M} \text{ and } \Phi_i = \frac{[H^+]_i^{n-m}}{[H_sB]_i^{N-M}} \quad (5)$$

A knowledge of the values of m and n is not required at this point. Leaving m and n unspecified, all other quantities in equation 4 are directly measurable except those that are enclosed in brackets. The four constants within brackets can be evaluated in terms of m and n by the determinantal solution of four equations of the form of equation 4. Hence measurements on four aqueous solutions having different phosphate concentrations and designated as α, β, γ and δ provide the following for k_1 and k_2

$$\frac{k_1}{[H^+]^m} = \frac{\left(\frac{\lambda_1}{[H_sB]_\alpha^M} - \frac{\lambda_2}{[H_sB]_\beta^M} + \frac{\lambda_3}{[H_sB]_\gamma^M} - \frac{\lambda_4}{[H_sB]_\delta^M}\right)}{\lambda_4 - \lambda_3 + \lambda_2 - \lambda_1} \quad (6)$$

$$\frac{k_2}{[H^+]^n} = \left(\frac{1}{[H_sB]_\alpha[H_sB]_\beta[H_sB]_\gamma[H_sB]_\delta}\right)^{N-M} \times \left(\frac{\lambda_5 - \lambda_6 + \lambda_7 - \lambda_8}{\lambda_4 - \lambda_3 + \lambda_2 - \lambda_1}\right) \quad (7)$$

where it is assumed that the hydrogen ion concentration is the same among these four solutions, and

$$\lambda_1 = \frac{(D_\alpha - D_1)}{[H_sB]_\alpha^{N-M}}\left[\frac{(D_\delta - D_\gamma)}{[H_sB]_\beta^{N-M}} - \frac{(D_\delta - D_\beta)}{[H_sB]_\gamma^{N-M}} + \frac{(D_\gamma - D_\beta)}{[H_sB]_\delta^{N-M}}\right] \quad (8)$$

$$\lambda_2 = \frac{(D_\beta - D_1)}{[H_sB]_\beta^{N-M}}\left[\frac{(D_\delta - D_\gamma)}{[H_sB]_\alpha^{N-M}} - \frac{(D_\delta - D_\alpha)}{[H_sB]_\gamma^{N-M}} + \frac{(D_\gamma - D_\alpha)}{[H_sB]_\delta^{N-M}}\right] \quad (9)$$

$$\lambda_3 = \frac{(D_\gamma - D_1)}{[H_sB]_\gamma^{N-M}}\left[\frac{(D_\delta - D_\beta)}{[H_sB]_\alpha^{N-M}} - \frac{(D_\delta - D_\alpha)}{[H_sB]_\beta^{N-M}} + \frac{(D_\beta - D_\alpha)}{[H_sB]_\delta^{N-M}}\right] \quad (10)$$

$$\lambda_4 = \frac{(D_\delta - D_1)}{[H_sB]_\delta^{N-M}}\left[\frac{(D_\gamma - D_\beta)}{[H_sB]_\alpha^{N-M}} - \frac{(D_\gamma - D_\alpha)}{[H_sB]_\beta^{N-M}} + \frac{(D_\beta - D_\alpha)}{[H_sB]_\gamma^{N-M}}\right] \quad (11)$$

$$\lambda_5 = \frac{(D_\alpha - D_1)}{[H_sB]_\alpha^M}\left[[H_sB]_\beta^{N-M}(D_\delta - D_\gamma) - [H_sB]_\gamma^{N-M}(D_\delta - D_\beta) + [H_sB]_\delta^{N-M}(D_\gamma - D_\beta)\right] \quad (12)$$

$$\lambda_6 = \frac{(D_\beta - D_1)}{[H_sB]_\beta^M}\left[[H_sB]_\alpha^{N-M}(D_\delta - D_\gamma) - [H_sB]_\gamma^{N-M}(D_\delta - D_\alpha) + [H_sB]_\delta^{N-M}(D_\gamma - D_\alpha)\right] \quad (13)$$

$$\lambda_7 = \frac{(D_\gamma - D_1)}{[H_sB]_\gamma^M}\left[[H_sB]_\alpha^{N-M}(D_\delta - D_\beta) - [H_sB]_\beta^{N-M}(D_\delta - D_\alpha) + [H_sB]_\delta^{N-M}(D_\beta - D_\alpha)\right] \quad (14)$$

$$\lambda_8 = \frac{(D_\delta - D_1)}{[H_sB]_\delta^M}\left[[H_sB]_\alpha^{N-M}(D_\gamma - D_\beta) - [H_sB]_\beta^{N-M}(D_\gamma - D_\alpha) + [H_sB]_\gamma^{N-M}(D_\beta - D_\alpha)\right] \quad (15)$$

A combination of four aqueous solutions will give values for $k_1/[H^+]^m$ and $k_2/[H^+]^n$ that are the same within experimental error as those from another combination of four aqueous solutions at the same hydrogen ion concentration only if the correct values for M and N have been used.

It should be noted that in equations 6 to 15 the only spectrophotometric quantities required are *differences* in optical densities. Hence one need not measure directly the optical density D_1, for example, but can obtain instead all of the necessary spectrophotometric data by measuring each of the four solutions *versus* the solution with pure A in it to give the quantities $D_\alpha - D_1$, $D_\beta - D_1$, $D_\gamma - D_1$ and $D_\delta - D_1$. This use of the technique of differential spectrophotometry should also give improved accuracy.[13]

All of the spectrophotometric data were obtained with a Beckman Model DU spectrophotometer. The cell compartment was thermostated at 25.0 ± 0.1° and the solutions were left in a 25.0 ± 0.1° constant-temperature bath for at least 10 hours before measurement. Solutions of hexavalent uranium are known to re-emit absorbed light in the form of fluorescent light with a wave length of 490 mμ and higher.[14,15] Since such fluorescence could have destroyed the Beer's law relation implicit in equation 3, all uranium solutions were measured with a light filter in the light path between the sample compartment and the phototube compartment. The wave lengths at which optical density measurements were made were below 400 mμ. Hence the filter that was used was a Corning No. 5970 Color Filter, which cut out light above 425 mμ.

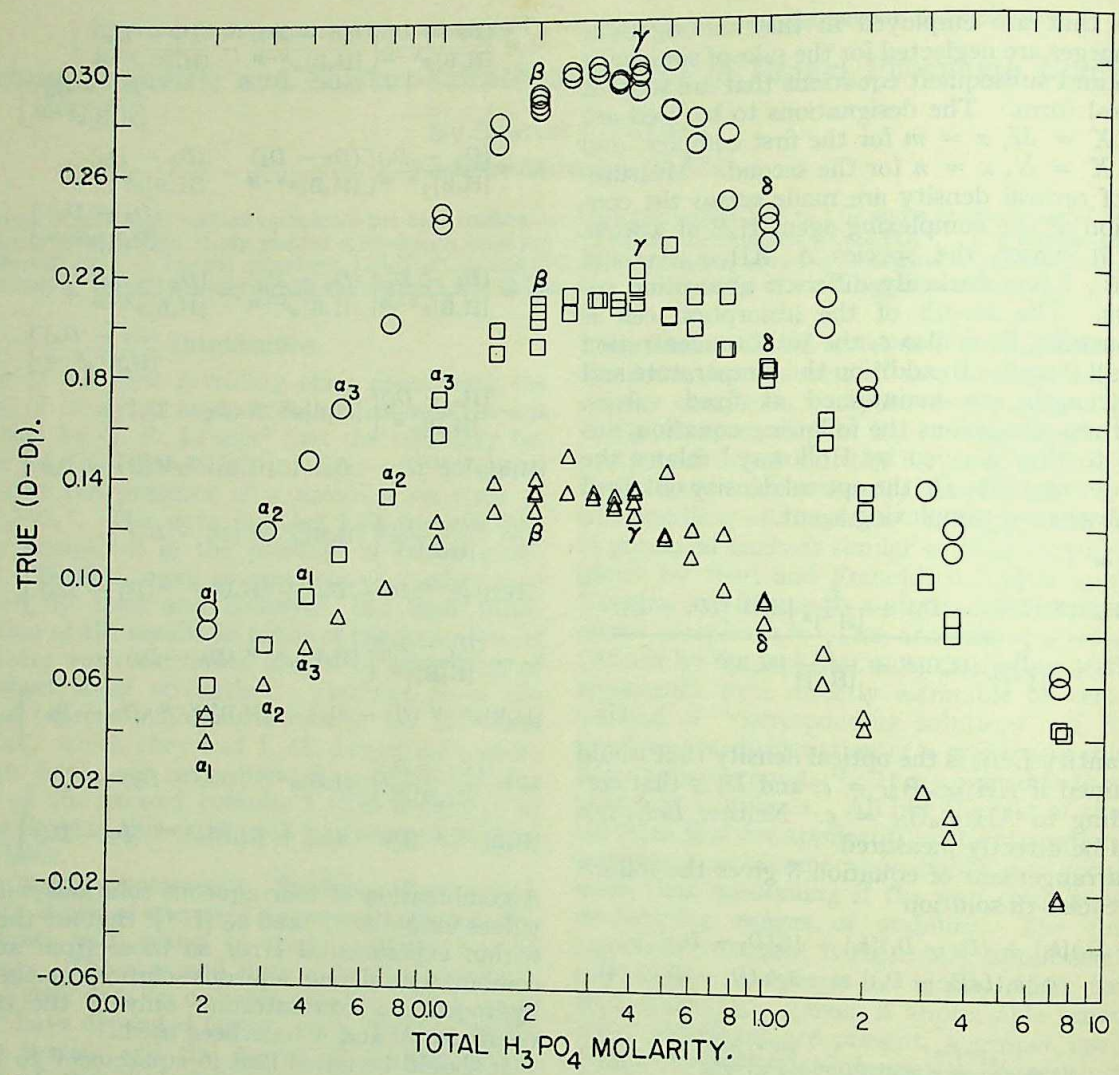

Fig. 1.—Spectrophotometric data at three wave lengths in $UO_2(ClO_4)_2$–H_3PO_4 solutions at 1.004 M H^+ and an ionic strength of 1.06: ○, at 393 mμ; □, at 388 mμ; △, at 383 mμ.

Four different wave lengths were found at which UO_2^{++} and the first two complexes had absorption coefficients favorable to the study of these two complexes. The four different wave lengths—393, 388, 383 and 376 mμ—were located in a region where the extinction coefficients varied rapidly with wave length. The solutions were measured in matched 10.00-cm. silica absorption cells and the appropriate blank corrections always were made. Exactly the same slit width was reproduced for each measurement at a given wave length. The band width was about 4 mμ. It was found that Beer's law was obeyed in the absence or presence of phosphoric acid. The fact that Beer's law was obeyed in 3.7 M phosphoric acid indicated that no significant amounts of polynuclear complexes were formed in the more concentrated phosphoric acid solutions. The concentration of uranium used in the subsequent spectrophotometric measurements was 0.01885 M, in the mid-section of the plots of Beer's law.

All of the spectrophotometric and solvent-extraction studies of the complex-ion equilibria were made in $HClO_4$–$NaClO_4$ solutions having a calculated ionic strength of 1.06 or 1.07. The contribution to the ionic strength of the 0.01885 M $UO_2(ClO_4)_2$ used in the spectrophotometric measurements was assumed to be $3 \times 0.01885 = 0.057$, but in many solutions the actual contribution to the ionic strength probably was as much as 0.019 less than that because of the effect of phosphate complexing.

The contribution to the ionic strength and to the hydrogen-ion concentration that was made by the dissociation of the phosphoric acid was calculated from a value of $k_{1a} = 0.019 \pm 0.001$ for the first concentration dissociation constant for this acid. This figure was determined at an ionic strength of 1.07 in $NaClO_4$ solutions having no uranium. The method was that of v. Halban and Brüll,[16] in which, for the present application, $HClO_4$ was the source of the known hydrogen-ion concentration and the indicator was thymolsulfonphthalein at a chemically negligible concentration. This value of k_{1a} agrees well with a value of 0.020 (30°, μ = 1.0 to 1.1) by Cher and Davidson[17] and a value of 0.021 (*ca.* 25°, μ = *ca.* 1) estimated by Baes, Jr.[6] (The second and third dissociations of phosphoric acid were ignored because their effect on the complex ion equilibria was negligible.)

The spectrophotometric data on the complexes were obtained at two different values of the hydrogen-ion concentration. Figure 1 represents the data at 1.004 M hydrogen ion and an ionic strength of 1.06. Similar data also were obtained with 0.510 M hydrogen ion and an ionic strength of 1.07. The values of "true $(D - D_1)$" were obtained by measuring the solution with phosphoric acid *versus* a solution having the same uranium concentration, hydrogen-ion molarity and ionic strength, but no phosphoric acid. The blank corrections were determined and applied for each solution. The values of corrected or true H_3PO_4 molarity were consistent within ±3% in every case with the final constants for the complexes as summarized at the end of the paper.

The data at the higher acidity were examined in order to determine M of equations 1 and 2 by plotting log $(D - D_1)$ *versus* log (true H_3PO_4 molarity) in a manner similar to that of Bent and French.[10] The slope was found to be +0.82 at about 0.020 M true H_3PO_4 molarity. This H_3PO_4 concen-

tration is a little too high to allow more than an approximate identification of M with the slope. A better approximation is to take $M = +0.82\ (1 + k_1[H_3PO_4]^M/[H^+]^m)$. Anticipating the values of $k_1 = 15.5$, $M = 1$ and $m = 1$, one calculates $M = 1.07$ which is 1 within experimental error. Hence a value of unity was taken for M. The data at both acidities were tested for the most consistent value for N by a method derived from a treatment for dibasic acids.[18] The best value by far for N was 2. However, the resulting values for $k_2/[H^+]^n$ varied considerably more than the values for $k_1/[H^+]^m$, thus indicating the probable presence of a still higher complex.

Because of the presence of the third complex it was decided not to estimate values of $k_2/[H^+]^n$ from the spectrophotometric data. Only values of $k_1/[H^+]^m$ were calculated by the method of equations 6 to 15, which automatically corrected for the presence of the second complex. Rules of thumb concerning the optimum spectrophotometric relations as summarized in an analogous treatment of dibasic acids[19] were modified to minimize the effect of the third complex. The data that were used were confined to solutions for which it was later estimated that the one with the highest phosphoric acid concentration (solution δ) had about 21% of the uranium in the form of the third complex. (The resulting percentage of error produced in $k_1/[H^+]^m$ should be much smaller than this, however.) Figure 1 and Table I indicate the points that were used at 1.004 M H^+. Likewise, Table II shows the data that were used at 0.510 M H^+. Equations 6, 8, 9, 10 and 11 were used in calculating the values of $k_1/[H^+]^m$ given in the last column of Tables I and II. The constancy within experimental error of these values within each table further confirms that $M = 1$ and $N = 2$. The average value of $k_1/[H^+]^m$ obtained from Table I is $k_1/1.004^m = 15.9 \pm 1.9$.

TABLE I

CALCULATION OF $k_1/[H^+]^m$ AT 1.004 M H^+ FROM EQUATION 6 ($\mu = 1.06$, $[H_3PO_4]_\beta = 0.180$ M, $[H_3PO_4]_\gamma = 0.373$ M, $[H_3PO_4]_\delta = 0.956$ M)

Wave length, mμ	$[H_3PO_4]_\alpha$, M	$D_\alpha - D_1$	$D_\beta - D_1$ (av)	$D_\gamma - D_1$ (av)	$D_\delta - D_1$ (av)	$\frac{k_1}{[H^+]^m}$
393.0	0.0159	0.084(av)	0.2884	0.2981	0.2388	15.3
393.0	.0242	.1195	.2884	.2981	.2388	16.6

Similarly, the average and standard deviation obtained from Table II is $k_1/0.510^m = 28.2 \pm 5.2$. Solving for the value of m one obtains $m = 0.85 \pm 0.32$. In view of the magnitude of the standard deviation, there is little justification for assuming m to be other than unity. Hence the value of m is taken to be exactly 1. Use of $m = 1$ gives $k_1 = 16.0 \pm 1.9$ and $k_1 = 14.4 \pm 2.7$, respectively, the grand mean of which is $k_1 = 15.5 \pm 1.6$.

TABLE II

It might be mentioned that in principle one could rigorously extend the method of this section as embodied in equations 4 to 15 to the case of the formation of three complexes instead of two. However, the solution of the sixth-order determinants that would be involved is thought to necessitate such a prohibitive amount of work as to be impractical.

2. Solvent-extraction Studies.—Although the spectrophotometric data had allowed an evaluation of the formula and stability of the first complex, they had not done so reliably for the second complex, and they had only shown the probable existence of a third complex species. However, experiments with solvent extraction were found to yield data that more readily delineated the nature of the second and third complexes.

The equilibria are expressed in terms of equations 1 and 2 with $y = 1$, $X = M = 1$, $x = m = 1$ and $k_1 = 15.5$ for the first complex; $y = 2$, $X = N$, $x = n$ for the second; and $y = 3$, $X = P$, $x = p$ for the third. The algebraic handling of Leden's method[20] by Sullivan and Hindman[21] can be extended to allow the implicit evaluation of the extraction equilibrium constant k, as well as the determination of k_2 and k_3 by means of the equations

$$k_2 = \frac{\left(1 - \frac{f_\alpha}{f_r} - \mu_\alpha k_1\right)\pi_\beta - \left(1 - \frac{f_\beta}{f_r} - \mu_\beta k_1\right)\pi_\alpha}{\nu_\alpha\pi_\beta - \nu_\beta\pi_\alpha} \quad (16)$$

$$k_3 = \frac{\left(1 - \frac{f_\beta}{f_r} - \mu_\beta k_1\right)\nu_\alpha - \left(1 - \frac{f_\alpha}{f_r} - \mu_\alpha k_1\right)\nu_\beta}{\nu_\alpha\pi_\beta - \nu_\beta\pi_\alpha} \quad (17)$$

where

$$\mu_i,\ \nu_i \text{ or } \pi_i = \frac{f_i[H_sB]_i^X}{f_r[H^+]_i^x} - \frac{[H_sB]_r^X}{[H^+]_i^x} \quad (18)$$

and $X = M, x = m$ for μ; $X = N, x = n$ for ν; and $X = P$, $x = p$ for π. The quantities f_α, f_β and f_r represent the fractions of aqueous uranium that are complexed at three different complexing agent concentrations none of which is zero. The quantities f_α/f_r and f_β/f_r are determined experimentally. The determination of N and P rests upon the fact that at the same acidity various pairs of solutions serving as α and β will give values of k_2 and k_3 that are constant within experimental error only if the right values have been chosen for N and P. Similarly, the obtaining of the same values of k_2 and k_3 at different acidities gives evidence of the proper choice for n and p.

Dibutyl phosphate dissolved in kerosene was used as the extracting agent. A purified grade of dibutyl phosphate, obtained from the Victor Chemical Works, was used without further purification. A sample of it was titrated with sodium hydroxide to determine its dibutyl phosphate content and the content of the likely contaminant monobutyl phosphate.[22] Its composition by weight corresponded to 96.0% dibutyl phosphate, 0.35% monobutyl phosphate and 3.65% of non-acidic material. This small amount of monobutyl phosphate would not appreciably extract uranium[23] nor

would it form a precipitate with it.[22] If the non-acidic material were tributyl phosphate, this component by itself should have no extracting action because no nitrate was present in these solvent-extraction experiments.[24] In any case the non-acidic material was considered to act only as a diluent. All concentrations reported herein for dibutyl phosphate have been corrected for these impurities. Kerosene was used as the organic solvent because it gave good phase separations. The dibutyl phosphate solutions always were prepared from the same stock of kerosene.

Studies by Wagner[22] have indicated that with 0.005 to 0.01 *M* dibutyl phosphate in a paraffinic hydrocarbon mixture (AMSCO 125-90 W) the extraction equilibrium conforms to the equation

$$UO_2^{++}(aq) + 2HD(org) = UO_2D_2(org) + 2H^+(aq) \quad (19)$$

$$k = \frac{(U)}{[UO_2^{++}]} \times \frac{[H^+]^2}{(HD)^2} \quad (20)$$

where (HD) is the molarity of free dibutyl phosphate in the organic phase and (U) is the molarity of UO_2D_2 in the organic phase. Equations 19 and 20 also have been verified for extractions with di-(2-ethylhexyl)-phosphoric acid in *n*-hexane over the range of 10^{-5} to 0.2 *M* initial uranium, 0.001 to 2 *M* extractant, and 0.1 to 2 *M* perchloric acid in the aqueous phase.[25] However, some results obtained by Stewart and Hicks[23] have indicated that with 0.004 to 0.015 *M* dibutyl phosphate in *n*-hexane and an aqueous phase containing 0.58 or 1.98 *M* HNO_3, the extraction coefficient varies as the third power of the concentration of free dibutyl phosphate. Studies by Burger[26] have indicated that appreciable dimerization of dibutyl phosphate might take place in the organic phase. The data of Table III were obtained in order to determine what dibutyl phosphate dependence was operative under the experimental conditions of this investigation. Since the total phosphoric acid molarity is the same for each solution, so also is the fraction of aqueous uranium that is uncomplexed. Under these conditions the slope of the log-log plot of the fourth *versus* the third column should be equal to the number of dibutyl phosphate molecules reacting with each uranyl ion in equation 19. The slope of the least-squares straight line drawn through these points is 1.99, *i.e.*, a value of 2 within experimental error. Hence these data indicate that equations 19 and 20 as written are the correct relations. (The values calculated for the third column of Table III were calculated on the assumption of two dibutyl phosphate groups per uranium atom in the extracted species.

TABLE III

THE DIBUTYL PHOSPHATE DEPENDENCE OF THE URANIUM EXTRACTION COEFFICIENT E AT 1.004 *M* TOTAL H_3PO_4

$V_{aq}/V_{org} = 1$, 0.510 *M* H^+

Initial (HD)	(U) at equilibrium	(HD) at equilibrium	E
0.0817	0.00733	0.0592	1.64
.0817	.00719	.0594	1.62
.1441	.01035	.1090	6.51
.192	.01682	.1399	8.29

However, the value of this assumed figure would influence the slope only slightly.) If the non-acidic impurity in the dibutyl phosphate were tributyl phosphate, the molarity of the latter would be 3% of the initial dibutyl phosphate molarity. Although the data of Table III provide support for the use of equations 19 and 20, it is possible that this small amount of tributyl phosphate might exert some synergistic influence on the extraction such as it has been found to do with di-(2-ethylhexyl)-phosphoric acid.[25] Of the data to be presented shortly in Table IV, the equilibration that would be affected the most by such an effect would be the one with a total phosphate molarity of 3.76, because the uranium loading in the organic phase would be the least in that equilibration. That equilibration was repeated in a separate experiment with the organic phase containing an amount of added Eastman tributyl phosphate equal to 3% of the dibutyl phosphate molarity. Thus this equilibration involved twice the tributyl phosphate concentration that those of Table IV might have. The extraction coefficient in this equilibration was 4% less than that of the otherwise identical one in Table IV. The difference probably was within experimental error and, in any event, no increased synergistic effect was observed. Hence, it is concluded that no such measurable effect is operative in the equilibrations presented in Table IV. The hydrogen-ion dependence as given in equations 19 and 20 receives approximate corroboration in the acid range 0.5 to 1.0 *M* H^+ of the present experiments from data obtained by Stewart and Hicks[23] with dibutyl phosphate dissolved in dibutyl ether.

TABLE IV

THE SOLVENT EXTRACTION OF URANIUM AT VARIOUS PHOSPHORIC ACID CONCENTRATIONS

If one equilibrates V_{org} milliliters of organic phase containing originally a dibutyl phosphate molarity of $(HD)_{in}$ with V_{aq} milliliters of aqueous phase containing uranium, the following relation holds at equilibrium

$$(HD) = \frac{(HD)_{in} - 2(U)}{1 + \frac{1}{k_{HD}}\left(1 + \frac{k_a}{[H^+]}\right)\frac{V_{aq}}{V_{org}}} \quad (21)$$

where k_{HD}, the distribution coefficient for undissociated dibutyl phosphate, has been determined to be 8.0 ± 0.4, and k_a, the aqueous ionization constant for dibutyl phosphate, is estimated to be 0.031 by means of Wagner's data[22] and the Debye–Hückel equation. Equation 21 is used in all of the solvent-extraction equilibrations reported here for calculating the molarity of free dibutyl phosphate in the organic phase at equilibrium. The equation

$$\frac{f_i}{f_r} = \left(\frac{[H^+]_i}{[H^+]_r}\right)^2\left(\frac{(HD)_r}{(HD)_i}\right)^2\left(\frac{E_i}{E_r}\right) \quad (22)$$

relates the desired quantity f_i/f_r for an i-th solution to the uranium extraction coefficients, E_i and E_r, of the i-th solution and the r-th, or reference, solution, respectively. In the present application the reference solution is the average of the two at the lowest complexing agent concentration in Table IV. The r-th solution had as its principal uranium species the first complex, the stability of which was known from the spectrophotometric studies. Thus the r-th solution, in effect, represents the evaluation of k in equation 20. This experimental arrangement allowed all extraction coefficients to be within a factor of about 10 of unity in order to minimize errors due to imperfect phase separations, and it allowed (HD) of Table IV to be within 13% of a constant value in order to minimize errors due to any slight deviation from equation 19.

The solvent-extraction equilibrations were conducted in separatory funnels shaken at maximum pitch on a Burrell Model BB Wrist-Action Shaker. The temperature was 24.0 ± 0.5°. The shaking time was 1 hour, which was proven by tests to give complete equilibration. At the end of this period the separatory funnels were allowed to stand for one more hour in order to allow complete phase separation before the phases were analyzed. Observations under a strong light at this time showed the aqueous phase to be completely free of suspended material, but the organic phase sometimes had a fine mist of aqueous droplets in it. Tests indicated that although longer standing caused the mist to

disperse, the analyses of the two phases remained unchanged. The data have been summarized in Table IV. The initial concentration of uranium in the aqueous phase was 0.0115 M. The initial concentration of dibutyl phosphate in the organic phase was 0.0817 M. If the equilibrated phases were allowed to stand several hours before analysis, a pale yellow precipitate would form. The precipitate may have been the uranyl dibutyl phosphate salt, judging from solubility figures that have been given for it by Wagner.[22] However, the data of Table IV were obtained in the absence of any precipitate, and presumably they should be explainable within the scope of equilibria that have already been formulated. The uranium concentration in the aqueous phase was determined by analyzing an aliquot by the procedure of Schreyer and Baes,[27] using smaller quantities of reagents and applying an indicator correction. The uranium concentration in the organic phase was determined on a 20-ml. aliquot by diluting it fourfold with kerosene, re-extracting with three successive 20-ml. portions of 1:3 85% H_3PO_4, and then using the same analytical procedure. Experiments indicated that the re-extraction procedure was quantitative. The values of true $[H_3PO_4]$ given in Table IV were calculated from the values of total phosphate molarity as in the spectrophotometric studies. They are consistent within ±1% with the final constants for the complexes as summarized at the end of the paper.

The values of $f/f_{0.35}$ in the last column of Table IV have been plotted *versus* phosphate molarity in Fig. 2. The values $N = 2$, $n = 2$, $P = 3$, $p = 2$ have been assumed in calculating the results given in Table V, which includes cal-

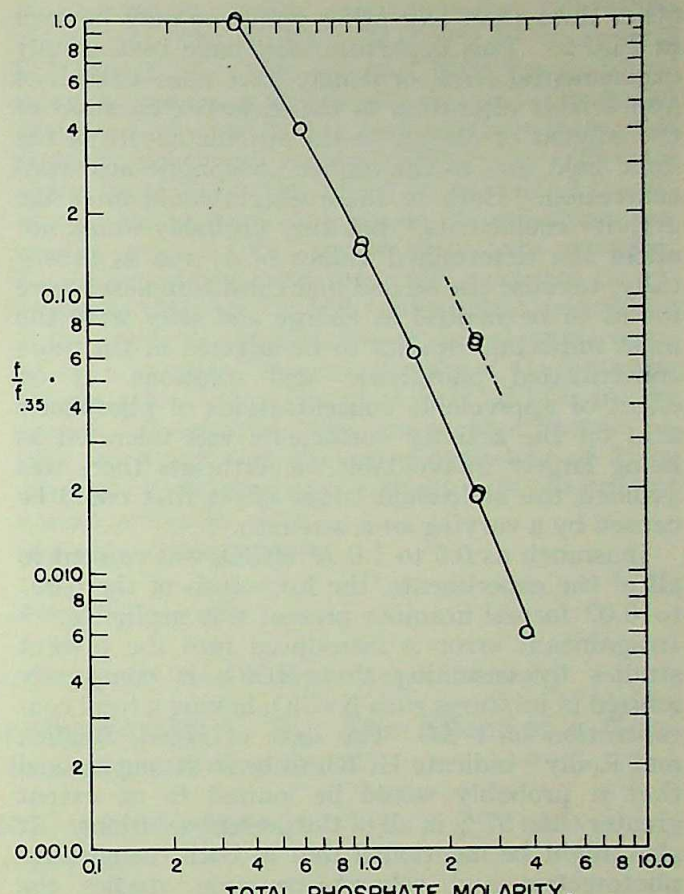

Fig. 2.—Values of $f/f_{0.35}$ *vs.* total phosphate molarity from Table IV and curves calculated from the three complex ion equilibria: solid curve, 0.510 M H^+; dotted curve, 1.036 M H^+.

Such combinations were omitted in order to keep the effect of experimental error to a minimum. The grand means of the results of Tables V and VI give $k_2 = 21.8 \pm 2.0$ and $k_3 = 10.2 \pm 0.5$ for these equilibria in equations 1 and 2. The curves that have been drawn in Fig. 2 have been calculated with the aid of these values.

Other assumed combinations of n and p fit the data much more poorly. An extension of the method of equations 16, 17 and 18 can be used to include a 1:4 uranyl phosphate complex. Since the value of k_4 thus found is 1 ± 2, it is concluded that no fourth complex is present.

Discussion

It is thought that nearly the best experimentally feasible conditions were obtained for the attainment of constancy of activity coefficients and concentration constants. Biedermann and Sillén have obtained evidence in $HClO_4$–$NaClO_4$ solutions of ionic strength 3 tending to indicate that the activity coefficients of cations remain constant from 0.0 M to at least 0.6 M $HClO_4$.[28] It has been assumed that a constancy of activity coefficients held for cations and neutral species in the present experiments. Appreciable concentrations of phosphoric acid had to be used in studying the uranyl phosphate complexes. The value of k_1 was determined entirely from points of 1 M H_3PO_4 or less. Most of the data used in calculating the values of k_2 and k_3 were obtained at phosphoric acid concentrations of 2.5 M or less. The one exception, the point at 3.76 M H_3PO_4, was used in less than 20% of these calculations. It departed more from the

other data than any other point, as may be seen in Fig. 2. This departure may have been simply experimental error, or it may have been a result of appreciable alteration in the dielectric constant of the solvent or change in the specific nature of the ionic field due to the higher phosphoric acid concentration. Both of these effects could alter the activity coefficients,[29] but they probably would not affect the determined values of k_2 and k_3 drastically, because the second and third complexes were found to be neutral in charge and they were the most important species to be affected in the more concentrated phosphoric acid solutions. If an effect of appreciable concentrations of phosphoric acid on the activity coefficients was tolerated as being largely unavoidable, nevertheless there was avoided the additional larger effect that could be caused by a varying ionic strength.

Inasmuch as 0.5 to 1.0 M $HClO_4$ was present in all of the experiments, the hydrolysis of the 0.001 to 0.02 formal uranium present was negligible.[30,31] Insignificant error is introduced into the present studies by assuming that $HClO_4$ is completely ionized in mixtures with $NaClO_4$ having a total concentration of 1 M. The data of Hood, Redlich and Reilly[32] indicate $HClO_4$ to be so strong an acid that it probably would be ionized to an extent greater than 97% in all of the present solutions. It also might be mentioned that in both the spectrophotometric and solvent-extraction studies the acid liberated by the formation of the uranyl phosphate complexes was considered not to alter appreciably the hydrogen-ion concentration of the solution. The maximum variation in the hydrogen ion so liberated was 0.027 M in the spectrophotometric data that were used. However, the resultant effect was negligible in the calculations pertaining to the first complex. The maximum variation of the concentration of hydrogen ion liberated in the solvent-extraction experiments was only 0.006 M; the effect probably was less than experimental error.

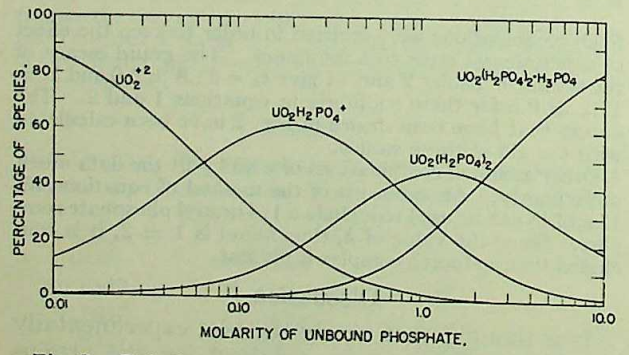

Fig. 3.—Relative amounts of species as a function of unbound phosphate concentration; 1.00 M H^+; μ = 1.06 to 1.07.

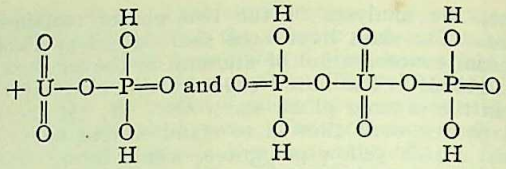
The structure of the first two complexes (exclusive of hydration) could be represented by



where the double bonds would be understood to have some ionic character. The third complex might owe its existence to hydrogen bonding as in one of the following structures or a combination of the two:

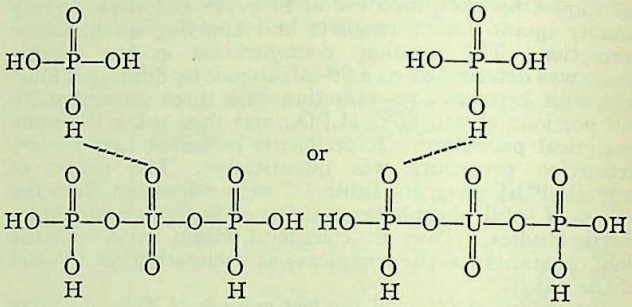


Figure 3 shows the percentage of each uranium species that is calculated from the above results to be present at any phosphoric acid concentration. It may be noted that the results recently obtained by Baes from spectrophotometric measurements in 1 M $HClO_4$ agree substantially with the above conclusions concerning the first and second complexes.[6] His formation quotient for the first complex would appear to be reliable, but the value for the second would be less so because the use of as much as 0.6 M H_3PO_4 would introduce appreciable amounts of a third complex, as may be seen from Fig. 3. His repetition of the spectrophotometric measurements with 0.1 M $HClO_4$–0.9 M $NaClO_4$ led him to consider the first complex to be a mixture of $UO_2H_2PO_4^+$ and $UO_2H_3PO_4^{++}$ and the second complex to be a mixture of $UO_2(H_2PO_4)_2$ and $UO_2(H_2PO_4)(H_3PO_4)^+$. Although the results of the present spectrophotometric study could have been interpreted in terms of the presence of a small amount of $UO_2H_3PO_4^{++}$ along with $UO_2H_2PO_4^+$, there was no statistical justification for doing so. It is thought that the solvent-extraction data at 2.545 M total phosphate, together with the other values in Table IV, provide striking evidence that the 1:2 and 1:3 uranyl phosphate complexes have the same charge as the uranium species that is extracted into the organic phase, *i.e.*, zero. Hence the species $UO_2(H_2PO_4)(H_3PO_4)^+$ must have been present to a much smaller extent than $UO_2(H_2PO_4)_2$ in the 0.5 to 1.0 M hydrogen-ion concentration of these experiments. It is evident that the conclusions based on the measurements of Baes in 0.1 M $HClO_4$–0.9 $NaClO_4$ might differ significantly from those of the present data in 0.5 M $HClO_4$–0.5 M $NaClO_4$, although there is good agreement at 1 M $HClO_4$. It is possible that the differences might have been caused by the existence of different activity coefficients in 0.5 and 0.9 M $NaClO_4$, even though the ionic strength was the same. The variation in activity coefficients from those in 1 M $HClO_4$ probably would be less in the present measurements than in Baes's spectrophotometric study. For example, this generalization would be

expected to hold for $\gamma_{\pm}$ of perchloric acid itself, judging from a study of activity coefficients in analogous 1 M chloride solutions.[33] Also, the corrections due to ionized phosphoric acid would be less at the higher acidity. Nevertheless an elucidation of the charges on the complex ions would require less accuracy from Baes's values for the formation constants.

The data of Schreyer and Baes on the solubility of uranyl phosphates in phosphoric acid[3,4,34] can be interpreted in terms of a 1:3 uranyl phosphate complex in addition to the lower complexes.[4,6] However, the interpretation of such data is futile whenever charged complexes are concerned unless a constant ionic strength is maintained. An interesting, possibly anomalous, phenomenon is the solubility behavior in phosphoric acid at 6.1 M H_3PO_4, the transition point between $UO_2HPO_4 \cdot 4H_2O$ and $UO_2(H_2PO_4)_2 \cdot 3H_2O$.[3,34] If a neutral 1:3 uranyl phosphate complex were the principal dissolved species at that point, the solubility would be expected to continue to increase there instead of sharply decreasing, as it actually does. The reversed solubility trend might be explained by assuming the average complex to be a polynuclear species, *e.g.*, a 3:5 uranyl phosphate complex. However, evidence confuting the existence of appreciable amounts of such polynuclear complexes at the uranium concentration of the present investigation is supplied by conformance of the uranium solutions to Beer's law at 3.7 M H_3PO_4 in the present investigation, the spectrophotometric results of Baes,[6] and the incompatibility of large amounts of polynuclear complexes with the present solvent-extraction data.

[Communication No. 1893 from the Kodak Research Laboratories, Eastman Kodak Company]

The Mechanism of Dye Formation in Color Photography. V. The Effect of a Non-ionic Surfactant on the Ionization of Couplers[1]

By L. K. J. Tong and M. Carolyn Glesmann

Received April 2, 1957

The effect of a non-ionic surfactant on the apparent ionization constant of phenolic and naphtholic hydrogen has been measured by a photometric method. The data have been interpreted by assuming a different solubilization of the acid and salt forms of these compounds. The solubilization constants, defined as distribution coefficients between the micelle and the aqueous phase, were found to be very similar to the corresponding distribution coefficients between *n*-octanol and water. The solubilized salts appear to be completely dissociated.

The dyes in many color photographic systems are products of the oxidative condensation of a developing agent, usually N,N-disubstituted-*p*-phenylenediamines and a coupler, a compound with an active coupling site. In the Kodacolor and Kodak Ektacolor systems, water-insoluble couplers are incorporated in a highly dispersed organic phase, in the aqueous gelatin medium of the photographic emulsion; and the developing agent is supplied to the film from a high-*p*H-bath during processing. The couplers, on contact with the alkaline developer solution, form salts, which presumably are oriented in high concentration at the very large interface. This reaction is probably rapid and reversible; therefore, equilibrium is likely to be established before an appreciable fraction of the coupler reacts with the oxidized developer to form dye.

Dye formation may take place both in the organic phase and at the interface. The relative importance of both sites for color formation depends on many factors, and it was one of our primary objectives in this work to investigate these factors. In this paper and in the next (Part VI) emphasis is placed on the phenomena at the interface. Systems containing micelle-forming colloids are convenient for such studies because of their large surface-to-volume ratio. The colloid used for this investigation was Triton X-100. This material, supplied by Rohm and Haas, is the condensation product of diisobutylphenol and ethylene oxide. From its origin and molecular weight the following formula has been derived

in which n has an average of 9.5 units. This surfactant was chosen because its properties as a micelle-forming agent are well known from the investigations of Marsden, Gonick and McBain.[2]

The equilibria of the molecular species involved in dye formation and their distribution are discussed in the present paper, thus laying the foundation for a study of the dye formation in the subsequent communication.

II. Experimental Method and Treatment of Data

The behavior of couplers in the presence of Triton X-100 was studied by means of light absorption and *p*H measurements of coupler solutions containing different concentrations of this colloid. Most of the experiments were carried out with solutions of constant ionic strength (μ = 0.43 to 0.45) and constant potassium ion concentration (0.25 M). Therefore, in the following equations, the equilibrium constants are expressed in terms of concentrations, and are equal to the products of the thermodynamic constants and of the activity co-

efficients which are assumed to be constant. The concentrations of the substances in the micelles are defined as the amounts of substance solubilized divided by the volume of the micelles. This volume is assumed to be the volume of Triton X-100 added in making up the solution less the volume at the critical micelle concentration (CMC), since this amount of Triton does not contribute to the micelles.

In accordance with Reich's[3] argument, it is further assumed that the volume of the individual micelles is approximately independent of the Triton X-100 concentration; therefore, the total interface is also approximately proportional to the micellar volume, and the following conclusions are equally valid, whether solubilization takes place in the interior of the micelles or at their periphery (adsorption). Let

$(HC)_m$ = concn. of the coupler acid in the micellar region
$(HC)_a$ = concn. of the coupler acid in the aq. region
$(C^-)_m$ = concn. of the coupler ion in the micellar region
$(C^-)_a$ = concn. of the coupler ion in the aq. region

The coupler dissociates in the aqueous region, according to eq. 1

$$K_0 = \frac{(C^-)_a\, 10^{-p\mathrm{H}}}{(HC)_a} \qquad (1)$$

The distribution of substances by solubilization is assumed to be governed by laws analogous to those on which distribution between bulk phases depends. This principle has been discussed by McBain and Hutchinson.[4] We, therefore, set

$$\alpha = \frac{(HC)_m}{(HC)_a} \qquad (2a)$$

and

$$\beta = \frac{(C^-)_m}{(C^-)_a} \qquad (2b)$$

For constant (K^+), β should be constant whether the salt is solubilized as (1) dissociated ions with the counterions in the outer layer of the electrical double layer or (2) as ion-pairs in the inner layer. For variable (K^+), however, β should remain constant under situation 1, but should vary in proportion to (K^+) under situation 2. The results in Table V show that β is independent of (K^+), and, therefore, situation 1 is indicated.

Let $\overline{(C^-)}$ and $\overline{(HC)}$ be the over-all concentrations of the salt and acid, defining

$$\overline{(C^-)} = \frac{v_a(C^-)_a + v_m(C^-)_m}{v_a + v_m} \qquad (3)$$

$$\overline{(HC)} = \frac{v_a(HC)_a + v_m(HC)_m}{v_a + v_m} \qquad (4)$$

where v_a = volume of the aqueous region and v_m = volume of the micellar region. Let

$$V_m = \frac{v_m}{v_m + v_a} \qquad (5)$$

and

$$V_a = \frac{v_a}{v_m + v_a} \cong 1 \text{ since } v_m << v_a \qquad (6)$$

The eq. 2 to 6 lead to

$$\overline{(C^-)} = (C^-)_a(1 + \beta V_m) \qquad (7)$$

$$\overline{(HC)} = (HC)_a(1 + \alpha V_m) \qquad (8)$$

Let us define

$$K = \frac{\overline{(C^-)}\, 10^{-p\mathrm{H}}}{(HC)} \qquad (9)$$

Combining eq. 1, 7, 8 and 9, we have

$$\frac{K}{K_0} = \frac{(1 + \beta V_m)}{(1 + \alpha V_m)} \qquad (10)$$

For analytical purposes, eq. 10 can be rearranged into a more useful form

$$\left(1 - \frac{K}{K_0}\right)\frac{1}{V_m} = \alpha\frac{K}{K_0} - \beta \qquad (11)$$

By the use of eq. 11, α and β can be obtained graphically by plotting the left-hand side of the equation *vs.* K/K_0, the two constants α and β are equal to the slope and the negative intercept of the straight line, respectively.

Evaluation of K, as just defined, was made from photometric and pH measurements. The molar extinction coefficients for each of the molecular species, C^- or HC, may be different, depending on whether the respective species is present in the aqueous region or in the micellar region. Although changes in pH will shift the equilibrium between the molecular species, the distribution coefficient of each of the species between the two regions is assumed not affected. Therefore, as long as V_m is kept constant, it is only necessary to find a wave length where the molar extinction coefficients for the salt and acid forms are sufficiently different in order to measure the ratio $\overline{(C^-)}/\overline{(HC)}$.

To determine K, we set

$$K = \frac{(D - D_a)}{(D_b - D)}\, 10^{-p\mathrm{H}} \qquad (12)$$

where, at a given wave length and with a constant total coupler concentration, D_a is the optical density in an acid solution; D_b is the optical density in a strong basic solution; and D is the optical density in buffers at intermediate and known pH values.

III. Results and Discussion

The effect of colloids on dissociation constants of acid indicators has been studied in recent years by Hartley,[5] by Hartley and Roe,[6] by Krishnappa, Doss and Rao,[7] and by Hiskey and Downey.[8] All these investigators, however, used ionic colloids. This introduces complications owing to (1) superimposing the effect of complex formation between the indicator and molecularly dispersed colloids on that of solubilization by the micelles and (2) high zeta-potentials causing a large and uncertain concentration of H^+ near the surface of the micelle.[6] Krishnappa, Doss and Rao interpreted their data entirely on the basis of molecular complexes, confining their results to concentrations below the CMC, but, judging from their data, some of the concentrations reported may have exceeded that limit. In our work, complex formation between colloids and substrates would introduce additional complications in the interpretation of the coupling rate obtained in the presence of the col-

loids. To minimize these complications, a non-ionic colloid, Triton X-100, was used.

A. Determination of *K*.—Table I shows three examples of α-naphthol measured in solution of different concentration of Triton X-100 as well as at different (K^+) values in order to illustrate the determination of *K* from photometric and *p*H measurements. For each set of determinations, the average error of *p*K calculated by eq. 12 is ± 0.02 unit for measurements within a *p*H range not greater than 0.5 unit from the average *p*K. In taking the average, more weight was given to the experiments at a *p*H very close to the *p*K of the coupler, because the accuracy of these data is the highest in this region. The average values of *p*K are listed in Table II. It is evident that *K* is practically independent of potassium ion concentration and ionic strength within the experimental range indicated.

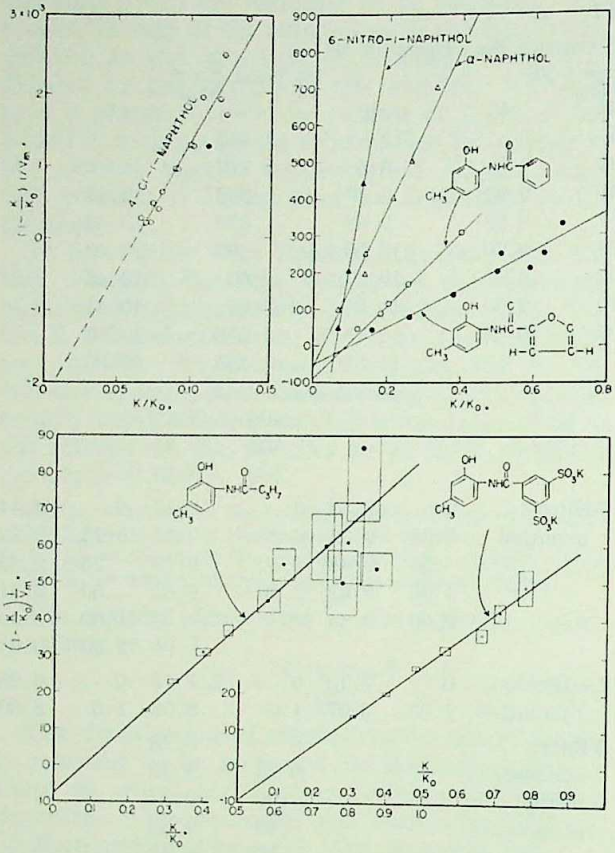

Figs. 1 and 2.—Graphical determination of the distribution constants α and β, according to equation 11.

sented by straight lines as required by the equation. It should be pointed out that accuracy is low at low V_m and/or high K/K_0. At low V_m, the uncertainty is caused mainly by the error inherent in obtaining a small difference from two relatively large quantities, one of them being the CMC of Triton X-100, 0.054 volume %.[9,10]

At high ratios of K/K_0, the factor $(1 - K/K_0)$ becomes uncertain. In Fig. 2, the rectangles represent the magnitude of error caused by ± 0.02 unit in pK (curve on the left) and ±0.01 unit in pK (curve on the right). The lines were drawn within these limits.

C. Distribution of Couplers between *n*-Octanol and Aqueous Buffers.—In this treatment, α and β were postulated as distribution constants of the acid and salt, respectively, between the micellar and the aqueous regions. Comparison of these constants with the distribution constants in organic solvents having properties similar to those of Triton may show the nature of solubilization. The couplers were distributed between the *n*-octanol and aqueous buffers, and the distribution constants, ϕ_{HC}, for the coupler acid are listed in Table III.

Unfortunately, accurate distribution constants of the salts ϕ_{C^-} could not be obtained for most of the couplers for the following reason. In order to determine the distribution constants, the total coupler concentration in each phase is measured and the distribution ratio, R, is expressed as

$$R = \frac{(HC)_S + (C^-)_S}{(HC)_a + (C^-)_a}$$

where the subscripts S and a indicate organic solvent or aqueous phase, respectively. At high pH, $(HC)_a$ can be neglected in comparison with $(C^-)_a$ and the expression becomes

$$R = \frac{(H^+)\phi_{HC}}{K_0} + \phi_{C^-} \qquad (13)$$

Since ϕ_{C^-} is calculated from eq. 13 as a difference between two experimentally determined quantities, its error will be large if its magnitude is relatively small.

TABLE III

DISTRIBUTION OF COUPLERS BETWEEN *n*-OCTYL ALCOHOL AND pH 6.5 BUFFER

Coupler	V_{aq}, cc.	V_{alc}, cc.	(Coupler)aq, $M \times 10^4$	(Coupler)alc, $M \times 10^4$	$\phi_{HC} \times 10^{-3}$
α-Naphthol	250	25	0.556	690	1.24
	250	25	.270	330	1.22
4-Cl-1-naphthol	250	25	.0445	564	12.7
	250	25	.0224	276	12.3
2,4-Dichloro-1-naphthol	500	50	.033	1880	57
6-Nitro-1-naphthol	250	25	.26	845	3.25
	250	25	.139	412	2.97
2-(2-Furamido)-5-methylphenol	500	10	.053	36.9	0.69
2-Butyramido-5-methylphenol	300	10	.112	19.7	.18
2-Benzamido-5-methylphenol	500	10	.254	29.8	1.2
2-(3,5-Disulfobenzamido)-5-methylphenol	25	100	2.0	Est. .04	< .00002

Preliminary experiments indicated that, for most couplers, $R \cong \phi_{HC}(H^+)/K_0$. Table IV shows the distribution of 2,4-dichloro-1-naphthol be-

TABLE IV

DISTRIBUTION OF 2,4-DICHLORO-1-NAPHTHOL BETWEEN *n*-OCTYL ALCOHOL AND pH 12 BUFFER, (K^+) VARIED

V_{alc} = 50 ml., V_{aq} = 150 ml.

	Coupler initially in alcohol phase			Coupler initially in aqueous phase		
(K^+), M	(Coupler)aq, $M \times 10^4$	(Coupler)alc, $M \times 10^4$	R	(Coupler)aq, $M \times 10^4$	(Coupler)alc, $M \times 10^4$	R
0.125	2.20	8.4	3.82	1.62	6.36	3.93
.25	1.49	10.5	7.05	1.12	7.86	7.02
.50	0.913	12.3	13.5	0.692	9.15	13.2
1.00	.537	13.4	25.0	.409	9.99	24.4

tween *n*-octanol and a strongly alkaline solution. The value of R was found to depend upon the (K^+) and the data can be represented by $R = 0.8 + 25(K^+)_a$. The last term of this expression, ϕ_{C^-}, is proportional to (K^+) because both ions of the salt are extracted together into the bulk organic phase; therefore, $(K^+C^-)_S/(K^+)_a(C^-)_a = 25$. The value 0.8 in the equation agrees with the calculated value of the first term on the right-hand side of eq. 13.

D. Comparison of the Micellar Distribution Constants α, β and the Bulk Distribution Constants ϕ_{HC}.—The constants α, β and ϕ_{HC} are summarized in Table V. The data show that the constants α and β or the ratio β/α for a given coupler do not vary over an eightfold change of (K^+), but Table IV shows that ϕ_{C^-} is directly proportional to (K^+). This is taken to mean that, in the presence of Triton, the salt is solubilized as dissociated ions (in contrast to ion-pairs) with the counterions in the double layer. The (K^+) in the double layer is proportional to that in the bulk of the aqueous phase, and in solutions of high buffer salt concentration they are nearly equal. Therefore, the effect of (K^+) variation on the activity of the salt in the two regions is also nearly equal. The solubilization of the salts may be regarded as the formation of mixed micelles with the coupler ions hydrated at the surface.

TABLE V

SUMMARY OF CONSTANTS α, β AND ϕ_{HC}

$(K^+) = 0.25\ M$, $\mu = 0.43$–0.45, unless otherwise noted

Couplers	$\alpha \times 10^{-3}$	$\beta \times 10^{-3}$	$\phi_{HC} \times 10^{-3}$	β/α	$\frac{\phi_{HC}}{\alpha}$
α-Naphthol	2.2	0.06	1.2	0.027	0.55
	2.4[a]	.06[a]			
	2.5[b]	.05[b]			
4-Cl-1-naphthol	37.0	2.4	12.0	0.065	.32
				.048[a]	
				.039[b]	
2,4-Dichloro-1-naphthol			57.0	.13	..
				.13[a]	
				.10[b]	
6-Nitro-1-naphthol	6.2	0.38	3.0	.061	.48
	4.5[a]	.30[a]			
	6.0[b]	.35[b]			
2-(2-Furamido)-5-methylphenol	0.50	.05	0.69	.10	1.4
	.48[a]	.04[a]			
	.68[b]	.05[b]			
2-Butyramido-5-methylphenol	.095	.008	0.18	.08	1.9
2-Benzamido-5-methylphenol	1.0	.09	1.2	.09	1.2
2-(3,5-Disulfobenzamido)-5-methylphenol	0.070	.009	$<2 \times 10^{-5}$	.13	$<3 \times 10^{-4}$

[a] $(K^+) = 0.125\ M$. [b] $(K^+) = 1.00\ M$.

All the couplers, with the exception of 2-(3,5-disulfobenzamido)-5-methylphenol, have values of ϕ_{HC} very nearly equal to their α values, as shown by the α/ϕ_{HC} ratios given in the last column of Table V. The similarity holds over a wide range of values of either term. One may surmise from these data that the solubilized non-ionized acids are located in the interior of the micelles where the environment is similar to the bulk of the octanol. The disulfo compound, however, exhibits a very small ϕ_{HC}/α. This may be explained by a large free energy of hydration of the ionized sulfonate groups, which inhibits extraction into the interior of the alcohol, but does not inhibit solubilization where the hydrated ions may be oriented at the surface of the micelle.

As pointed out by Hiskey and Downey,[8] the shift in the apparent pK can be interpreted equally well by either solubilization or complex formation. In the experiments described by Hiskey and Downey, the complex was isolated, and, in the experiments of Krishnappa, Doss and Rao,[7] the surfactant concentrations were low, probably below the CMC. Therefore, the results of both investigations were justifiably interpreted with complex formation. In our case, however, the concept of differential solubilization is preferable because a non-ionic colloid is used at concentrations above the CMC. As further evidence of the similarity of the two interpretations, it is noteworthy that the equation derived by Krishnappa, Doss and Rao expressing the change in pH as the same form as eq. 10 expressing the change in pK.

IV. Experimental

A. Ionization.—Solutions of the couplers in Triton and phosphate buffer ranged in concentration from 10^{-4} to $7.5 \times 10^{-4}\ M$. Solutions with a $(K^+) = 0.25\ M$ and lower were prepared by mixing and diluting stock solutions of 0.0833 M potassium phosphate (tribasic) containing Triton and 0.25 M potassium phosphate (monobasic) containing Triton. Solutions with $(K^+) = 1.0\ M$ were prepared by adding potassium chloride to the same stock solutions.

The densities of the solutions were measured in a Beckman model DU spectrophotometer in the region between 300 and 350 mμ, with the exception of 6-nitro-1-naphthol solutions, which were measured at 520 mμ. The pH of the solutions was measured with a Beckman Model G pH meter. The solutions were kept in a thermostat at 25° and the absorption cell was surrounded by a jacket through which 25° water was circulated.

B. Distribution.—To obtain ϕ_{HC}, the couplers were distributed between n-octyl alcohol and pH 6.5 phosphate buffer, with (K^+) equal to 0.25 M and ionic strength equal to 0.375. With α-naphthol, 4-chloro-1-naphthol and 6-nitro-1-naphthol, weighed amounts of the coupler were dissolved in n-octyl alcohol and shaken with the buffer. After clarification by centrifuging, the coupler in the aqueous solution was analyzed by measuring the density of the butyl acetate extract of the dyes formed by coupling with excess 4-amino-2-methyl-N-diethylaniline at pH 8. The distributions were measured at two different coupler concentrations.

The phenolic-type couplers were first dissolved in the aqueous pH 6.5 buffer and then shaken with the alcohol. The coupler in the aqueous phase was analyzed before and after distribution by the procedure just described.

The 2-(3,5-disulfobenzamido)-5-methylphenol showed an apparent increase in coupler concentration in the aqueous phase after distribution, which was attributed to the extraction of water into the alcohol. A maximum value for the distribution coefficient was estimated after correction for volume change.

Experimental details of the distribution of the acid form of the couplers appear in Table III.

The distribution of 2,4-dichloro-1-naphthol salt (pH 12) was found to be dependent on the potassium ion concentration. In this experiment, a weighed amount of the coupler was dissolved in $^1/_{12}\ M$ potassium phosphate (tribasic). After the solution of potassium phosphate (tribasic) was diluted with water or mixed with KCl solution to give the desired (K^+), it was shaken with n-octyl alcohol. The coupler in the aqueous phase, after distribution, was analyzed by measuring the optical density of the butyl acetate extract of the dye formed by coupling with excess 4-amino-N-diethylaniline at pH 6.5. The distributions at each level of (K^+) were repeated with the coupler initially in the alcohol phase. For details, see Table IV.

C. Materials.—**Inorganic salts** used in preparing the buffers were reagent grade K_3PO_4, KH_2PO_4 and KCl.

The ***n*-octyl alcohol** used in the distribution experiments was Eastman White Label Grade.

The ***n*-butyl acetate** was Eastman Special Grade.

Triton X-100 was purchased from Rohm and Haas Company. The molecular weight and composition of this material have been determined and found to be in reasonable agreement with the information furnished by the manufacturer.

The **α-naphthol** was Eastman White Label Grade, further purified by sublimation, followed by recrystallization from cyclohexane, m.p. 97–98°.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

The **2,4-dichloro-1-naphthol** was Eastman White Label Grade, recrystallized from methanol; m.p. 106–107°.

The **6-nitro-1-naphthol**, m.p. 178–180°, was prepared and purified in accordance with the procedure of Hodgson and Turner.[11]

The **4-chloro-1-naphthol**, m.p. 119–120°, was prepared by the method of Kast.[12]

The following compounds were prepared by C. R. Barr, of these Laboratories, using as starting materials commercially available Eastman White Label Grade chemicals. The final products are all crystalline and in acid form except 2-(3,5-disulfobenzamido)-5-methylphenol, which is a dipotassium salt.

2-Benzamido-5-methylphenol.—To a solution of 12.3 g. (0.1 mole) of 2-amino-5-methylphenol[13] and 26 g. (0.2 mole) of quinoline in 150 ml. of dioxane was added, with stirring, at 25°, 15.5 g. (0.1 mole) of benzoyl chloride in 30 ml. of dioxane. The temperature rose rapidly to 40°. The reaction mixture was stirred at room temperature for one hour and then was poured into two liters of 5% hydrochloric acid. The solid product was collected by filtration, dried and recrystallized from ten parts of toluene, giving 15 g. (68%); m.p. 168–169°. *Anal.* Calcd. for $C_{14}H_{13}NO_2$: C, 74.0; H, 5.7; N, 6.2. Found: C, 74.3; H, 5.8; N, 6.4.

2-Butyramido-5-methylphenol.—Prepared as described in the preceding section, this material (10 g., 52%) melted at 114–115° after crystallization from ligroin. *Anal.* Calcd. for $C_{11}H_{15}NO_2$: C, 68.4; H, 7.8; N, 7.3. Found: C, 68.8; H, 7.9; N, 7.4.

2-(2-Furamido)-5-methylphenol.—Prepared similarly to the preceding compound, this material gave a yield of 10 g. (46%); m.p. 167–168°. *Anal.* Calcd. for $C_{12}H_{11}NO_3$: C, 66.4; H, 5.1; N, 6.5. Found: C, 66.8; H, 5.4; N, 6.6.

2-(3,5-Disulfobenzamido)-5-methylphenol Potassium Salt.—To a solution of 18.5 g. (0.15 mole) of 2-amino-5-methylphenol and 15 g. (0.18 mole) of sodium acetate in 300 ml. of 90% acetic acid, 50 g. (0.15 mole) of 3,5-dichlorosulfonylbenzoyl chloride was added, with stirring, at 30°. The temperature rose rapidly to 37°. The reaction mixture was stirred at room temperature for 5 hr. and diluted with 300 ml. of water. The solid was collected, dried and recrystallized from 26 parts of xylene, giving 44 g. (70%) of **2-(3,5-dichlorosulfonylbenzamido)-5-methylphenol**, melting at 173–174°. *Anal.* Calcd. for $C_{14}H_{11}Cl_2NO_6S_2$: N, 3.3. Found: N, 3.2.

To a refluxing solution of 28 g. (0.066 mole) of the dichlorosulfonyl compound in 140 ml. of methyl alcohol, 100 ml. of water was added. The resultant clear solution was heated at reflux for one-half hour and then concentrated to dryness under reduced pressure. The residue was dissolved in 80 ml. of water, and a solution of 13.8 g. (0.066 mole) of barium chloride in 40 ml. of water was added. The mixture was left standing at room temperature overnight, **the barium salt of 2-(3,5-disulfobenzamido)-5-methylphenol** separating in the form of fine, white needles; yield 20 g. (58%). *Anal.* Calcd. for $C_{14}H_{11}NO_8S_2Ba$: C, 32.2; H, 2.1; N, 2.7. Found: C, 32.4; H, 2.5; N, 2.6.

The barium salt (19.9 g., 0.038 mole) was dissolved in 150 ml. of hot water and converted to the potassium salt by the addition of 6.6 g. (0.038 mole) of potassium sulfate in 50 ml. of water. The barium sulfate was collected, and the filtrate was concentrated under reduced pressure. The residue was washed with 50 ml. of methyl alcohol and dried. Crystallization from 30 parts of glacial acetic acid gave 12 g. (68%) of the **dipotassium salt of 2-(3,5-disulfobenzamido)-5-methylphenol**. *Anal.* Calcd. for $C_{14}H_{11}NO_8S_2K_2$: C, 36.3; H, 2.4; N, 3.0. Found: C, 36.1; H, 2.7; N, 2.8.

The Mechanism of Dye Formation in Color Photography. VI. The Effect of a Non-ionic Surfactant on the Rate of Coupling

BY L. K. J. TONG AND M. CAROLYN GLESMANN

RECEIVED APRIL 2, 1957

The kinetics of coupling in the presence of a non-ionic surfactant between phenols (and naphthols) and quinonediimines formed by oxidation of disubstituted-*p*-phenylenediamine have been resolved in terms of simultaneous reactions in the micellar and in the aqueous regions. Both reactions involve the ionized form of the coupler exclusively. A method has been devised for calculating the amount of the reaction in each region.

Introduction

In the preceding paper,[1] the distribution constants α and β were calculated for both the acid and the salt forms of the couplers between aqueous and micellar regions in colloid solutions. The effect of this partition on the rate of coupling with the oxidized developing agent will be discussed in the present paper. The data are interpreted on the assumption that (1) simultaneous and independent reactions occur in the micellar and in the aqueous regions, and (2) the rate in each region is proportional to the product of reactant concentrations determined from the constants α and β.

The symbols have the same meaning as those in Part V of this series.

Since the quinonediimine T^+ is predominantly an hydrophilic cation, it is not solubilized to any great extent in the interior of the micelle; but if the electrical double layer is regarded as part of the micelle, then we can write

$$\gamma = \frac{(T^+)_m}{(T^+)_a} \qquad (1)$$

and

$$(\overline{T^+}) = (1 + \gamma V_m)(T^+)_a \qquad (2)$$

Since the addition of Triton will not, however, remove more than a very small fraction of T^+ from the aqueous region, we can set $(\overline{T^+}) \doteq (T^+)_a$. This assumption is justified by the absence of a measurable influence of Triton X-100 on the rate of deamination of T^+ (see under Results and Discussion).

The coupling rates were measured for the overall solution and the rate constants were therefore calculated in terms of the total concentrations

$$\frac{d(\overline{dye})}{dt} = k[(\overline{C^-}) + (\overline{HC})](\overline{T^+}) \qquad (3)$$

(1) For Part V, see L. K. J. Tong and M. Carolyn Glesmann, THIS JOURNAL, **79**, 4305 (1957).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

To resolve the observed rate into its components, we assume

$$(v_m + v_a)\frac{d(\overline{dye})}{dt} = v_a k_a (T^+)_a (C^-)_a + v_m k_{1,m} (T^+)_m (C^-)_m + v_m k_{2,m} (T^+)_m (HC)_m \quad (4)$$

The terms on the right-hand side of equation 4 express, respectively, the coupling rate of: (1) the coupler ion in the aqueous region, (2) the coupler ion in the micellar region, and (3) the non-ionized coupler acid in the micellar region. The term expressing the coupling rate of the coupler acid in the aqueous phase has been omitted from the equation because from the earlier work[2] it is known to be negligible.

Equation 4 holds equally well whether the reaction takes place in the interior or at the surface of the micelle; for, as long as the size of individual micelles remains constant, the extents of the two regions are proportional to each other. Combining equations 1 to 4 with those in Part V, we have

$$k[1 + 10^{(pK - pH)}] = \frac{k_a + k_{1,m}\gamma\beta V_m}{(1 + \beta V_m)} + \frac{k_{2,m}\gamma\alpha V_m(\overline{HC})}{(1 + \alpha V_m)(\overline{C^-})} \quad (5)$$

If, for a given V_m, the second term on the right of equation 5 is zero, the product, $k[1 + 10^{pK - pH}]$, will be independent of pH and will be the specific rate constant based on the total coupler ion concentration. Conversely, if the variation of k with pH can be predicted on the basis of $(\overline{C^-})$ alone, then the second term on the right of equation 5 and also the final term of equation 4 are negligible.

The fractional part of the reaction which takes place in each region can be calculated more conveniently from equation 6, which can be obtained from the earlier equations.

$$k\left[\left(\frac{\alpha(H^+)}{K_0} + \beta\right)V_m\right] = k_a + \left[k_{1,m}\beta + k_{2,m}\frac{\alpha(H^+)}{K_0}\right]\gamma V_m \quad (6)$$

using 10^{-pH} as (H^+).

Experimental

Coupling rates were determined by steady-state flow methods, either using direct analysis of the end product or comparison with a competing reaction of known kinetics, as described previously.[2] Unless otherwise stated, the method used in the present experiments is the "continuous method," in which the extent of the reaction is measured by the optical density of the dye solution as it passes through the absorption cell at the end of the flow system. All reactions were carried out at 25°.

The solutions were made up as described[2] except that Triton X-100 was added to the alkaline coupler solution. Therefore, the reaction mixtures have, as before, the ionic strength $\mu = 0.375$ M, and $(K^+) = 0.19$ to 0.25 M.

The molar extinction coefficients of the dyes involving 4-chloro-1-naphthol were obtained from solutions of the purified dyes. In the case of 2-(disulfobenzamido)-5-methylphenol, the molar extinction coefficient of the dye was obtained from the product of the coupling reaction with excess coupler.

All dye solutions containing Triton X-100 were found to obey Beer's law within the dye-concentration range of the experiments. The molar extinction coefficients were independent of the Triton X-100 concentration. The solutions of 2-(disulfobenzamido)-5-methylphenol dye in the absence of Triton X-100 did not obey Beer's law. In this case, the dye concentrations in the reaction mixtures were obtained from empirical calibration curves, using solutions of the same pH and ionic strength.

Materials.—The developing agents and couplers used in these experiments were prepared and purified as described in earlier papers of this series. The 4-amino-N,N-diethyl-3-methylaniline hydrochloride[3] is the same sample used in Part III of this series.[2] The 4-amino-3-methyl-N-ethyl-N-(β-methylsulfonamidoethyl)-aniline sulfate[4] is the same sample as in Part III of this series. The 4-chloro-1-naphthol is the same sample as in Part V of this series, m.p. 119–120°.[5] The 2-(3,5-disulfobenzamido)-5-methylphenol (dipotassium salt) is the same sample as in Part V of this series.

Results and Discussion

The addition of Triton X-100 does not alter the characteristics of the coupling reactions. Second-order rate plots produced in most cases smooth curves with constant slopes which could be extrapolated through the origin. Second-order rate constants k were calculated according to equation 3, using the total concentrations of the coupler and quinonediimine. Table IA shows that k is

unaffected by variation of the initial concentration of the reactants, by excess ferricyanide, $(B)_0 > (A)_0$, or by excess developing agent, $(A)_0 > (B)_0$. The last two facts have been pointed out in an earlier paper as evidence against mechanisms involving semiquinone in the rate expression. The independence of k on $(C)_0$ indicates that the rate of diffusion of quinonediimine to the micelle is not a controlling factor.

At constant Triton X-100 concentration, the rate constants k are proportional to the over-all degree of ionization calculated from K (see Table II, Part V). In Fig. 1, k was calculated as a function

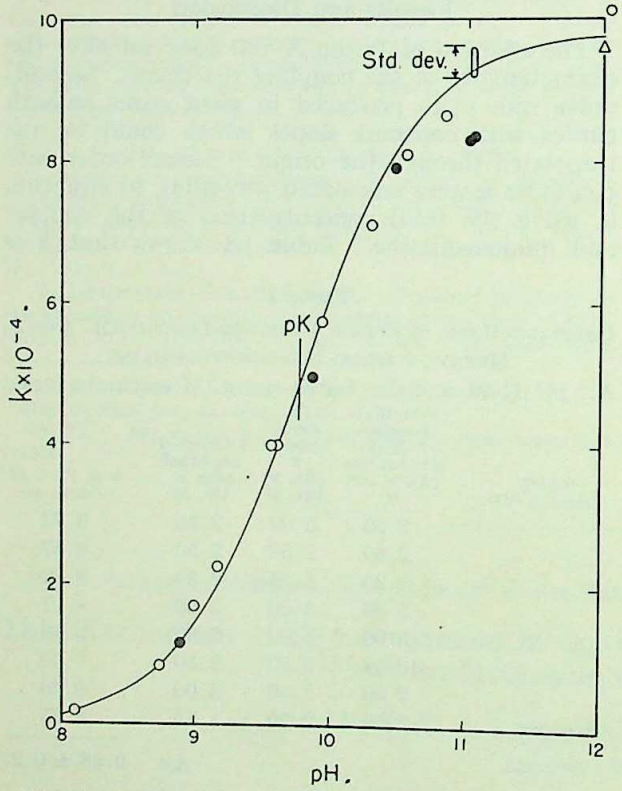

Fig. 1.—Rate of coupling between 4-chloro-1-naphthol and 3-methyl-4-amino-N,N-diethylaniline; Triton X-100 concentration = 0.25 (vol. %); curve calcd; experimental methods: O, continuous; △, competitive; ●, chemical stop.

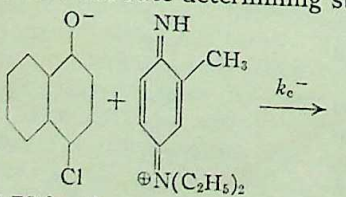
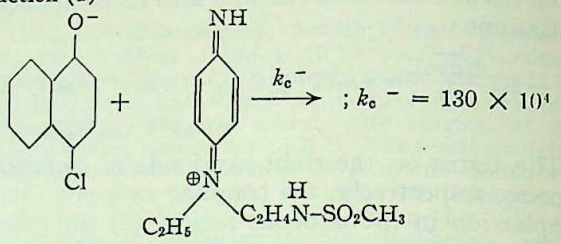
of pH for the reaction between 4-chloro-1-naphthol and 3-methyl-4-amino-N,N-diethylaniline, it being assumed that the rate-determining step is



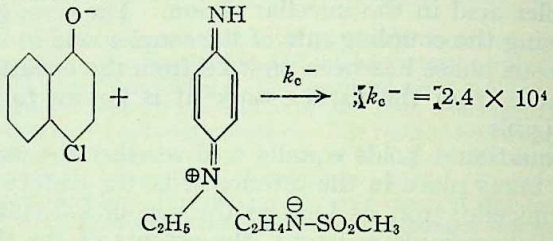
with $pK = 9.78$ for the coupler, and $k_c^- = 9.80 \times 10^4$, the specific rate constant of the ion. In Fig. 2, the rates for the reaction between 4-chloro-1-naphthol and 4-amino-3-methyl-N-ethyl-N-(β-methylsulfoamidoethyl)-aniline have been resolved into the rates of the two reactions: one involving the cation and the other involving the zwitterion of the quinonediimine in the rate-determining step.

In the experimental range of pH, reaction 1 is predominant; the sharp peak in Fig. 2 is due to the

Reaction (1)



Reaction (2)



fact that the pK of the coupler (9.78) is very near the pK of the quinonediimine (9.56).[6]

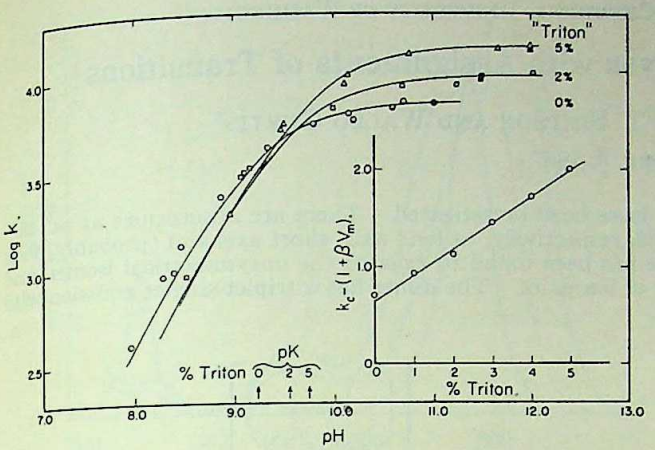

Fig. 3.—Rate of coupling between 5-methyl-2-(3,5-disulfobenzamido)-phenol and 3-methyl-4-amino-N,N-diethylaniline. Triton X-100 concentrations are indicated.

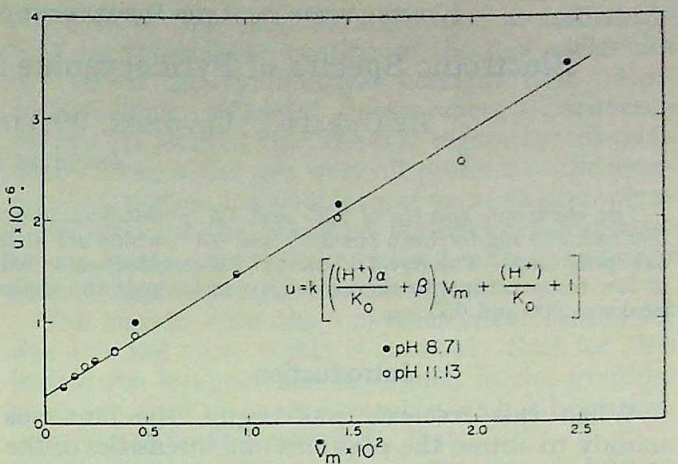

Fig. 4.—Effect of Triton X-100 on coupling rate between 4-chloro-1-naphthol and 3-methyl-4-amino-N,N-diethylaniline u (defined in figure) *vs.* V_m.

The values of log k_c^- (horizontal asymptotes) increase with Triton concentration, as shown.

The experimental points in Figs. 1 and 2 are in agreement with the calculated lines, within the accuracy of the *p*H measurements. In Fig. 3, the errors are slightly higher than can be expected from the error in *p*H. In the low *p*H region, however, the curves seem to deviate by a constant value in the log k scale. They show no tendency to approach a constant value of k, which would be expected if any of the rate terms containing (HC) were significant.

At constant *p*H, the rate constants vary with the Triton X-100 concentration, as shown by Table IB. These results were used to calculate the values of the left-hand side of equation 6. In Fig. 4, these data are plotted *vs.* V_m. Although the coupler is ionized only slightly at the lower *p*H values, and almost completely at the high *p*H values, the two sets of data, when plotted, lie practically on the same line. This again shows the insignificance of any term involving the un-ionized coupler in the rate expression. The extrapolated value at $V_m = 0$ is k_a, the rate constant in the aqueous region in equilibrium with the micelles. At any other value of V_m, the ratio $(\mu - k_a)/k_a$ represents the ratio of the reaction rate in the micelle to that in the aqueous region. From Fig. 4 it can be estimated that, in the presence of 2% Triton X-100, 90% of the coupling reaction takes place in the micelles. The effect of the molecularly dispersed Triton X-100 on the coupling rate could be observed by comparing k_a obtained by extrapolation with k measured directly in the absence of Triton; unfortunately, the latter cannot be obtained for the reaction shown in Fig. 4, owing to the precipitation of the dye. The reaction shown in Fig. 3, however, has been followed without Triton X-100. The insert in Fig. 3 shows a plot of equation 6, with k_c^- obtained at high *p*H. The point at zero Triton concentration obtained directly agrees well with k_a obtained by extrapolation; this shows that there is no measurable effect of the molecularly dispersed Triton X-100 on the coupling rate. The points at high *p*H in Fig. 3 were either obtained by the "continuous method," corrected for deamination in the calculation, or by the method of competing reactions described earlier, the rate of deamination being used as a standard. The rate of deamination has been found independently to be unaffected by Triton X-100, up to a concentration of 5%. The independence of deamination rate on Triton X-100 concentration indicates that very little quinonediimine has been removed from the aqueous phase by solubilization. This argument is valid except for the improbable situation where the deamination of the solubilized and the unsolubilized quinonediimine would have the same rate. This situation seems improbable, especially since we have found that the presence of an anionic surfactant, *e.g.*, (Duponol) where solubilization is likely to be high, lowers the deamination rate very markedly. The ratios $\gamma k_m/k_a$ for the reactions of 3-methyl-4-amino-N,N-diethylaniline with 4-chloro-1-naphthol, and with 2-(disulfobenzamido)-5-methylphenol are 0.30 and 4.1, respectively. The ratio probably depends on the orientation of the coupler ion in the micelle, which influences the availability of the reactive site of the solubilized coupler. Systematic studies with this point in mind may prove instructive both with respect to problems of solubilization and of reaction kinetics.

Electronic Spectra of Pyridocyanine Dyes with Assignments of Transitions[1]

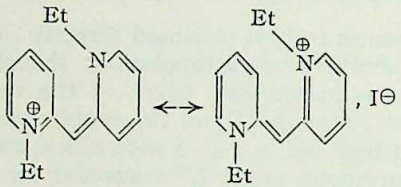
BY GERALD S. LEVINSON, WILLIAM T. SIMPSON AND WALDO CURTIS[2]

RECEIVED APRIL 3, 1957

The electronic spectra of 2,2′- and 4,4′-pyridocyanine dyes have been investigated. There are absorptions at *ca.* 490, 360 and 260 mμ for both the 2,2′- and 4,4′-, which are assigned, respectively, as long axis, short axis and (probably) long axis polarized. The dye 1,1′-diethyl-2,2′-pyridocyanine iodide has been found to exist as the unsymmetrical isomer, and at low temperatures to aggregate into an ion pair and a dimer of ion pairs. The dimer has a triplet-singlet emission with peaks at 600 and 650 mμ.

Introduction

When this research was begun, the aim was mainly to obtain the positions and intensities of the electronic transitions in the visible and quartz ultraviolet for the dye 1,1′-diethyl-2,2′-pyridocyanine iodide[3] (called dye I). (The Kekulé resonance in

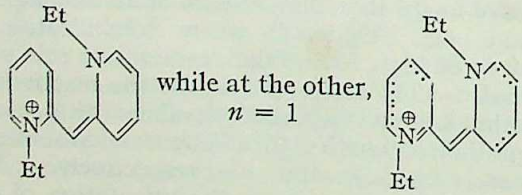


I

the pyridinium rings is not shown.) One reason for studying this dye was that it is but a single step up in complexity as compared with the family of straight chain dyes

$$R_2\overset{\oplus}{N}{=}CH{-}(CH{=}CH)_n{-}NR_2$$

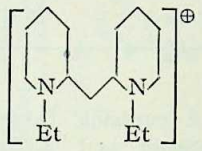
for which the wave length of absorption varies linearly with chain length. The step is significant because it no longer becomes possible to define a chain length. At one extreme, the effective chain length corresponds to $n = 5$



This means that empirical correlations between chain length and color are ruled out; some sort of interpretation guided by quantum theory is called for.

In the course of the investigation of dye I, it was found that certain chemical effects had to be understood before the spectroscopic investigation could be considered reasonably complete.[4]

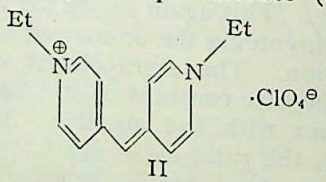
In the first place, it was found necessary to decide which of the plausible isomers was in preponderance, the one given above or the symmetrical one.



Second, it was found that aggregation, while not observed in dilute methanol solutions at room temperature, becomes very marked at liquid–nitrogen temperatures.

Isomerism.[5]—In the absorption spectrum of dye I there are strong peaks at 486 and 357 mμ (Fig. 1). It is believed these represent transitions to the first two singlet excited states. The polarization of the second transition (357 band) relative to the first was determined using the method of polarized fluorescence, and was found to be positive, though less so than the first transition. If the symmetrical isomer predominates, as was anticipated from a superficial consideration of steric hindrance, this positive polarization can only mean that the directions of oscillation of charge for the two transitions are intrinsically the same, and in all probability along the long axis. However, the theoretical treatments all favor having the first two transitions, respectively, long axis and short axis polarized.

Turning to the closely related substance 1,1′-diethyl-4,4′-pyridocyanine perchlorate[6] (dye II)



II

we again find two peaks in the absorption spectrum, one at 505 mμ and one at 372 mμ (Fig. 1), corresponding to those found for dye I at 486 and 357. This time the peak at 372 is markedly weaker than for dye I. There is only one isomer possible for dye II: it has to be symmetric. Although we tried and were unable to measure the polarization by fluorescence experiments, still the natural conclusion is that the 372 band of dye II represents a short axis polarized transition, because of its low intensity compared to the corresponding band of dye I. The band in dye I may be considered to have gained its strength (and positive polarization) through borrowing from the strong first band. This borrowing

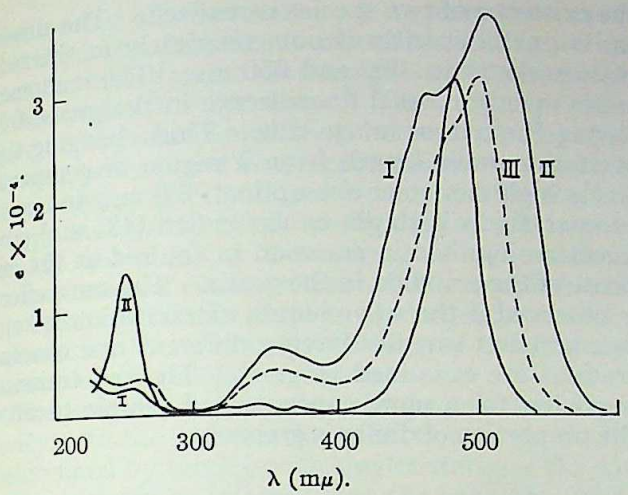

Fig. 1.—Room temperature absorptions of 2,2′-pyridocyanine (dye I), 4,4′-pyridocyanine (dye II), and crowded 2,2′-pyridocyanine (dye III) in methyl alcohol.

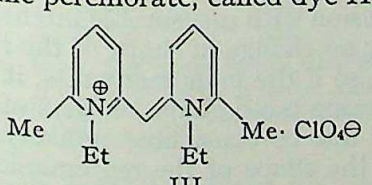
could only be induced by departure from symmetry. On this basis it is concluded that dye I exists as the unsymmetrical isomer.

The polarized fluorescence measurements on dye I, interpreted in conformity with our findings on aggregation at low temperatures (see below) might be explained another way, by assuming that the predominant monomeric species at low temperatures is an ion pair consisting of the symmetrical dye cation bonded unsymmetrically to the anion. The lack of symmetry would be considered as producing the borrowing referred to above. If this were the case, however, the room temperature absorptions in a region of concentration for which Beer's law is obeyed would show the 357 band as weak (as for dye II), and the band would strengthen markedly as ion pair formation develops on cooling. Effects of this nature were sought but not found. Thus the evidence favors our first conclusion, that for dye I the unsymmetrical isomer predominates.

In attempting to test this conclusion directly, we synthesized dyes designed to be forced sterically into the symmetrical configuration. The best example found was 1,1′-diethyl-6,6′-dimethyl-2,2′-pyridocyanine perchlorate, called dye III.[7]



III

The spectrum of this substance (Fig. 1) shows a considerable reduction in the height and area of the 357 band as compared with the corresponding band of dye I (the curve in Fig. 1 is dotted because the values on the ordinate are not quantitative. Instead, the height is made equal to that for dye I in the 486 region.). The reduction in the relative intensity of this band is interpreted as indicating that an appreciable fraction of the dye molecules is now in the symmetrical configuration. Notwithstanding, polarized fluorescence experiments on dye III showed that the 357 region is still positive. Even if the dye were all present as the symmetrical isomer, ion pair formation at the temperatures used for the polarized fluorescence measurements would have to be reckoned with as possibly influencing the polarization direction.

The reason why the unsymmetrical isomer of dye I is the more stable is probably that for this isomer the local permanent dipoles in the pyridine rings are lined up more favorably, as has been suggested to us by Professor J. R. Platt.

Aggregation.—Efforts to determine a unique emission spectrum of dye I were at first unsatisfactory, and the analysis of the difficulties led finally to the discovery that there were two separate species present, each with its own absorption and emission spectrum.

Absorption spectra at two initial concentrations of dye I at 77°K in a rigid glass[8] are shown in Fig. 2.

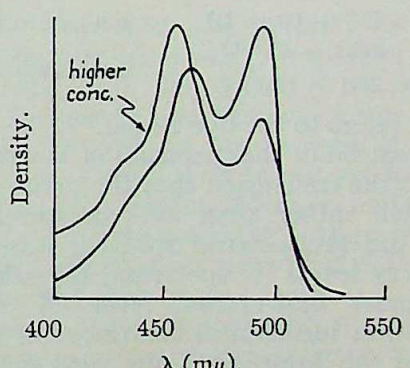


Fig. 2.—Absorption spectra at 77°K. of dye I taken at two different initial concentrations. Solvent is isopropyl alcohol–isopentane mixture.

The dependence on concentration shows aggregation. If pairs of curves such as those in Fig. 2 are worked up by scaling the ordinates to be the same at 495 mμ and subtracting, then a spectrum is obtained substantially like the one in Fig. 3 marked as belonging to species Y, where Y is the species which grows as the concentration is increased. This process is based on the assumption that Y does not absorb appreciably at 495, and the fact that pairs of curves corresponding to various concentrations all give the same curve for Y is taken as effectively proving the assumption. A curve for a second species, X, was not so easily found because there is no useful wave length where X does not absorb. However, the ratio of optical densities at 495 and 455 was plotted against the optical density at 495 as abscissa for various concentrations. The resulting curve was extrapolated to the value of the abscissa equal to zero, to determine the value of the ratio of infinite dilution. This gave the ratio of densities at 495 and 455 for the X component of the mixture. From this information together with the derived spectrum of Y, and using the absorption obtained with the least concentration of dye, a curve for pure X was constructed (Fig. 3).

The degree of polymerization could unequivocally be obtained from a typical law of mass action plot[9] if it were not for the fact that the solutions be-

(7) The method of reference 3 was used in the synthesis. The condensation was carried out between 2,6-lutidinium ethiodide and 2-methyl-6-iodopyridinium ethiodide in propyl alcohol with 2.1 moles of triethylamine. The iodopyridinium salt was prepared by heating 1 mole of 2-methyl-6-bromopyridine with 4 moles of ethyl iodide in a sealed tube at 100° for three days. The 2-methyl-6-bromopyridine was prepared by Mr. F. Bell under the supervision of Dr. A. G. Anderson.

(8) All rigid solutions used were made by dissolving the dye in a mixture of 3 parts of isopropyl alcohol and 7 parts of isopentane, by volume.

(9) The concentration of X can be determined from the composite spectrum at 495 mμ and the concentration of Y by subtraction. Beer's law is, of course, assumed for the components.

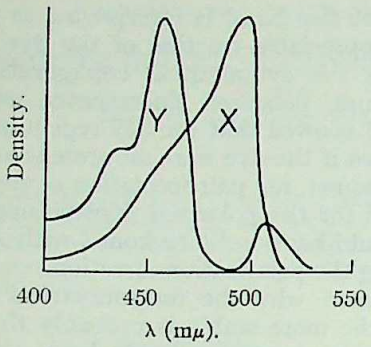

Fig. 3.—Absorptions derived from curves like those in Fig. 2, for species X and Y.

come rigid on approaching (but prior to) 77°K., where the absorption measurements are made. The actual result of a mass action study was to give an order of polymerization equal to the integer two within experimental error. The closeness to two is taken as indicating that the equilibria turned out to be all measured at the same effective temperature. The possible aggregation processes of order two are

$$\left.\begin{aligned} D^+ + I^- &= DI \\ 2D^+ &= D_2^{++} \\ 2DI &= (DI)_2 \end{aligned}\right\} \quad \begin{aligned} &\text{ion pair formation} \\ &\text{dimerization} \end{aligned}$$

where D^+ refers to the dye cation.

A comparison of the spectrum of Y with that for X leads to the conclusion that the process is one of dimerization rather than ion-pair formation, because of the symmetrical splitting into two separate energy levels (Y spectrum) on either side of the monomer first-excited level (X spectrum). The quantum mechanical treatment of this effect is given in the Appendix along with some further consideration of the experimental results.

The experiments have all been repeated using the dye perchlorate instead of the iodide. The half dimerization point is reached at a much lower concentration, and the split between the peaks (Y) is noticeably greater than for the iodide. This means that the anion must be involved in the dimer (and also rules out enhanced singlet-triplet absorption as an explanation of the first absorption). Moreover, since the order of polymerization is only two, the monomeric species (X) has to be the ion pair.

The driving force for the dimerization reaction is essentially the difference between two heats of ion-pair formation. The greater stability of the dimer is to be attributed to the fact that the resonance in the dye cation puts approximately one-half of a positive charge on each ring. By bringing two dye cations together to form a sandwich (see Fig. 7) an arrangement is obtained which allows each fully charged iodide anion to be adjacent to two half charges (one half for each dye cation). In contrast, for the monomeric ion pair the negative iodide can only be adjacent to a full positive charge by polarizing the dye, at the expense of the resonance stabilization of the ground state.

Emission Spectra.[10]—The pattern of the emission spectra is simple in its broad outlines, once the existence of two species is realized. The dimer emits predominantly if not completely in the red, with peaks at *ca.* 600 and 650 mμ. The monomer emits mainly normal fluorescence in the green, following the mirror image rule. Thus changing the excitation wave length from a region of comparatively high monomer absorption (470 mμ) to one of comparatively high dimer absorption (435 mμ) produces an increase in emission in the red at the expense of the emission in the green. The same effect is observed if the wave length of excitation is kept constant but samples having different dye concentrations are examined (Fig. 4). The red emission is greater for a more concentrated sample because the proportion of dimer is greater.

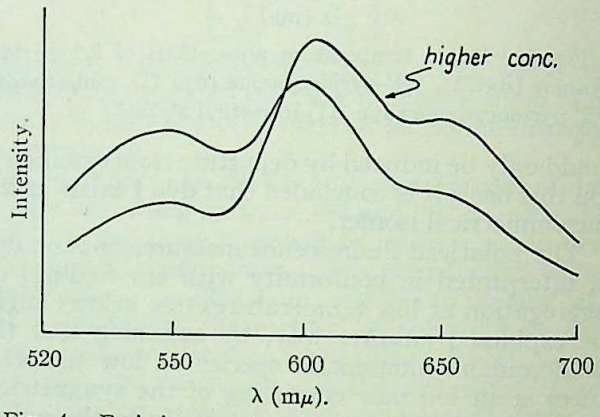

Fig. 4.—Emission spectra of dye I taken at two different initial concentrations (in isopropyl alcohol–isopentane glass at 77°K.).

Using a high concentration and keeping the excitation as much as possible in the dimer absorption region gives an emission spectrum which is approximately that for the pure dimer. From experiments of this type it was found that dimer emission in the green is at least an order of magnitude weaker than in the red.

To see whether or not there is any red emission from the monomer, measurements were carried out using very dilute solutions. However, the results are inconclusive because it was not found possible to lower the dimer concentration by dilution and still have a sufficient monomer concentration to give an emission with measurable intensity. There was little or no change in shape of the red emission on dilution, so if the monomer emits, it is with virtually the same band shape as that of the dimer. This would not be considered unlikely. The reason is that the shape of the red emission in simultaneous emission experiments is the same as that seen through a phosphoroscope (Fig. 5) so the emission is considered to be triplet-singlet. The dimer triplet-singlet emission spectrum would be expected to be virtually identical with the monomer spectrum because the resonance force coupling disappears after the inter-system crossing into the triplet state.

Examination of the emission curves for dilute solutions allows us to say that if the monomer phos-

(10) The spectra were obtained either photoelectrically or photographically. The exciting light was suitably modified using combinations of Corning filters, or a monochromator. Photoelectric detection was with a Photovolt Multiplier Photometer unit adopted to monitor the output of an infrared sensitive photomultiplier tube (Dumont Type K 1292). All spectra were recorded at 77°K. in the isopropyl alcohol, isopentane glass described above.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

phoresces at all, the intensity is no more than about one-third the fluorescent intensity. Thus we see that the inter-system crossing probability is considerably higher for the dimer. The crossing rate is governed by the competition between the intrinsic crossing process and fluorescent emission. Fluorescent emission for the dimer would be from the low energy state (510 band in Fig. 3), which is only weakly absorbing. The corresponding smallness in spontaneous emission probability coupled with the closeness of this state to the triplet state may account for the greater probability of crossing and hence phosphorescent emission.[11]

The emission in the red is always polarized negatively. If the polarization direction were simply determined by mixing with singlet states of the dye cation it could be inferred that the negative polarization would have to involve an out-of-plane singlet-singlet transition. The alternative is ruled out because the in-plane directions ($\parallel$ and $\perp$) are not strongly differentiated by the spin-orbit coupling, so the mixing would be with the closest levels, resulting in long-axis (hence positive) polarization. It was suggested by Dr. D. S. McClure that the existence of neighboring iodide ions might complicate this interpretation. What could be involved, say, is mixing with a charge-transfer transition polarized in the direction of a line joining iodide to nitrogen (see Fig. 7).

Energies, Intensities and Assignments.—The spectra of the 2,2′- and 4,4′-pyridocyanines in the visible and quartz ultraviolet are much alike (Fig. 1). In addition to the bands around 490 and 360, there is a band at about 260 mμ. Absorption is stronger in the 360 region than in the 260 region for the 2,2′-dye, though for the 4,4′-dye this order of intensity is reversed. The transition moment lengths are given in Table I together with the positions of the long wave length peaks.

TABLE I

TRANSITION MOMENT LENGTHS[a] AND LOCATION OF FIRST PEAKS FOR THE 2,2′- AND 4,4′-PYRIDOCYANINES[b]

2,2′ (Dye I)		4,4′ (Dye II)	
λ(mμ)	q(Å.)	λ(mμ)	q(Å.)
486	1.40	505	1.50
357	0.66	372	0.27
260	0.35	254	0.72

[a] Calculated from the areas using the formula $q^2 = -1.09 \times 10^{-19} \int \epsilon d \log \lambda$ (here q is in cm. and ϵ is the molar extinction coefficient). [b] The intensities for the 4,4′-dye were obtained by Mr. R. Lund.

The emission spectrum of dye I is typical in that there is fluorescence from the lowest energy excited singlet, represented by the 486 band in absorption; and, also, phosphorescence at longer wave lengths. The 0,0 value for the singlet-singlet transition is estimated to be $1.9_8 \times 10^4$ cm.$^{-1}$ and for the singlet-triplet, $1.7_2 \times 10^4$ cm.$^{-1}$.

The first singlet-singlet transition is assigned as long axis polarized from the observation that the transition moment length depends directly on the physical chain lengths of members of vinylogous series of cyanine dyes. The ion of dye II has a plane of symmetry perpendicular to the plane of the molecule, so the wave functions and in-plane transitions may be described by reference to the following simple character table .

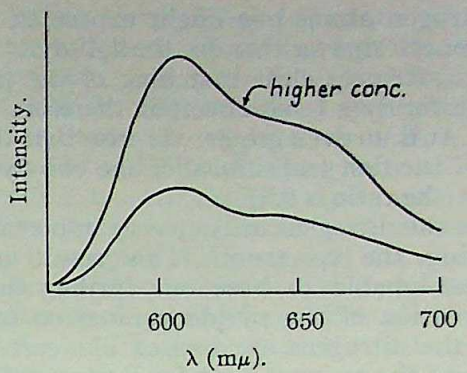

Fig. 5.—Phosphorescence emission spectra of dye I at two different initial concentrations (in isopropyl alcohol–isopentane glass at 77°K.).

	E	σ
A ($\perp$)	1	1
B ($\parallel$)	1	−1

The ground state is almost certainly totally symmetric so the long wave length transition described as "long axis" (and denoted as $\parallel$) is assigned as A → B. Because of the markedly lower intensity, which increases after an unsymmetrical perturbation, the next transition is presumed to be A → A($\perp$). The transition at 254 mμ is tentatively assigned as A → B because of the pattern of alternating intensity behavior for dyes II and III as compared with dye I (Fig. 1).

The point of view adopted with regard to dye I is that there is a close correspondence between its levels and the levels for dye II, and that as explained above the intensity changes are caused by the asymmetry (in the placement of the nitrogen atoms) considered as a perturbation. Thus the increase in the 357 region for dye I is attributed to mixing with the adjacent A → B transition at 486 and (with the above assignment) to a lesser extent with the one at 260. It is consistent with this interpretation that these essentially long axis transitions are reduced in intensity as compared to those in the symmetrical dye II. In fact, there seems to be something very close to conservation of intensity operative. The extra intensity in the 357 region for dye I is taken as $0.66^2 - 0.27^2$, the difference between the squares of the transition moment lengths. It is 0.36 Å.^{2}. This is balanced by the extra intensity in the 505 region for dye II, $1.50^2 - 1.40^2$ or 0.31 Å.^{2}.

Theoretical Interpretation.—Referring to the structural formula for the straight chain dyes in the Introduction, the 4,4′-dye has a chain length characterized by $n = 3$. Consistent with this it absorbs at around 500 mμ, in accord with our expectation based on counting 100 mμ for each pair of π electrons in conjugation. The second transition for a simple straight chain dye with $n = 3$ comes, however, at 305 mμ, compared with 372 mμ for the pyridocyanine. As noted in the Introduction, for the 2,2′-dye a chain length cannot be unambiguously selected, but considering the placement of

(11) We have learned from Professor M. Kasha that phosphorescence seems to predominate over fluorescence in a variety of cases where the concentration or other conditions are such as to favor aggregation.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

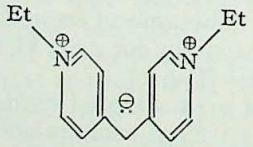
Digitized by Arya Samaj Foundation Chennai and eGangotri

the nitrogen atoms one might expect an effective chain length shorter than for the 4,4′-dye.

The extremely close matching of the transition energies for dyes I and II comes, therefore, as a surprise. It is an even greater surprise that the intensities of the first transitions for the two dyes are so similar (the ratio is 0.87).

Thus the nitrogens are not very important in determining the spectrum. This result makes it seem reasonable to base our further theoretical consideration of the pyridocyanines on models in which the nitrogens are treated like carbons. At this point the avenues open for interpretation are a molecular orbital approach or an approach using valence bond structures. The most fruitful procedure for dealing with cyanine dye spectra appears to be to abandon the idea of finding a uniquely simple and effective scheme, and to use the various contemporary approximate theories in their full variety.[12] Such a procedure has been used throughout the course of the present research, but it would be impractical to go into too much detail here. Nonetheless, we shall go on to consider the pyridocyanines according to first an orbital and then a structures approach.

According to the Hückel theory, virtually the same pattern of orbital energies is obtained as for benzene; though there is an extra non-bonding orbital, and all the levels except the non-bonding one are doubled. The non-bonding orbital exists roughly speaking because of structures like



The energy level pattern is shown in Fig. 6. Symmetries of orbitals are given by lower case letters, and of states and configurations by capitals; in each case using species as shown in the character table in the last section.

The ground configuration has symmetry A and may be denoted by the product of species of the two highest energy electrons.

$$\ldots a^2$$

The first excited configuration is threefold degenerate

$$\ldots ab(B) \quad \ldots aa'(A) \quad \ldots ab'(B)$$

Allowing for the nitrogens by changing α's does split the degeneracy but gives the wrong result; namely, that for the 4,4′-dye the first transition would be $a^2 \rightarrow ab(\parallel)$, but for the 2,2′-dye it would be $a^2 \rightarrow aa'(\perp)$! This is analogous to the situation involving pyridine and benzene, where the degenerate configurations obtained on the assumption of an all-carbon model have to be allowed to interact first before the hetero atom is taken into account.

If we allow the configurations to interact here, we find the upper levels ordered

B, A, B

simply by virtue of the "repulsion" between the B configurations. The first transition is now given as A → B, in agreement with experiment, but only after going to a higher order of approximation. This may be compared with the situation encountered using structures, where resonance between structures must be considered before a reasonable description of the ground state emerges.

Using the Hückel theory before configurational interaction, we can calculate the center of gravity of the triad of absorptions, say, in terms of the center of gravity of the benzene tetrad (average absorption at 210 mμ). Using the orbital energies for the two cases, we find for the dye triad a wave length

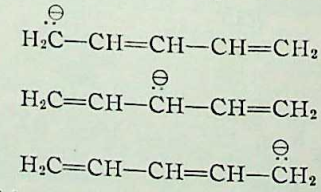
$$210 \text{ m}\mu \frac{2.133}{1.333} = 337 \text{ m}\mu$$

which agrees with what is observed (the average of the six transition energies listed in Table I corresponds to absorption at 346 mμ).

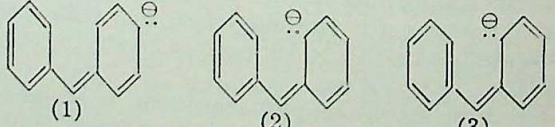
The transition moment length for one of the A → B transitions is 1.9 Å. and for the other, 0.4 Å. These values fit the values in Table I reasonably well when it is remembered that configuration interaction is involved. The transition moment length for the A → A (⊥) transition is calculated to be 0.6 Å., which is too high.

The A. O. coefficients squared in that b orbital which best characterizes the first B state (that is, with transition moment length 1.9 Å.) are larger at the 4,4′-positions than at the 2,2′-positions. Moreover, the non-bonding (a) orbital does not discriminate between the 2- or 4-positions. Thus putting in nitrogen atoms at the 4,4′-positions would, according to first-order perturbation theory, make the transition energy for the intense first transition somewhat smaller than for the 2,2′-dye, as observed.

If we want to emphasize calculating the position of the first transition, a method using structures proves to be more satisfactory. The basic interaction is considered to be very similar to what occurs in allyl anion, so that the straight chain dye with $n = 1$ would be treated using wave functions corresponding to the following three structures[13]



For the pyridocyanines there are a large number of interactions of allylic type, and there is the Kekulé interaction in the pyridinium rings as well. The allylic interaction is illustrated by the first two structures



The magnitude of the allylic interaction matrix element is taken so as to give correctly the color of the $n = 2$ dye (λ 409 mμ). Interaction between functions, illustrated by the second and third

(12) This is illustrated in the recent paper on dyes of J. R. Platt, *J. Chem. Phys.*, **25**, 80 (1956).

(13) The method is described by W. T. Simpson, THIS JOURNAL, **73**, 5350 (1951).

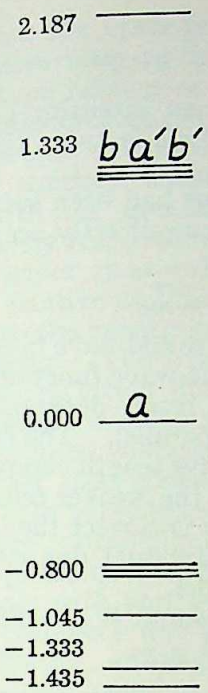

Fig. 6.—Diagram of energies of L.C.A.O: M.O.'s according to Hückel theory. Energies are in units of $|\gamma|$; and highest two levels (+4.000 and +5.076) have been omitted.

structures, is taken so as to put the $A_{1g} \rightarrow B_{2u}$ transition in benzene at 260 mμ. If the charge moves more than two carbon atoms the interaction is set equal to zero, as it is also when there are multiple interactions. In addition, the wave functions are assumed to be orthogonal. The upper corner of the secular equation for the pyridocyanine corresponding to the structures as numbered above would for example, be

	1	2	3
1	$-\lambda$	G	0
2	G	$-\lambda$	K
3	0	K	$-\lambda$

where G is the allyl anion resonance parameter and K is the Kekulé resonance parameter. The ratio $K/G = 0.787$.

The first few energies in units of G and the calculated absorption wave lengths are given in Table II where it will be seen that the calculated wave length of the first transition falls very nicely between the $n = 2$ and $n = 3$ dye colors, as observed.

TABLE II

TERM VALUES IN UNITS OF G AND POSITIONS OF THE PEAKS AS CALCULATED USING STRUCTURES

	Chain dyes			
	$n = 1$	$n = 2$	$n = 3$	Pyridocyanine
E_1	1.414	1.618	1.732	3.047
E_2	0	0.618	1.000	2.201
E_3	−1.414	−0.618	0	1.696[b]
$\lambda(E_2 - E_1)$, mμ	289	(409)	559	470
λ (obsd.)[a]	309	409	511	486–505
$\lambda(E_3 - E_1)$				330 (double)
λ (obsd.)				360 and 260

[a] W. T. Simpson, *J. Chem. Phys.*, 16, 1124 (1948). [b] Doubly degenerate.

The transition moment length for the first (A → B) transition is calculated to be 1.90 Å., the same as for the most intense transition in the first triad according to the Hückel theory. The third energy level obtained using structures is accidentally degenerate, with absorption at 330 mμ and species A and B. The transition moment lengths to these two states are, respectively, 0.25 Å. (short axis polarized) and 0.14 Å. (long axis polarized). The transition moment lengths agree with what is observed for the 4,4′-dye (Table I) if the absorption at 372 mμ is assigned as A → A, and if it is assumed that the actual absorptions at 254 and 505 correspond (after some mixing has taken place) to the first two A → B transitions calculated to come at 470 and 330.

Appendix

We shall start by reviewing the theory of the splitting of the monomer levels upon formation of the dimer.[14] It is assumed that the molecular planes of the dye cations are parallel in the dimer, forming a sandwich. One possible arrangement is as shown in Fig. 7.

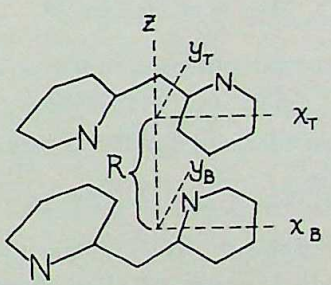

Fig. 7.—One of two possible structures for dimer of dye I. Location of each anion would be in a plane between the two dye cations, as close to a pair of nitrogen atoms as possible.

Neglecting interaction between the monomeric parts the electronic wave functions for the ground state and the (doubly degenerate) first-excited state would be in the form of products

$$\psi_T\psi_B$$

$$\psi_T\dagger\psi_B,\ \psi_T\psi_B\dagger$$

where T and B refer to "top" and "bottom" molecules, and the dagger denotes electronic excitation, in the present example corresponding to the 486 band of the monomer. The electrostatic interaction in the dipole approximation is the sum of the static coulomb energy, which can be disregarded, and the potential

$$V = (-2\Sigma z_T \Sigma z_B + \Sigma x_T \Sigma x_B + \Sigma y_T \Sigma y_B)e^2/R^3$$

Here, for example, Σz_T means a sum over the z components of the electrons in the top molecule, and x, y and z are referred to origins in the respective molecules, as shown in Fig. 7.

(14) An assumption necessary in order that the theory have the simple form outlined here is that the vibrational parts of the wave functions for the dimer excited states can be factored from the electronic parts, which leads to what is called strong coupling. The appropriateness of this assumption is judged by evaluating the terms in the coupling inequality (see W. T. Simpson and D. L. Peterson, *J. Chem. Phys.*, **25**, 588 (1957)). The monomer band width for the absorption at 486 mμ, $\Delta \approx 3000$ cm.$^{-1}$ while the splitting for the iodide is actually less, $2v \approx 2300$ cm.$^{-1}$; and for the perchlorate more, $2v \approx 4800$ cm.$^{-1}$. According to this the perchlorate dimer is in the strong coupling range $2v/\Delta > 1$, and the iodide is in the intermediate coupling range. The theory in this Appendix is a strong coupling theory, but it corresponds fairly well to the iodide.

Only terms of the type

$$\int \psi_T^\dagger \psi_B V \psi_T \psi_B^\dagger d\tau_T d\tau_B$$

are considered important. That is, the permanent moments, like

$$e \int \psi_T \Sigma x_T \psi_T d\tau_T$$

are taken as zero. The first-order energy correction for the ground state is therefore zero. The correct wave functions for the degenerate manifold are

$$\psi_\pm = 2^{-1/2}(\psi_T^\dagger \psi_B \pm \psi_T \psi_B^\dagger)$$

The expectation value of V for these functions does not involve the term

$$-2\Sigma z_T z_B$$

because the transition moments for the monomeric component species are in-plane. What is left is actually the dot product of the respective transition moments, each referred to its own coördinate frame

$$W_\pm = \pm \vec{m}_T \cdot \vec{m}_B / R^3$$

where the x component, say, of $\vec{m}_T$ is

$$(m_T)_x = e \int \psi_T \Sigma x_T \psi_T^\dagger d\tau_T$$

The transition moment for the dimer absorption is

$$\vec{m}_\pm = e \int \psi_T \psi_B [\vec{i}(\Sigma x_T + \Sigma x_B) + \vec{j}(\Sigma y_T + \Sigma y_B)] \, 2^{-1/2}(\psi_T^\dagger \psi_B \pm \psi_T \psi_B^\dagger) d\tau_T d\tau_B = 2^{-1/2}(\vec{m}_T \pm \vec{m}_B)$$

To illustrate the use of these formulas, let us now assume that the nitrogen atoms in the molecules are in fact oriented as shown in Fig. 7. We would then have

$$\vec{m}_T = -\vec{m}_B$$

Substituting in the formula for the energy we find that the lower energy state is W_+

$$+ m_T \cdot (-m_T)/R^3$$

with the corresponding wave function ψ_+. The transition moment from the ground state (long wave length component of the doublet) is

$$2^{-1/2}(m_T + (-m_T)) = 0$$

The transition moment to the state with wave function ψ_-, and energy

$$W_- = + m_T^2/R^3$$

is $2^{-1/2}\ \vec{m}_T$, leading to an intensity proportional to the square, $2|m_T|^2$ which is twice the intensity for a single molecule.

Even if the orientations had been switched so as to put the nitrogen atoms directly on top of one another, giving

$$\vec{m}_T = \vec{m}_B$$

the same physical result would have been obtained, although the phases in the wave functions would be reversed. The physical result depends on having the transition moments parallel. The fact that experimentally the long wave length component (species Y in Fig. 3) is much the weaker tells us that if a sandwich configuration is correct then the transition moments of the individual dye cations must indeed be virtually parallel.

The dimer split is, of course, $W_- - W_+$ or

$$2|m_T|^2/R^3$$

From this we may obtain R by using $|m_T|$ from Table I and the observed splittings for iodide and perchlorate, respectively, 2300 and 4800 cm.$^{-1}$. This gives for the iodide R = 5.8 Å., and for the perchlorate R = 4.5 Å.

The dipole approximation introduces some error (It would give a calculated split which is too high by *ca.* 1/3. Thus we should use $\sim$4/3 the observed splits, which would reduce the calculated R by 10%.) Also, taking the splitting as the energy difference between the peaks results in uncertainty. Even so the values obtained are certainly reasonable. The usual distance between centers for un-charged aromatic systems on top of each other is 3.4 Å. Considering the fact that the dye cations are charged and that this charge cannot be neutralized perfectly by the anions, it seems as if the cations in the perchlorate dimer are virtually in contact. In the iodide it appears that the dye cations actually are separated to a degree by the iodide ions entering as "filling" to the sandwich. If the iodide ions were completely inside the sandwich, R would be 7.7 Å., based on an iodide ion diameter of 4.3 Å.

Chemorheological Study of Polyurethan Elastomers[1]

BY P. C. COLODNY[2] AND A. V. TOBOLSKY

RECEIVED APRIL 26, 1957

Two series of polyurethan elastomers were prepared which contained (a) predominantly urethan linkages and (b) equal numbers of urethan and substituted urea or biuret groups. The chemorheology of these samples was investigated by stress relaxation experiments. It was found that the urethan linkages underwent scission at a rate one-tenth that of the combined rate of the substituted urea and biuret groups.

Introduction

The chemorheology of polyurethan elastomers based on polyester and polyether chains has recently been investigated by Offenbach and Tobolsky.[3] Polyester rubbers cured with benzoyl peroxide had been studied previously.[4] From these works it was concluded that neither the scission of

the ester nor the ether links along the chain contributed appreciably to the stress relaxation of the Vulcollan type rubbers or du Pont Adiprene B at elevated temperatures. The cause of the stress decay at constant elongation was attributed to the scission of urethan, substituted urea and biuret linkages with the urea and biuret groups being thought chiefly responsible.

In this paper clear evidence is presented that shows the relative stability of the urethan groups compared to the substituted urea linkages and the biuret linkages. The basis of this evidence rests with stress relaxation data of rubber samples so prepared from the same linear polyester that one class of specimens contains nearly all urethan links and the other class contains half urethan and the other half both substituted urea and biuret groups. The samples containing principally urethan linkages were prepared first by the direct reaction of the polyester with stoichiometric amounts of isocyanate. Sample I was prepared by the reaction of this polyester, an 80–20 mole % ethylene–propylene adipate, with an equivalent amount of 2,4-toluene diisocyanate. This gave a linear product that flowed at elevated temperature. Sample II was prepared by the reaction of the polyester with methyl triphenyl triisocyanate. Samples III and IV discussed below were prepared as follows. An isocyanate terminated polyester (A), commonly referred to as "prepolymer,"[5] was prepared by the addition of excess diisocyanate to the polyester. Sample III was formed by curing this prepolymer with 1,4-butanediol. A linear material similar to I was obtained which indicates that little or no cross-linking was introduced by allophanate formation. Sample IV was prepared by treating this same prepolymer with 1,2,6-hexanetriol. Sample V was prepared from prepolymer A by the addition of water to form a network containing substituted urea linkages and biuret cross linkages, the sum of these being equal to the number of urethan linkages.

$$\sim OH + OCN{-}R{-}NCO + HO\sim \longrightarrow \sim O{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{H}{|}}{N}{-}R{-}\overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}O\sim$$

$$HO\sim OH + 2OCN{-}R{-}NCO \longrightarrow OCN{-}R{-}\overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}O \sim O{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{H}{|}}{N}{-}R{-}NCO$$

(A)

Another prepolymer (B) was prepared using another polyester, Thiokol ZL-219, and the same diisocyanate. Sample VI was prepared by curing this prepolymer with excess water. A substantial number of trisubstituted biuret linkages were also formed in V and VI by the reaction of free isocyanate with the urea hydrogen atoms as indicated by the network structure of the elastomer. The purpose of this duplication was to minimize the possibility of erroneous results due to catalytic effects from trace impurities.

$$OCN\sim NCO + 2H_2O \longrightarrow \sim \overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{H}{|}}{N} \sim \overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{H}{|}}{N}\sim$$

(B)

$$\overset{\overset{H}{|}}{\sim N}{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{H}{|}}{N}\sim + \sim NCO \longrightarrow \sim \overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{H}{|}}{N}\sim$$

(VI)

Experimental

Material.—The polyester used was the Thiokol ZL-219 and an 80-20 mole % ethylene–propylene adipate. The Thiokol polyester had an acid no. of 2.4 and an isocyanate equiv. wt. of 1170 while the ethylene–propylene adipate had an acid no. of 3 and an isocyanate equiv. wt. of 1580. These were dried by heating for 4 hours at 120–130° while a stream of nitrogen was bubbled through the material. The triisocyanate used was Mobay Mondur TM consisting of a 20% solution of methyl triphenyl triisocyanate in CH_2Cl_2. The diisocyanate was du Pont Hylene T which analyzed for 95% 2,4-toluene diisocyanate. The diol and triol were highly purified 1,4-butanediol and 1,2,6-hexanetriol.

Preparation of Elastomers with Predominantly Urethan Linkages.—Sample I was prepared by the reaction of 50.0 g. (0.0316 isocyanate equiv. wt.) of the ethylene–propylene adipate with 2.75 g. (0.0316 equiv.) of 2,4-toluene diisocyanate in a mold at 70° for 4 hours. 131 g. (0.0826 isocyanate equiv. wt.) of the polyester was treated with 10.1 g. (0.0826 equiv.) of methyl triphenyl triisocyanate in CH_2Cl_2 solution for the preparation of II. The reaction was carried out in a sample mold placed in a vacuum oven at 75°. As the sample contained numerous bubbles due to the evaporation of the solvent it was passed through a rubber mill and pressed out at 150° for 30 min. at 20,000 p.s.i.

The prepolymer for III, IV and V was prepared by the addition of 49.5 g. (0.284 mole) of 2,4-toluene diisocyanate, a 10% excess, to 409.9 g. (0.258 isocyanate equiv. wt.) of ethylene–propylene adipate at room temperature and under an atmosphere of nitrogen. The mixture was allowed to react for 48 hours to give a prepolymer with an equiv. wt. of 1760. III was prepared by the reaction of 52.3 g. (0.0298 equiv.) of this prepolymer with 1.34 g. (0.0298 equiv.) of 1,4-butanediol while IV was formed from 51.5 g. (0.0294 equiv.) of prepolymer and 1.31 g. (0.0294 equiv.) of 1,2,6-hexanetriol. The conditions were the same as for I.

Preparation of Samples with Substituted Urea and Biuret Linkages.—Sample V was prepared by the reaction of 50.0 g. (0.0285 equiv.) of this same prepolymer and 1 g., fourfold excess, of water. A prepolymer prepared from 2400 g. (2.03 isocyanate equiv. wt.) of Thiokol Polyester ZL-219 and 394 g. (2.23 moles), a 10% excess, 2,4 toluene diisocyanate gave an equiv. wt. of 1230. 50.0 g. (0.0406 equiv.) of this was mixed with 1 g., also a fourfold excess, of water to give VI. These reactions were carried out at 75° and required 72 hours for completion.

Stress Relaxation Measurements.—All measurements were made on Firestone relaxometers[6] which had been modified for strip samples.[7] All samples were post cured for 1 week at 100° prior to physical study to ensure complete cure.

Results and Discussion

Stress relaxation studies were performed on these samples over a temperature range from 100 to 140° at 20% elongation. The data have been plotted as relative stress, f/f_0, as a function of logarithmic time. As it had been shown in previous studies that such relaxation curves are independent of elongation up to fairly large strains, elongation was not investigated as a variable. The reference stress, f_0, was determined by graphical interpolation for the time 0.01 hour. Duplicate determinations were completely superimposable.

The data for the cure of the ethylene–propylene adipate polyester with the triisocyanate are presented in Fig. 1. Figure 2 contains a comparison of the stress decay curves at 120°. It is apparent

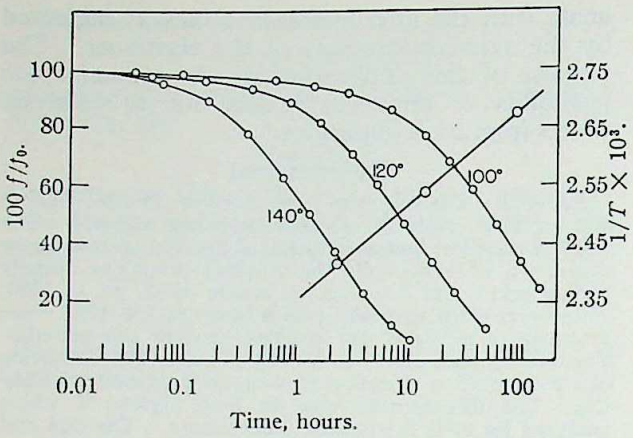

Fig. 1.—Stress relaxation of II.

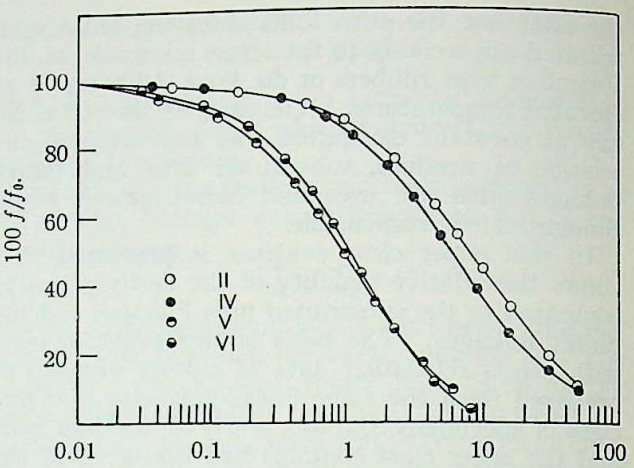

Fig. 2.—Stress relaxation at 120°.

that all samples approached zero stress asymptotically and underwent a major portion of decay within two decades of logarithmic time. Similar behavior had been observed for the polysulfide,[8] natural and silicone[9] rubbers and other polyurethans.[3] The cause for the stress decay in these materials has been attributed to chemical scission of network chains. Decay due to molecular flow has been shown to extend not over two but over many cycles of logarithmic time.

The stress at a time, t, is related to the number of effective network chains[10] by the equation

$$f = NkT\left(\alpha - \frac{1}{\alpha^2}\right)$$

where f is the stress based on the original cross section at relative length α and N is the number of network chains per cubic centimeter which have never been cut. The stress decay at constant strain and elevated temperature of these rubbers has been found to obey approximately the equation $f/f_0 = e - t/\tau$, where τ is the relaxation time of the sample at the specified temperature. The relaxation time, τ, is equal to the time required for the stress to decay to $1/e$ or 36.8% of its reference value. As τ may be considered to be the reciprocal of a chemical rate constant, it is possible to calculate an activation energy for the process from the slope of a plot of log τ *vs.* $1/T$. The relaxation times in hours and activation energies are listed in Table I. The values for samples I and III were approximately zero.

TABLE I

STRESS-RELAXATION TIME (HOURS)

Sample	τ100°	τ120°	τ140°	$E\ddagger$(kcal./mole)
II	87	14	2.3	27.7 ± 1.5
IV	66	9.7	1.6	28.4 ± 1.5
V	12.7	1.6	0.28	29.2 ± 1.0
VI	14	1.65	0.25	30.8 ± 2.0

Structure of Polymers.—Samples I, II, III and IV contain, besides the polyester backbone, predominantly urethan linkages prepared by the reaction of the hydroxyl terminals with isocyanate

$$2HO \sim OH + OCN{-}R{-}NCO \longrightarrow \sim O{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{H}{|}}{N}{-}R{-}\overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}O\sim$$

Small amounts of amide and substituted urea groups also are present due to the reaction of terminal carboxyl groups[11] with isocyanates resulting with the formation of a mixed anhydride which is followed by the loss of carbon dioxide. The mixed

$$R{-}NCO{-}R'{-}\overset{\overset{O}{\|}}{C}{-}OH \longrightarrow R{-}\overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}O{-}\overset{\overset{O}{\|}}{C}{-}R' \longrightarrow R{-}\overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}R' + CO_2$$

$$2R{-}\overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}O{-}\overset{\overset{O}{\|}}{C}{-}R' \longrightarrow R{-}\overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}O{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{H}{|}}{N}{-}R + R'C{-}O{-}C{-}R'$$

anhydride can also undergo a disproportionation into anhydrides of carboxylic and carbamic acids

$$R{-}\overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}O{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{H}{|}}{N}{-}R \longrightarrow R{-}\overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{H}{|}}{N}{-}R + CO_2$$

from which a disubstituted urea is formed upon the loss of carbon dioxide. More substituted urea linkages are formed by the reaction of isocyanate groups with traces of water.[12] Despite the anhydrous conditions of the preparation procedures it is likely that this reaction occurred to a small degree.

$$R{-}NCO + H_2O \longrightarrow R{-}\overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}OH \longrightarrow R{-}NH_2 + CO_2$$

$$R{-}NH_2 + R{-}NCO \longrightarrow R{-}\overset{\overset{H}{|}}{N}{-}\overset{\overset{O}{\|}}{C}{-}\overset{\overset{H}{|}}{N}{-}R$$

From the zero relaxation time of sample I and III it can be concluded that the urethan hydrogen atom reacted with free isocyanate to a negligible

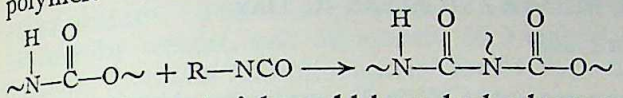
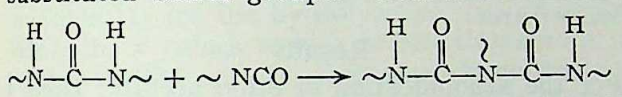
Digitized by Arya Samaj Foundation Chennai and eGangotri

extent to form the allophanate.[13,14] This is particularly evident in III which contained a 10% excess of the diisocyanate in the preparation of the prepolymer. Even if this reaction occurred only



partially the material would have had a loose network structure with a measurable relaxation time instead of undergoing complete flow at the temperature of the relaxation studies. Such behavior is indicative of a linear polymer containing little or no crosslinking.

Samples V and VI were prepared by the addition of water to a prepolymer containing excess diisocyanate. In addition to the formation of disubstituted urea linkages a substantial amount of crosslinking occurred by the reaction of free isocyanate with the urea hydrogen atoms to form trisubstituted biuret groups. This is evidenced by



the stress relaxation data for these samples which indicate that the materials possess a network structure. Also, it has been found by chemical methods that this reaction proceeds at a rate comparable to that of water and isocyanate.[15] The structures of these samples are summarized in Table II.

TABLE II

ELASTOMER STRUCTURE

Sample	Linkages
I	Ester, urethan, no cross-linkages
II	Ester, urethan, triisocyanate cross-linkages
III	Ester, urethan, no cross-linkages
IV	Ester, urethan, triol cross-linkages
V	Ester, urethan, urea, biuret cross-linkages
VI	Ester, urethan, urea, biuret cross-linkages

Possible Sites of Chain Cleavage.—The possibility of ester–ester interchange may be ruled out as a major factor contributing to the stress decay on the basis of previous work involving benzoyl peroxide vulcanizates of the Paraplex type and succinic acid–propylene glycol[4] type originating from the Bell Telephone Laboratories. The relaxation times of these materials were at least ten times longer than those of the samples involved in this investigation. Also, polyurethans having polyester backbones gave comparable relaxation times to polyurethans having polyether backbones which also indicates that neither the ether nor the ester groups were responsible for the stress decay.

The thermal instability of urethans has long been known.[16] It has been shown that aromatic urethans dissociate[12] to isocyanates around 180°. More recently quantitative studies have been made of the kinetics of urethan dissociation[17] in a series of solvents. As the reaction rate was greatly affected by the solvent, little correlation can be made with the present investigation.

It is also well known that substituted ureas dissociate[16] to isocyanates and amines between 170–180°.[12] Kinetic studies[18] of these decompositions in several solvents indicate that the reaction proceeds at an appreciable rate at 150°.

It is obvious from Table I that the samples with predominantly urethane linkages, II and IV, have relaxation times five times greater than those with 50% urethan and 50% substituted urea and biuret groups, V and VI. If this is the effect on the relaxation rate of replacing one half the urethan groups with biurets and ureas, a sample containing all urea and biuret linkages would decay at a rate ten times that of II and IV. Since the relaxation time is inversely proportional to the rate constant for the chain scission reaction it appears that the rate constant for the dissociation of the urethan group is less than one-tenth that for the combined effect of the substituted urea and biuret groups under these experimental conditions. A more quantitative statement differentiating between the substituted urea linkages and the biuret cross linkages is not possible at this time.

Acknowledgment.—The authors wish to express their gratitude to the Thiokol Chemical Corporation for the coöperation extended to us which made this research possible.

Solvent Effects and Ester Interchange in Basic Hydrolysis of Esters

BY GEORGE A. GALLAGHER, JOHN G. MILLER AND ALLAN R. DAY

RECEIVED MARCH 1, 1957

The saponification of ethyl acetate and methyl acetate has been measured at 30° in dioxane–water mixtures containing additional solvents found earlier to facilitate ammonolysis and concurrent hydrolysis of these esters. The effect of these additional solvents in the highly basic solutions is different from that found for the ammoniacal solutions. Ester interchange was observed with methanol and ethylene glycol as additives. The alcohols as well as glycol and some lactamides decrease the velocity of the hydrolysis, probably by solvating the hydroxyl ion through hydrogen bonding, thereby decreasing its reactivity. The effect of acetone, which increases the rate of saponification, is probably due to solvation of the activated complex.

In studies of the effect of hydroxylated substances and especially substances containing the groupings O–C–C–O or O–C–C–N upon the rate of ammonolysis of methyl acetate, it has been observed that these substances also accelerated the concurrent hydrolysis of the ester.[1] To investigate separately the effect of these and other solvents upon the hydrolysis reaction alone, the present study deals with the saponification of esters in dioxane–water systems to which these solvents were added in partial replacement of the dioxane. Thus, the reference standard reaction system was 20 molar water in dioxane and at the start of reaction contained 0.048 *M* NaOH and 0.040 *M* ester. In the other systems, the added substances merely replaced some of the dioxane, the standard amounts of water, NaOH and ester remaining constant.

Experimental

Reagents.—Dioxane, methyl acetate, methyl alcohol, ethylene glycol, lactamide, N-methyllactamide and N,N-dimethyllactamide were purified as described previously.[1] The pinacol was Eastman Kodak white label material and was used without further purification; m.p. 42.5–43°.

Ethyl acetate was dried over anhydrous potassium carbonate and fractionally distilled through a 35 cm. packed column; b.p. 77.0°, $n^{25}D$ 1.3704. Acetone was purified by refluxing with addition of small quantities of solid potassium permanganate until a pink color persisted. It was then fractionally distilled; b.p. 56.1°, $n^{25}D$ 1.3567. Ethyl alcohol was dried by the method of Lund and Bjerrum[2] and was then distilled; b.p. 78.4°, $n^{25}D$ 1.3599.

Procedure.—A stock solution of 0.1 *N* NaOH in dioxane was made by weighing the calculated amount of carbonate-free 0.2 *N* NaOH into a 1-liter volumetric flask, followed by weighed addition of sufficient water to give a final water concentration of 40 molar. The flask was filled close to the mark with dioxane, thermostated for two hours at 30° and then filled to the mark with dioxane. This stock solution was stored in a paraffin-coated flask under nitrogen. New solutions were made every three weeks. Determinations of the normality of the solution at the beginning and end of the three-week period showed a variation of only one part per thousand.

Runs were made in the following typical way. A freshly-prepared dioxane solution of known added solvent concentration was added volumetrically in desired amount to a reaction flask, followed by the requisite amount of stock solution, also measured volumetrically. After mixing, the flask was thermostated for at least two hours and then brought to volume with dioxane. Reproducibility of NaOH concentration at this stage was shown to be within one part per thousand.

Next, the ester was weighed to the nearest 0.1 mg., in a 1-ml. glass-stoppered weighing bottle and added to the thermostated reaction flask. The empty weighing bottle was also dropped in to ensure complete transfer of ester. By this procedure, shaking could be started within one to two seconds after addition of ester. After shaking for 25 seconds, the flask was replaced in the thermostat. Ten-ml. aliquots were removed periodically and added to 25 ml. of chilled 0.025 *N* HCl to stop reaction. Back-titration was run with 0.025 *N* NaOH.

The thermostat was kept within ±0.01 of 30° in all runs. Frequent reference determinations (no solvent catalyst added) were run.

Results

For the saponification of ethyl acetate, Table I lists the results showing the effects of acetone, pinacol, and a group of substances found earlier[1] to facilitate the ammonolysis and concurrent hydrolysis of esters. The values for the water–dioxane systems at 2, 4 and 8 *M* additional water may be compared with the results of other workers.

The 2 and 8 *M* solutions correspond nearly to 60 and 50 volume % dioxane, concentrations at which Nair and Anantakrishnan[3] found k to be 7.44×10^{-2} and 8.58×10^{-2} l. mole^{-1} sec.$^{-1}$ at 30° for ethyl acetate. The 4 *M* system is about 57.5% dioxane by weight, and at exactly 57.9 weight % dioxane, Tommila and co-workers[4] found the value 8.16×10^{-2} l. mole^{-1} sec.$^{-1}$ at 30° for this ester. In the concentration range in which we have worked these and other workers have observed the same increase in rate with increase in amount of water.

The other results are not directly comparable to any other values in the literature for the reason that no one else has reported measurements of the hydrolysis of ethyl acetate in these ternary solvent mixtures.

Table II shows the behavior of the hydrolysis of ethyl acetate in water–methanol–dioxane and water–ethylene glycol–dioxane systems at 30°. Closely related to these data are the results shown in Table III for the hydrolysis of methyl acetate. While the k values were constant throughout any run for methyl acetate, they show large drifts upward for ethyl acetate in the presence of methanol and ethylene glycol. That these increases are due to ester interchange is apparent from the dependence of the change upon the amount of methanol or ethylene glycol present and of the near equality of the velocity constants of methyl acetate hydrolysis at 4 and 8 *M* methanol with the specific rates for ethyl acetate near the end of the runs in the presence of 4 and 8 *M* methanol. For ethyl acetate and NaOH concentrations nearly the same as ours, Tommila and co-workers[4] reported that a similar increase in k took place during reaction in methanol–water and ethylene glycol–water mixtures, this increase being ascribed to transesterification. These workers noted that when the solutions contained 70 weight % or more of methanol, k was almost constant, which they took to indicate that the conversion of ethyl acetate to methyl acetate is very rapid at that concentration. Our highest methanol concentration was only 27 weight %.

Extrapolation of the ethyl acetate rates to zero time, *i.e.*, to a condition of no transesterification, shows that the saponification of that ester is hindered by both methanol and ethylene glycol, the magnitude of the effect of methanol being nearly the same as that of ethanol. The results also agree with the finding of Tommila[4] that in aqueous systems the solvent effects of ethylene glycol and methanol were closely similar in depressing the alkaline hydrolysis of ethyl acetate. Figures 1 and 2 show the extrapolation of the ethylene glycol runs and the methanol runs at higher methanol concentrations. At the lowest concentrations

the extrapolations of the methanol data were uncertain.

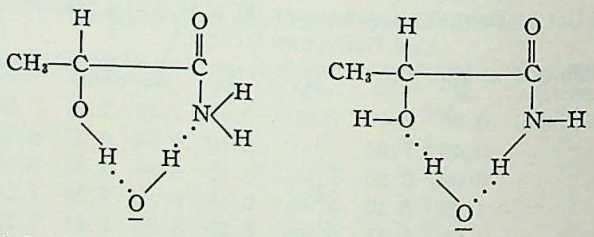
Discussion

The normal alkaline hydrolysis of an ester[5] such as studied here is a reaction between an uncharged ester molecule and an hydroxyl ion. Due to the low solubility of esters in water, the reaction is often carried out by adding organic solvents to the water. The extensive recent work by Tommila and co-workers[4,6] has reviewed the many studies in this field and stresses the role of solvation of both the reactants and the transition state.

In measurements of the solvent effect in concurrent ammonolysis and hydrolysis of esters,[1] there were observed strikingly parallel effects upon the competing reactions by solvents containing structures suitable for production of hydrogen-bonded complexes with ammonia and water. The action of these solvents was looked upon as catalytic in the sense that by attachment of the solvent to the attacking species in these pre-equilibria, a more reactive particle was produced, in contrast to the usual stabilization caused by solvation. Since water was present in large amount in those systems, it appeared improbable that the action of solvent was through complete removal of a proton from ammonia to form free amide ions as the principal attacking species in ammonolysis. It also appeared unlikely that the effect of the added solvent was exerted through transesterification, for the rate constants did not show strong drifts during progress of reaction. Indeed, direct tests showed that no appreciable ester interchange in the simple ammonolysis of esters is probable in ethylene glycol–water mixtures.[7] In anhydrous systems containing alcohols, the reaction of free amide ions and the role of ester interchange may be more important.[8–10]

It is now apparent that the simulated hydroxyl ions pictured for hydrolysis in the ammoniacal reaction systems are of small importance in competition with the hydroxyl ions in the more basic media. Indeed, the addition of alcohol at nearly constant water concentration causes a decrease in reactivity of the hydroxyl ions in the highly basic media. Since Tommila[4,6] has shown that the effect due to complete transfer of a proton from alcohol to the ion probably is not appreciable until alcohol concentrations much higher than those used here are reached, the decrease in rate may be due to solvation of the type R–O–H. . .$\bar{O}$H.

The lactamides exerted a strong effect in comparison with methanol or ethanol. Here, cyclic hydrogen bonded complexes of the types shown here for lactamide



might be operative. For N,N-dimethyllactamide, which showed relatively little activity, the second type would not exist and the first type might not form due to the bulk of the methyl groups attached to the nitrogen atom.

Pinacol would be expected to have small effect because of the steric hindrance and electron release effects of the methyl groups attached to the carbon atoms holding the hydroxyl groups. Kuhn[11] has suggested that in the presence of any given hydrogen acceptor, the hydrogen bond formed by various alcohols would be stronger the more acidic the alcohol. We note also that little ester exchange would be expected for this tertiary alcohol, as confirmed by the constancy of the velocity constants throughout the runs with pinacol.

Finally, we may inspect the effect of acetone. In binary mixtures with water, methanol and ethylene glycol always decrease the rate of basic hydrolysis of esters. On the other hand, addition of ethanol and other aliphatic alcohols, as well as acetone and dioxane, increases the reaction velocity at low temperatures and up to a mole fraction of

less than 0.1 for the organic solvent. Tommila[4,6] has ascribed the increase in rate to the existence of both hydrophilic and hydrophobic groups in the activated complex. Because of the specific attractions of these groups, solvation of the complex should be greater in some mixtures of water and organic solvents than in water alone. The effects found for dioxane and acetone in binary mixtures with water were remarkable for their near equality,[4] and our results show that in the ternary solvent system dioxane–acetone–water these effects augment each other up to a mole fraction of acetone higher than 0.2.

The Photochemical Decomposition of Cyclohexanone, Cyclopentanone and Cyclobutanone[1]

BY F. E. BLACET AND ARNOLD MILLER

RECEIVED MARCH 2, 1957

Quantum yields of the photodecomposition products of these cycloketones have been determined in the ranges 3130–2537 Å. and 100–300°. Cyclohexanone principal products were carbon monoxide, cyclopentane and pentene-1; minor products were ethylene and propylene. At 2537 and 2654 Å. quantum yields were temperature independent. At 3130 Å. the yields of carbon monoxide, cyclopentane and pentene-1 increased with temperature. Cyclopentanone products were carbon monoxide, cyclobutane and ethylene. The yields were temperature dependent at 3130 Å., but independent at 2654 and 2537. Cyclobutanone products were carbon monoxide, cyclopropane, ethylene, propylene and presumably ketene. Yields were temperature independent at 3130 and 2654 Å. All the ketones gave some evidence of polymer formation and a polymerization quantum yield is given based on material balance. A general mechanism of photodecomposition has been proposed involving two primary chemical reactions, which accounts moderately well for all experimental results.

The photochemistry of cyclic ketones was initially investigated by Norrish and co-workers[2,3] and later by Benson and Kistiakowsky,[4] utilizing full radiation from mercury arcs. In this paper are given quantum yields obtained under controlled conditions of wave length and temperature for the vapor phase photolyses of cyclohexanone, cyclopentanone and cyclobutanone. Dunn and Kutschke[5] have published a few results obtained with cyclohexanone since the information given herein was reported originally.[1]

Experimental

Photolyses were performed in a 20-cm. cylindrical fused silica cell of 3 cm. diameter which could be maintained at desired temperatures. Monochromatic radiant energy obtained by the use of a quartz monochromator was measured with the aid of a phototube which had been calibrated at each wave length involved with a thermopile-galvanometer system. Photolysis products were identified and quantitatively analyzed by means of both mass spectrometric and microgas analytical techniques.

The cyclohexanone and cyclopentanone were prepared by drying and fractionating standard Eastman White Label material. Both the boiling points and refractive indices of the final products checked published values. Cyclobutanone was synthesized by the method of Roberts and Sauer.[6] The boiling point was 98.2° at 755 mm. and $n^{25}D$ was 1.4191. These values are to be compared to 98–100° and $n^{25}D$ 1.4189 reported by Roberts.

Absorption spectra of the three compounds determined in heptane solution, and determined also in the vapor phase for cyclohexanone and cyclopentanone, were in agreement with those reported previously.[4] The electronic absorption region of interest extends approximately from 2400 to 3400 Å. Cyclobutanone and cyclopentanone have several prominent absorption bands in this region, while the cyclohexanone spectrum has only a faint indication of structure.

Quantum yields obtained in the study of all three of the ketones are given in Table I. All values are averages based on duplicate runs at each temperature, except for one experiment shown for cyclobutanone in which water vapor was added to the reaction system. Mean deviations of quantum yields were from 4 to 7%. Exposure times averaged between three and four hours and at the several wave lengths absorbed intensity, I_a, varied between 1×10^{-8} and 1×10^{-9} Ein./l./sec. Where temperature ranges are indicated, quantum yields were found to be constant for runs

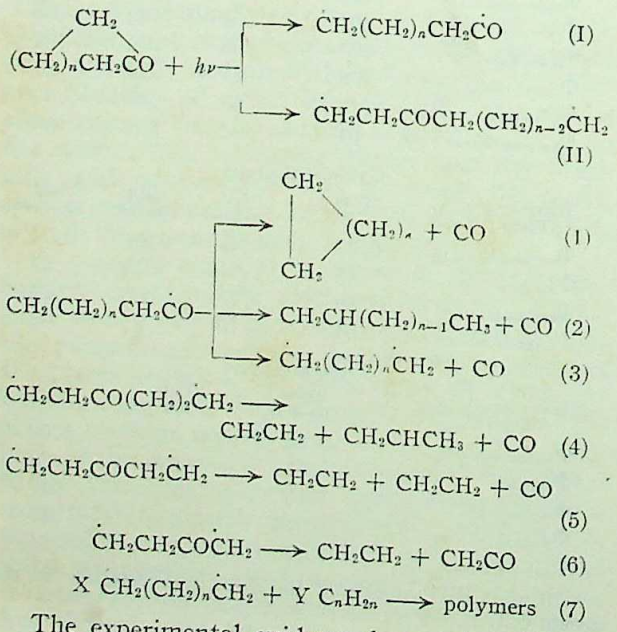
made at seventy-five degree intervals within the range. Pressures of the ketones in all runs were between 100 and 150 mm., measured at 125°. "$\Phi_{polymerization}$," in the table, is a function postulated to attain material balance and is considered to be a measure of polymer formation, giving rise to an equivalent amount of carbon monoxide without production of like amounts of low molecular weight hydrocarbons. A light yellow non-volatile residue became evident in the reaction cell after several runs, especially at the shorter wave lengths. Mass spectra of butanone photolysis products contained prominent 42 and 41 peaks which were attributed to ketene. Because of experimental difficulties, no other direct evidence was obtained for this compound.

Discussion

Often temperature independence of quantum yields signifies intramolecular rearrangement in the primary process followed by unimolecular dissociation. Free radical primary processes, on the other hand, often lead to quantum yields which are temperature dependent since secondary reactions involving a radical and a normal molecule may occur requiring an activation energy of several kilocalories per mole. In this study, each ketone, at two different wave lengths, gave quantum yields which are temperature independent over a two-hundred-degree range, thus indicating non-free radical primary processes. Opposed to this concept, cyclohexanone and cyclopentanone show temperature dependence at 3130 Å. and all the ketones gave some polymerization under all experimental conditions. These facts perhaps can best be explained by postulating as primary photochemical processes the formation of biradicals by opening the rings followed for the most part by rapid dissociation of these radicals in a variety of ways to give stable molecules. The general mechanisms may be the following in which, however, reactions 4, 5 and 6 deal with biradicals from specific ketones.



$$\text{(CH}_2\text{)}_n\text{CH}_2\text{CO} + h\nu \longrightarrow \begin{cases} \text{CH}_2(\text{CH}_2)_n\dot{\text{C}}\text{H}_2\dot{\text{C}}\text{O} & \text{(I)} \\ \dot{\text{C}}\text{H}_2\text{CH}_2\text{COCH}_2(\text{CH}_2)_{n-2}\dot{\text{C}}\text{H}_2 & \text{(II)} \end{cases}$$

$$\text{CH}_2(\text{CH}_2)_n\text{CH}_2\text{CO} \longrightarrow \begin{cases} \text{CH}_2 \\ \quad (\text{CH}_2)_n + \text{CO} & \text{(1)} \\ \text{CH}_2 \\ \text{CH}_2\text{CH}(\text{CH}_2)_{n-1}\text{CH}_3 + \text{CO} & \text{(2)} \\ \text{CH}_2(\text{CH}_2)_n\text{CH}_2 + \text{CO} & \text{(3)} \end{cases}$$

$$\text{CH}_2\text{CH}_2\text{CO}(\text{CH}_2)_2\text{CH}_2 \longrightarrow \text{CH}_2\text{CH}_2 + \text{CH}_2\text{CHCH}_3 + \text{CO} \quad (4)$$

$$\text{CH}_2\text{CH}_2\text{COCH}_2\text{CH}_2 \longrightarrow \text{CH}_2\text{CH}_2 + \text{CH}_2\text{CH}_2 + \text{CO} \quad (5)$$

$$\text{CH}_2\text{CH}_2\text{COCH}_2 \longrightarrow \text{CH}_2\text{CH}_2 + \text{CH}_2\text{CO} \quad (6)$$

$$\text{X CH}_2(\text{CH}_2)_n\text{CH}_2 + \text{Y C}_n\text{H}_{2n} \longrightarrow \text{polymers} \quad (7)$$

The experimental evidence leaves doubtful the number of primary processes. However, *a priori* reasoning has led the authors to postulate two which lead to chemical change: reaction I, in which an α-carbon is separated from the carbonyl carbon, and reaction II, in which the energy absorbed in the carbonyl group is perhaps transmitted both ways around the ring causing rupture at or near the opposite side. (I) is the logical precursor of reactions 1, 2 and 3 and (II) of (4), (5) or (6), depending on the particular ketone under investigation. In considering the mechanics of the processes, it is reasonable to assume the initial breaking of a single carbon–carbon bond followed by other reactions of the resulting biradicals. The constant ratios of (1) and (2), and presumably (3), over a wide temperature range indicates that the biradicals first produced in (I) rapidly rearrange and dissociate without environmental influence. Since only photons of equal energy were used in a given experiment, this implies that the state of a ketone molecule at the moment of light absorption determined which of the three secondary adjustments would take place. Why this should be is not evident. It is not clear, also, why the ratios of (I) and (II) for all three compounds remain constant, as determined by the quantum yields of the products, at each of two wave lengths over a two-hundred-degree temperature range.

Cyclohexanone.—It follows from the assumed mechanism that Φ_{CO} is a measure of the sum of primary quantum yields, ϕ_I and ϕ_{II}. Reaction (II) is followed by (4), perhaps so inevitably that they could be combined in one concerted process. Thus, the quantum yields of ethylene or propylene, which are equal under all conditions employed, are a measure of ϕ_{II}. Since ϕ_{II}, thus estimated, was always small, Φ_{CO} is an approximate measure of ϕ_I. At wave lengths 2537 and 2654 Å. this indicates about 20% of the absorbed energy was dispersed by photophysical means, *i.e.*, by fluorescence or by thermal deactivation, independent of temperature over the range 100–300°. At λ 3130 Å., however, ϕ_I increases from about 0.2 to 0.9 over the range 125–300°, indicating that at this wave length the quantum energy is near, and perhaps slightly less than the activation energy which is necessary to rupture the molecules by (I).

At λ 3130 and λ 2654, the sum of quantum yields of pentene-1, cyclopentane and ethylene (or propylene) is equal to Φ_{CO}. This is not so at λ 2537 and $\Phi_{polymerization}$, involving reactions 3 and 7, was devised to account for the difference. In reaction 7, C_nH_{2n} may represent other biradicals or, as photolysis proceeded, the olefin products also may have become involved. Perhaps the marked decrease in quantum yield of pentene-1 found at λ 2537 from that obtained at λ 2654 can be accounted for in this way.

Cyclopentanone.—For this compound also, Φ_{CO} is a measure of the sum of ϕ_I and ϕ_{II}, and the values indicate that from one-fourth to two-thirds of the absorbed energy was dissipated photophysically, depending on experimental conditions. Reaction (II) presumably was followed always by (5), thus $\frac{1}{2}\,\Phi_{ethylene}$ equalled ϕ_{II}. The absence of a butene among the reaction products shows that under no condition employed did reaction (2) occur and, therefore, from the mechanism, (I) could be followed only by (1) and (3). At λ 3130 and 125°, $\frac{1}{2}\,\Phi_{ethylene}$ plus $\Phi_{cyclobutane}$ equals Φ_{CO}, indicating that (3) was not occurring, and therefore $\Phi_{cyclobutane}$ was a measure of ϕ_I. At 225° and this

wave length and at both λ 2654 and 2537 over the temperature range studied, this simple relationship no longer held, indicating that reaction 3, followed by (7), was taking place. The absence of butene among the photolysis products may be interpreted to mean that the free radical cyclization reaction has a substantially lower activation energy than the reaction involving a hydrogen shift to form an olefin. This is to be expected since considerable strain would be present in the transition state required to form butene.

Cyclobutanone.—The large amount of ethylene formed from cyclobutanone indicates that reaction 6, involving the production of ketene, is important. Because ethylene was produced in excess of carbon monoxide at λ 3130, it was suggested originally that ketene further decomposed. To evaluate this hypothesis, water vapor was added in one instance on the assumption that it would react with the ketene vapor to form acetic acid. Experimental difficulties left the test for acetic acid in doubt and it may or may not have been produced. However, it is apparent from the results given in Table I that the water had no important effect on quantum yields and it follows, also, that it did not trap the postulated biradicals. In view of the results later obtained at λ 2654, appreciable ketene decomposition does not appear to have occurred in any event.

The general mechanism postulated above applies to this cycloketone, also. Accepting this mechanism, Φ_{CO} is a measure of ϕ_I and $\Phi_{ethylene}$ is a measure of ϕ_{II}. ϕ_I plus ϕ_{II}, estimated in this way, is about 0.9 at λ 3130 and 1, within experimental errors, at λ 2654; thus, for this compound, photochemical conversion of absorbed energy is high. Polymerization, reaction 7, was important under all conditions in which this ketone was studied.

Kinetic Studies of Thiourea Derivatives. III. Trimethylthiourea and Tetramethylthiourea

By William H. R. Shaw and David G. Walker

Received March 20, 1957

Trimethylthiourea has been studied kinetically in aqueous solutions at elevated temperatures. This substance decomposes to form methylamine, dimethylamine and carbon oxysulfide as ultimate products in acid solutions. The decomposition is first-order and is uninfluenced by ionic strength in media of low *p*H. Rate constants at various temperatures and Arrhenius parameters are reported. Tetramethylthiourea also has been studied under similar conditions. This substance shows little or no tendency to react in neutral solutions. In acidic or basic media, however, hydrolysis is observed. The significance of these findings and their relevance to previous work is discussed.

Introduction

Thiourea,[1] methylthiourea[2] and the dimethylthioureas[3] have been studied previously in this Laboratory. Although some information on the chemistry of trimethylthiourea[4] and tetramethylthiourea[5] is available, no kinetic investigations with these compounds have been reported. The present work was, consequently, undertaken to secure rate data for these substances and to complete, thereby, our kinetic study of the methylated thioureas.

Experimental

Trimethylthiourea (1,1,3-trimethyl-2-thiourea) was prepared by the addition of dimethylamine to methyl isothiocyanate.[6] It was crystallized, m.p. 87° (lit.[4] 87°) twice from water solutions.

Anal. Calcd. for $C_4H_{10}N_2S$: C, 40.68; H, 8.54; N, 23.70. Found: C, 40.77; H, 8.50; N, 23.74.

Tetramethylthiourea (1,1,3,3-tetramethyl-2-thiourea) was prepared by heating bis-(dimethylthiocarbamyl) sulfide under air reflux for several hours,[7] followed by twice crystallizing the resulting mass from water. The product was then distilled at atmospheric pressure, b.p. 243° (lit.[8] 245°). Recrystallization from water gave the final product, m.p. 78° (lit.[8] 78°).

Anal. Calcd. for $C_5H_{12}N_2S$: C, 45.45; H, 9.14; N, 21.1. Found: C, 44.94; H, 8.68; N, 19.6.

The analytical methods for thiocyanate, ammonia, methylamine and dimethylamine have been described.[1-3] Total amine produced was also determined according to the following procedure. Reaction solutions of the thiourea under study were made 10 to 20 m*M* in standard acid, and the samples were then allowed to react until the total amine concentration was approximately 4 m*M*. The unreacted acid in the samples was subsequently determined by titration with standard NaOH (approximately 10 m*M*). During the titration the *p*H was read at convenient intervals and the end-point taken as the point when the change of *p*H with a small increment of standard basic solution was a maximum. Titration blanks were always run on aliquots of the unreacted experimental solutions. Results given by this method were compared with those obtained by our usual spectrophotometric techniques. Within the combined experimental uncertainties, the two methods gave identical results.

The procedures used in conducting the kinetic runs and the apparatus employed in this investigation have been described in previous work.[1-3]

Results

Reacted solutions of trimethylthiourea were found to contain methylamine, dimethylamine and carbon oxysulfide. The rates of formation of methylamine and dimethylamine were followed and the corresponding empirical first-order rate constants, k_3 and k_4, were calculated by the rate equation previously presented. Measurements were made with 0.015 *M* H_2SO_4 and 0.015 *M* HNO_3 solutions. These solutions also contained tri-

methylthiourea at concentrations ranging from 9.2 to 73.5 mM. In these acid media at 100° the following values were obtained for k_3 and k_4, respectively, $38.2 \pm 3.8 \times 10^{-7}$ and $37.2 \pm 2.2 \times 10^{-7}$ sec.$^{-1}$. Moreover results in acid solutions containing added sodium nitrate varying in concentration from 0.00 to 1.02 M demonstrated that the rate, under these conditions, was independent of ionic strength. Thus in acid media k_3 and k_4 are, within experimental error, equal and independent of average trimethylthiourea concentration, $\bar{u}$. No thiocyanate ion or ammonia could be detected in the reaction mixtures by our rather sensitive techniques. A first-order reaction producing methylamine and dimethylamine in equimolar amounts is clearly indicated.

The drastic dependence of k_4 on pH (Fig. 1) is quite different from the behavior of the analogous constant obtained with *unsym*-dimethylthiourea, but is very similar to the pH dependence of the k_3's obtained with methylthiourea and *sym*-dimethylthiourea.

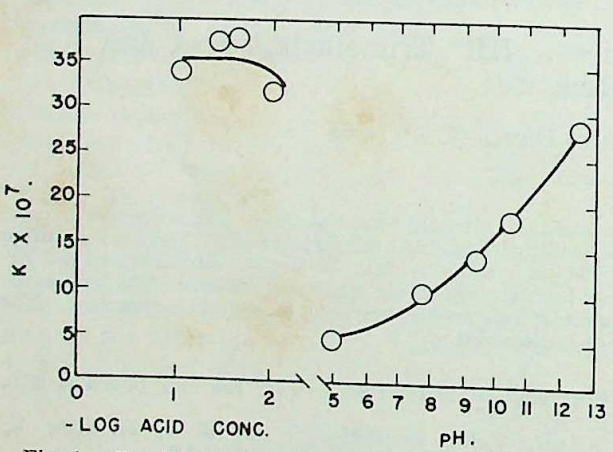

Fig. 1.—Empirical first-order rate constant (k_4) based on dimethylamine production as a function of acid concentration. Runs below pH 8 were made in HNO_3 solutions. Results recorded above pH 8 were obtained with 0.01 M borax buffers. An initial trimethylthiourea concentration of 50 mM was used with reaction times of 3.23 hr. on the basic side and 6.00 hr. in the low pH media.

A least squares analysis of data obtained spectrophotometrically at various temperatures in acid media (Table I) gave a frequency factor of 7.89×10^{14} sec.$^{-1}$ and an activation energy of 34.9 kcal. for k_4. A similar analysis applied to the data obtained by total amine analysis yielded a frequency factor of 4.98×10^{14} sec.$^{-1}$ and an activation energy of 34.4 kcal. The total amine analysis is somewhat more precise.[9]

Tetramethylthiourea was studied in various media at elevated temperature (Table II). In sharp contrast to the methylated thioureas containing a hydrogen bonded to nitrogen, this compound did not react extensively in neutral solution even at high temperatures and long reaction periods. Significant reaction in acidic and basic media did, however, occur producing dimethylamine and carbon oxysulfide. Ammonia, methylamine and thiocyanate ion were not detected in the reacted samples. Consequently since the slight reactivity of the compound was most probably due to hydrolysis and not to a simple decomposition no detailed quantitative studies were attempted.

(9) These parameters will reproduce the rate constants in Table I obtained by the titration method with a maximum deviation of 4%.

Table I

Rate Constants Obtained at Various Temperatures in Acid Solutions

Temp. ± 0.1°	$\bar{u}$[a]	t[b]	First-order rate constant,[c] sec.$^{-1} \times 10^7$ k_4
71.2	49.7	43.7	0.64
79.5	20.1	12.6	2.45[d]
80.0	49.5	21.4	2.38
90.0	49.0	11.0	8.10
90.0	99.9	6.15	9.83[d]
100.0	48.3	3.57	37.2
100.0	29.4	5.97	37.1[d]
109.6	8.91	5.85	120[d]
110.3	48.1	3.86	129
119.9	4.01	3.78	366[d]

[a] $\bar{u}$ is the average concentration of trimethylthiourea (mmoles/l.). [b] t is reaction time in hours. [c] The constant is based on the rate of dimethylamine production measured spectrophotometrically except values marked with superscript *d*. [d] These values were obtained by the titration method described in the Experimental section.

Table II

The Hydrolysis of Tetramethylthiourea

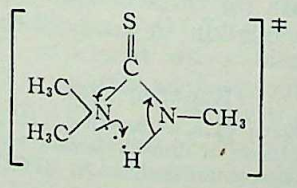
Medium	Time, hr.	Temp., °C.	Initial tetramethylthiourea, mM	Me_2NH[a] formed, mM
Water	123	110 ± 2	98.5	0.334
Water	18.5	150 ± 5	200	4.5
0.5 M HNO_3	25.5	110 ± 2	98.5	55.2
0.5 M NaOH	70	110 ± 2	98.5	137

[a] No NH_3, $MeNH_2$ or NCS^- could be detected in the reaction mixtures.

Discussion

All of the data obtained with trimethylthiourea can be rationalized by the reaction scheme

$(CH_3)_2N—CS—NH(CH_3) \rightleftharpoons$



(1)

$CH_3NCS + (CH_3)_2NH \longleftarrow$

$CH_3NCS + H_2O \longrightarrow CH_3NH_2 + COS$ (2)

Since reaction 2 is fast in acid solution, methylamine and dimethylamine should be produced in equimolar amounts. The stoichiometry (Results) is in accord with this reasoning since $k_3 = k_4$. As before the behavior of the empirical rate constant k_4 with increasing pH can be attributed to the occurrence of complicating reactions. With increasing pH the amines are no longer predominantly in the protonated form. Since the reverse of reaction 1 must take place through the unionized amine the reverse reaction will be more important at high pH. The other possible reaction

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

$$CH_3NCS + CH_3NH_2 \longrightarrow (CH_3NH)_2CS \quad (3)$$

is also most probably involved.

The finding that tetramethylthiourea does not decompose establishes that a hydrogen atom bonded to nitrogen is necessary for decomposition to take place. It also provides additional strong support for the conclusion previously presented[3] that methyl groups do not migrate and that decomposition takes place by intramolecular hydrogen transfer and dissociation of the activated complex.

A more detailed theoretical interpretation of this and other data will be presented in the last paper of this series.

The Polarography of Quinoxaline[1]

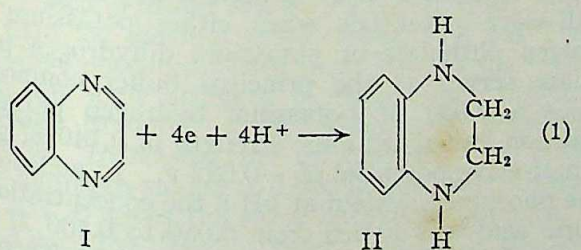
BY MURRAY P. STRIER AND J. C. CAVAGNOL[2]

RECEIVED APRIL 2, 1957

The reductions of quinoxaline at the dropping mercury electrode, conducted in buffered media in the *p*H range of 1 to 10, show well-defined, *p*H dependent waves. The influence of variations in buffer components, concentration and ionic strength on the nature of the waves have been investigated. The course of the reduction at all *p*H levels is not affected by changes in buffer components, buffer concentration or ionic strength. However, certain variations in half-wave potentials and diffusion current constants occur. Reduction to 1,4-dihydroquinoxaline is postulated for the whole *p*H range. From *p*H 1 to *p*H 2 reduction may proceed by a bimolecular, one-electron process that is not completely reversible. Reduction may also proceed by this process at *p*H 3 but this is apparently not true as the concentration of buffer components is increased. Over the *p*H range of 4 to 10 the simultaneous addition of two protons and two electrons is presumed to occur in an essentially reversible manner. Catalytic hydrogen waves are manifested following the formation of dihydroquinoxaline at *p*H's < 7 but are absent at higher *p*H's. At *p*H 7 the catalytic wave appears only at high buffer concentration.

Introduction

The polarography of quinoxaline (I) was undertaken in order to determine whether 1,2,3,4-tetrahydroquinoxaline (II) could be obtained by electrochemical methods. The over-all reduction is represented by



(1)

I II

The literature on polarography involving reduction at the dropping mercury electrode contains only two references to simple quinoxalines. Winkel and Proske[3] obtained a polarographic wave for 2,3-dimethylquinoxaline in 0.1 *M* ammonium chloride solution, but no analysis is given. Sartori and Furlani[4] studied the polarographic reduction of quinoxaline, its methiodide and its di-N-oxide. They found that quinoxaline gives a nearly reversible, 2-electron wave having an $E_{0.5}$ of -0.267 v. S.C.E. at *p*H 0 and 25°. Both prewaves and kinetic waves were found, in agreement with the present work. The formation of dihydroquinoxaline and the absence of the tetrahydro form were postulated. The roles of ionic strength and buffer composition were minimized, in contrast to the present paper.

Equation 1 demonstrates that *p*H is a critical factor in governing the reduction process. The need for employing buffered solutions having adequate ionic strength as supporting electrolytes has been stressed elsewhere.[5] Quinoxaline was studied systematically by varying buffer components, ionic strength, buffer concentration, *p*H and reductant concentration.

Experimental

Materials.—Quinoxaline was prepared by the method of Cavagnol and Wiselogle.[6] The product, resublimed prior to use was colorless and melted at 31.0–31.5°. It was used in the form of a 0.010 *M* stock solution stored under nitrogen in the dark. All supporting electrolyte components were C.P. grade and the suitability for polarographic work was established by blank runs.

Stock solutions of 0.110 *N* sodium hydroxide and 0.205 *N* hydrochloric acid were prepared and stored under nitrogen.

Apparatus.—A manual instrument of the type described by Kolthoff and Lingane[7] was used. Both the applied potential and the resulting current (as the potential across a 10,000-ohm precision resistor) were measured with a Leeds and Northrup student-type potentiometer. With this apparatus, solutions of 5.8×10^{-4} *M* cadmium sulfate in 0.100 *M* potassium chloride gave an $E_{0.5}$ value of -0.597 ± 0.001 v. *vs.* S.C.E. and an $I_d/Cm^{2/3}t^{1/6}$ value of 3.38 ± 0.02 at 25°.

All measurements were performed in a 100-ml. Berzelius

beaker thermostated at 25 ± 0.05°. A saturated calomel electrode, stored permanently in the constant temperature bath, served as the reference electrode. This electrode was connected to the electrolysis cell by means of a saturated potassium chloride–agar bridge fitted with a sintered glass tip. Two capillaries, prepared from Corning marine barometer tubing, delivered mercury into distilled water at rates of 2.09 and 2.14 mg. sec.$^{-1}$. The height of the mercury column was fixed at 58.0 cm. for all measurements.

The *p*H measurements were made with a Beckman Model G *p*H meter and all resistances were measured with a Serfass Conductance Bridge, Model RC M15.

Procedure.—Preliminary experiments showed that the most suitable working range of the instrument was from 1 to 7 ma. Under these conditions the half-wave potentials were reproducible to ±2 mv. and the diffusion current constants varied less than ±1%.

The constituents of the Clark and Lubs buffer system were used in the *p*H range of 1 to 9. In order to study the effect of the reduction wave, it was necessary to employ other buffer systems. At *p*H 1 and *p*H 2 potassium hydrogen sulfate was substituted. Sodium hydrogen tartrate was used at *p*H 3 and the phosphate buffer system served well at *p*H 10. The concentrations of buffer salt (acid) were varied from 0.05 to 0.8 *M* with ionic strengths being 0.05 to 1.4 *M*.

Test solutions containing buffer components other than Clark and Lubs were prepared as follows. The appropriate solid buffer was weighed, dissolved in distilled water and standard acid or base added until the desired *p*H was reached. Sufficient potassium chloride or sodium chloride then was added to bring the ionic strength to the desired level. A final adjustment of *p*H was made by adding standard acid or base. Gelatin was added as maximum suppressor from a stock solution so that after dilution to volume (100 ml.), its concentration was 0.01%. Finally, quinoxaline stock solution was added to obtain the desired concentration without changing the *p*H.

Current and applied potential measurements were made in an atmosphere of purified nitrogen. After scanning the complete working range at 0.1 v. intervals and plotting the data, intermediate points were taken at 0.01 v. intervals. The mercury drop time was measured at 0.1 v. intervals over the significant portions of the wave. At the conclusion of each polarogram the cell resistance was determined to correct the half-wave potential for *iR* drop across the cell.

Results

In Table I are summarized the results obtained for the reduction of 4.5×10^{-4} *M* solutions of quinoxaline in two different buffer systems. The first buffer system employed is the Clark and Lubs buffers and will be designated henceforth as the "Low" buffers. The second buffer system, designated as the "High" buffers, is characterized by having a higher concentration of buffer components and ionic strength than the "Low" buffers at all *p*H's. The level of ionic strength for the "High" buffers is 0.6 *M* and the *p*H range covered is 1 to 10. The *p*H range covered with the "Low" buffers is 1 to 9.

Two major waves are obtained for quinoxaline over the *p*H range of 1 to 7. Only the first major wave is present at *p*H's > 7. The second major wave is not evident at *p*H 7 in the "Low" buffer and is measured with difficulty at this *p*H in the "High" buffer. The first major wave is partially differentiated into two equal segments at *p*H 1 and *p*H 2 in each buffer system but this is less distinct at *p*H 2. At *p*H 3 faint evidence of differentiation for the first major wave exists in the "Low" buffer but not in the "High" buffer. Some differentiation of the second major wave occurs in the "Low" buffers at *p*H 1 and *p*H 2, but this vanishes with increasing buffer concentration.

Generally, the concentration of quinoxaline was varied from 2.5×10^{-4} *M* to 7.0×10^{-4} *M* in both "Low" and "High" buffers. Also at each *p*H the effect of such variables as buffer constituents, concentrations and ionic strengths[8] on the nature of the polarographic waves, half-wave potentials and diffusion current constants were ascertained for 4.5×10^{-4} *M* solutions of quinoxaline. The results obtained can be given[9] briefly as follows:

A. First Major Wave.—At *p*H 1 the half-wave potential remains constant as the concentration of potassium hydrogen sulfate is varied from 0.400 to 0.800 *M* with an accompanying increase in ionic strength from 0.620 to 1.43 *M*. No uniform variations in half-wave potentials with increased buffer concentration and ionic strength can be discerned at *p*H 2. At *p*H 3 there is no apparent change in half-wave potential in going from 0.050 *M* potassium hydrogen phthalate buffer to 0.050 *M* sodium hydrogen tartrate buffer. Increasing the concentration of sodium hydrogen tartrate at this *p*H to 0.300 *M* leads to decreasingly negative half-wave potentials. Either increasing the ionic strength to 0.601 *M* by addition of neutral salt or increasing the concentration of sodium hydrogen tartrate to 0.400 *M* while maintaining the ionic strength constant at 0.601 *M* has no further influence on the half-wave potential. At *p*H 4 the half-wave potential varies from −0.488 to −0.480 v. as the concentration of potassium hydrogen phthalate increases from 0.050 to 0.250 *M* with the ionic strength increasing from 0.050 to 0.258 *M*. The half-wave potential then remains constant as the concentration of potassium hydrogen phthalate is increased to 0.450 *M*.

At each *p*H level in the range of 5 to 9 inclusive, there are only small changes in half-wave potentials with variations in any of the experimental conditions. At *p*H 6 there is little if any difference in half-wave potentials when either potassium hydrogen phthalate or potassium dihydrogen phosphate serves as the principal buffer component since a 0.050 *M* potassium hydrogen phthalate solution having an ionic strength of 0.140 *M* gives a half-wave potential of −0.622 v. In addition to the phosphate system at *p*H 8 the concentration of boric acid was varied from 0.050 to 0.400 *M* and the ionic strength ranged from 0.050 to 0.600 *M*. For the phosphate buffers at the same *p*H the concentration of potassium dihydrogen phosphate was varied from 0.050 to 0.300 *M* with accompanying variations in ionic strengths ranging from 0.144 to 1.014 *M*.

In studies conducted at *p*H 10 when the concentration of potassium dihydrogen phosphate is 0.050 *M*, increasing the ionic strength from 0.153 to 0.600 *M* renders the half-wave potential less negative by 0.018 v. Increasing the concentration of potassium dihydrogen phosphate to 0.320 *M* as the ionic strength is kept at 0.600 *M* and then increasing the ionic strength to 1.015 *M* have no further effect on the half-wave potentials.

Half-wave potentials are independent of con-

(8) With one exception, potassium chloride was employed in effecting increases in ionic strength in addition to the contribution made by buffer constituents. At *p*H 3 sodium chloride was used with sodium hydrogen tartrate buffer.

(9) In these discussions *p*H values are expressed as the nearest whole number to clarify the exposition. Precise values are given in Table I.

[a] L "Low" buffer; H "High" buffer. [b] Adjusted to final *p*H with sodium hydroxide or hydrochloric acid solution. Ph = phthalate, Tr = tartrate. [c] Too low to be measured more accurately.

centration in the *p*H range of 2 to 9. Variations of 5% are observed at *p*H 1 where differentiation into minor waves is more extensive.

The diffusion current constants for the first major waves have the same order of magnitude throughout the *p*H range of 1 to 10. However, their values tend to decrease with increasing buffer concentration and to a lesser extent with increasing ionic strength. Variations of quinoxaline concentration in both buffer systems give diffusion current constants having deviations of 2 to 8%.

B. Second Major Wave.—The trends are different than for the first major wave. At *p*H 1 the half-wave potential varies from −0.772 to −0.803 v. as the ionic strength of the "Low" buffer is increased to 0.617 *M* by addition of potassium chloride. Increasing the concentration of potassium hydrogen sulfate to 0.800 *M* and ionic strength to 1.434 *M* gives the same half-wave potential as found with the "High" buffer. At *p*H 2, the half-wave potentials become more negative with increasing ionic strength and buffer concentration. At *p*H 3, the half-wave potential remains essentially constant as the ionic strength in the "Low" buffer is increased to 0.606 *M* by addition of potassium chloride. Also, the change to the sodium hydrogen tartrate buffer does not affect the half-wave potential as the concentration of this salt is raised to 0.400 *M* and the ionic strength is increased to 0.601 *M*. At *p*H 4 the half-wave potential varies uniformly from −1.011 v. in the "Low" buffer to −0.982 v. in a buffer of 0.250 *M* potassium hydrogen phthalate and potassium chloride having an ionic strength of 0.368 *M*. Further increases in concentration of potassium hydrogen phthalate to 0.450 *M* and the ionic strength to 0.647 *M* do not affect half-wave potentials. At low *p*H the wave is too small to be evaluated accurately in the "Low" buffer. Increasing the buffer concentration to 0.350 *M* potassium dihydrogen phosphate affords a sufficiently high wave for quantitative evaluation. The half-wave potential varies uniformly from −1.079 to −1.101 v. as the concentration of potassium dihydrogen phosphate is increased from 0.350 to 0.600 *M*, and the ionic strength is increased from 0.600 to 1.000 *M* with potassium chloride.

Contrary to the trend noted for the first major wave, the half-wave potentials for the second major wave generally become more negative as the concentration of quinoxaline is increased in the "Low" and "High" buffers. Exceptions are noted at *p*H 1 in the two buffers, *p*H 2 in the "Low" buffer, *p*H 4 in the "High" buffer and possibly at *p*H 6 in the "Low" buffer. In these cases the trends are not uniform and in nearly each instance the size and form of these waves make their evaluations somewhat uncertain. In all cases polarograms were run at quinoxaline concentrations of 2.5×10^{-4} *M*, 4.5×10^{-4} *M* and 7.0×10^{-4} *M*.

The diffusion current constant for the second major wave generally appears to increase with increasing concentration of buffer components, with the influence of ionic strength not being too significant. At *p*H 3, the diffusion current constant is higher in the potassium hydrogen phthalate buffer than in the sodium hydrogen tartrate buffer. In the latter, the diffusion current constant fails to increase with buffer concentration. At *p*H 4 there are no significant increases in diffusion current constants with increasing buffer concentration.

In Fig. 1 is shown the variation in diffusion current constants with *p*H for the second major wave of 4.5×10^{-4} *M* solutions of quinoxaline in both systems of buffers. The heights of these waves are not only dependent upon *p*H but also upon buffer composition, as already noted.

The diffusion current constants for the second major wave tend to decrease with increasing concentration of quinoxaline both in the "Low" and "High" buffers. Furthermore, these values tend to have average deviations > ±5% in each buffer system at every *p*H level. It is evident that the

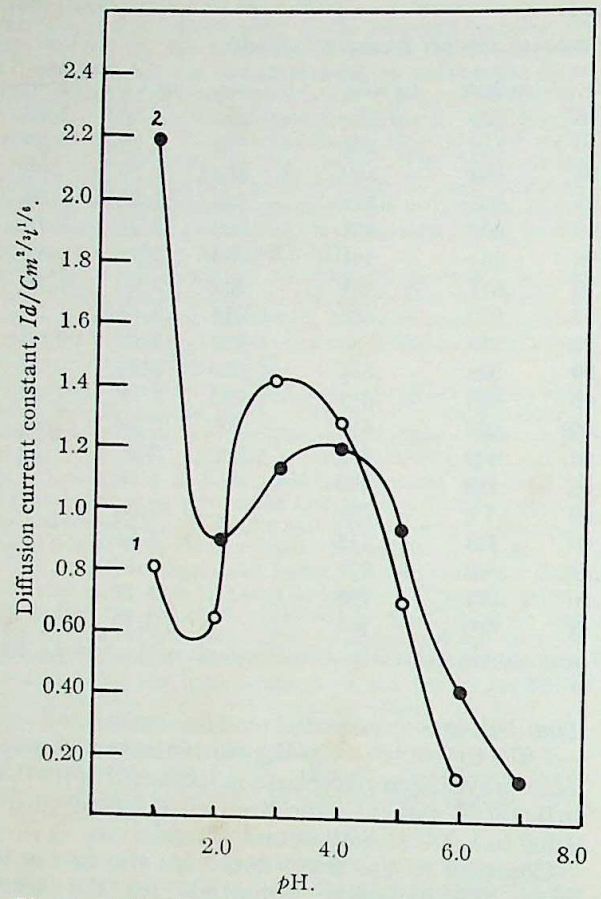

Fig. 1.—Diffusion current constants *vs.* *p*H for 4.5×10^{-4} *M* quinoxaline: 1, Clark and Lubs ("Low") buffers; 2, "High" buffers.

two major waves for quinoxaline represent decidedly different reduction processes.

Evaluation of *n* and Discussions

A. First Major Wave.—The significant aspects of this wave are (1) diffusion current constants have the same order of magnitude throughout the range of *p*H explored, indicating the same number of electrons involved in reduction, (2) diffusion current constants decrease somewhat with increasing buffer concentration and ionic strength at each *p*H, (3) except for the cases noted at *p*H 1 and *p*H 2, half-wave potentials are independent of the concentration of quinoxaline and (4) with certain exceptions noted at *p*H's 1, 2, 3 and 10 the half-wave potentials are independent of the nature of buffer components, concentration and ionic strength.

Efforts were made to evaluate *n* of this wave for 4.5×10^{-4} *M* quinoxaline solutions in the "Low" and "High" buffers by means of the Ilkovic equation

$$n = id/605D^{1/2}Cm^{2/3}t^{1/6} \qquad (2)$$

A value for *D* in the above equation was calculated from the Stokes–Einstein equation where the molar volume of 6-methylquinoxaline was employed. The density for 6-methylquinoxaline of 1.1125 at 25°, reported by Cavagnol and Wilson[10] was used to calculate the molar volume. The value of *D* obtained by this method is 6.55×10^{-6} cm.^{2} sec.$^{-1}$ at 25°. For 4.5×10^{-4} *M* solutions of quinoxaline in the "Low" buffers and in the "High" buffers the values of *n* varied from 1.9 to 2.5 with the average being 2.3.

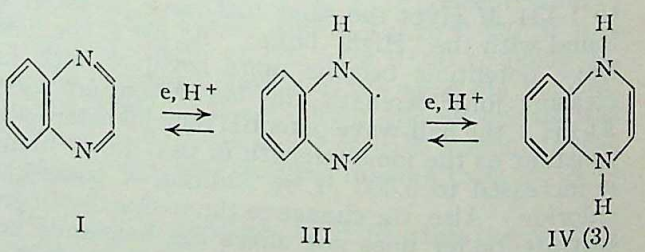
It is evident that the first major wave represents reduction involving two electrons. At *p*H's 1 and 2 wave differentiation into two equal portions signifies that reduction may proceed as a bimolecular reaction in two successive one-electron steps. It has been observed in our laboratory that the quinoxalinium ion behaves as a strong acid which makes it unlikely that the conjugate acid is being reduced. This condition may exist at *p*H 3 in the "Low" buffer but as an increase in buffer concentration appears to remove evidence of such differentiation completely then the wave differentiation may have been due to inadequate buffering. At higher *p*H's, reduction must proceed by the simultaneous addition of two electrons.

The equation of a reversible electrode process for an inorganic substance involving the addition of *n* electrons and *n* protons in a buffered solution indicates that the variation of half-wave potential with *p*H should be linear with the slope being −0.059. The plot of half-wave potential *versus* *p*H for 4.5×10^{-4} *M* solutions of quinoxaline in the "Low" buffers gives a straight line from *p*H 1 to *p*H 5 having a slope of 0.070. A straight line can be drawn from *p*H 4 to *p*H 9 having a slope of 0.063.

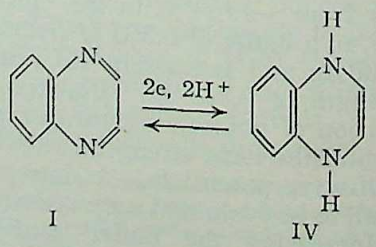
A similar plot for 4.5×10^{-4} solutions of quinoxaline in the "High" buffers gives a straight line from *p*H 1 to *p*H 10 having a slope of 0.063. Evidently, similar orders of reversibility are prevalent in the "Low" buffers and the "High" buffers. Reduction occurring at the low *p*H's is not as reversible as the reduction occurring at higher *p*H's.

On the basis of the analysis of results for the first major wave, the following mechanisms are proposed.

In the *p*H range of 1 to 2 inclusive, dihydroquinoxaline is formed by two consecutive single-electron steps



At *p*H's > 4 reduction follows the simultaneous two-electron process



(4)

At *p*H 3 reduction may proceed by either of the above processes.

It is postulated that 1,4-addition occurs in preference to 1,2-addition owing to the greater electronegativity of nitrogen. Also, it has been found in the polarographic reduction of other simple nitrogen-containing systems such as quinoline[11–13] and acridine[14] that reduction to the *dihydro* stage occurs at the 1,4-position.

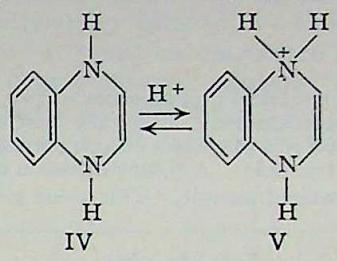
The tendency for nitrogen-containing heterocyclic systems to undergo reduction to the *dihydro* form by a semiquinone process in acid media and by a simultaneous two-electron process in alkaline media has been observed for 2-carboxyquinoline,[11] 8-carboxyquinoline,[12] 4-carboxyquinoline,[13] and methylpyridinium hydroxide.[15]

B. **Second Major Wave.**—The significant aspects of this wave are (1) it is present in acidic media but vanishes at *p*H's > 7, (2) the height increases with increasing concentration of acidic buffer component but not necessarily increasing ionic strength, except at *p*H 3 and *p*H 4. At *p*H 3 and *p*H 4 the diffusion current constants appear to be independent of concentration of potassium hydrogen phthalate and of ionic strength, (3) the variations in the diffusion current constants with quinoxaline concentration at each *p*H are greater than those of the first major wave. This suggests that the second major wave does not strictly follow the Ilkovic equation relating diffusion current and reductant concentration, (4) the half-wave potentials become more negative with increasing concentration of quinoxaline except for the results found in the "Low" buffers at *p*H 1, 2 and 6 where there are no uniform trends, (5) the half-wave potentials of this wave generally appear to be more sensitive to variations in buffer components, buffer concentration and ionic strength than those for the first major wave.

Kolthoff and Lingane[16] gave the relation describing the change of half-wave potential with change in acid concentration due to hydrogen discharge for a weak acid in an excess of indifferent supporting electrolyte as

$$\Delta E_{0.5}/\Delta \log [HA] \simeq -0.089 \text{ v.} \qquad (5)$$

where HA represents the weak acid. By taking $\Delta E_{0.5}/\Delta \log [HA]$ quotients from the results obtained in this investigation for the variation in half-wave potentials of the second major wave with quinoxaline concentration, an average value of −0.083 v. is obtained for quinoxaline in both buffers. On this basis it is postulated that the second major wave is hydrogen reduction catalyzed by the 1,4-dihydroquinoxalinium ion (V), *viz.*



IV V (6)

It is believed that the catalytic action is caused by the dissociation of V which is presumed to be a weak acid. According to Cavagnol and Wilson,[10] the first and second acid dissociation constants of 1,2,3,4-tetrahydroquinoxaline are 7.8×10^{-3} and 1.45×10^{-5}, respectively. Electronic considerations dictate that 1,2,3,4-tetrahydroquinoxaline is a weaker acid than 1,4-dihydroquinoxaline. Thus the proton leading to the catalytic wave comes from the monobasic acid.

The conclusion that the second major wave is due to hydrogen discharge catalyzed by the *dihydro* form of quinoxaline, is not unique for heterocyclic systems. Knobloch[17] observed that the reduction of nicotinamide proceeded to the dihydro stage which catalyzed the evolution of hydrogen in acid and neutral media. Catalytic hydrogen waves have been reported to follow the reduction of quinoline in weakly acidic media.[18] Kirkpatrick[19] found catalytic hydrogen waves for a number of alkaloids containing the indole structure as well as for quinine and quinidine. The failure to obtain tetrahydroquinoxaline in aqueous media at *p*H's > 7 where kinetic waves are absent must be due to the existence of the isolated double bond in the 2,3-position. Compounds containing a single ethylenic function are not ordinarily reduced at the dropping mercury electrode.[20]

Dynamic Electrical Birefringence Studies of Poly-γ-benzyl-L-glutamate[1]

BY IGNACIO TINOCO, JR.[2]

RECEIVED MARCH 20, 1957

The dynamic electrical birefringence of two samples of different molecular weight poly-γ-benzyl-L-glutamate in ethylene dichloride has been studied. A specific Kerr coefficient (B/c) of 0.057 cm.^{4}/volt g. for M_w = 84,000 and 0.31 cm.^{4}/volt g. for M_w = 350,000 was obtained. Both permanent and induced dipole moments contributed to the orientation of the molecules in the electric field. A rotary diffusion coefficient ($\Theta_{20,w}$) at infinite dilution of 9.8×10^2 sec.$^{-1}$ was obtained for the high molecular weight sample. This value gives a length of 2.7×10^3 Å. for a rigid rod or ellipsoid.

Introduction

Poly-γ-benzyl-L-glutamate (PBLG) should be an excellent model substance for dynamic electrical birefringence measurements. Doty, *et al.*,[3] have shown that in certain solvents this polypeptide exists in a wide range of molecular weights as unassociated rigid rods with the α-helix[4] configuration. Besides its known structure, PBLG has special advantages for electrical birefringence studies because it is soluble in non-conducting solvents and is uncharged. The interpretation of previous electrical birefringence experiments on charged molecules in water[5-9] is complicated by ion atmosphere[5,9] and proton migration[10-11] effects which are absent in these non-conducting systems. Furthermore, the polarizability ellipsoid of a helix must be a figure of revolution and the dipole moment must be along the symmetry axis (except for end effects). This simplifies the equations for the dynamic birefringence[11] to those given by Benoit.[6]

The orientation of a rigid molecule in a time dependent parallel electric field can be characterized by three parameters: the dipole moment μ, the polarizability α, and the rotary diffusion coefficient Θ. The decay of the orientation after application of a square electrical pulse gives a direct measure of Θ. Unlike the values obtained from hydrodynamic experiments such as flow birefringence[12] and viscosity,[13] this Θ does not depend upon explicit assumptions about the shape, for an asymmetric molecule. Values of the dipole moment μ and the electrical (α_E) and optical (α_0) polarizabilities cannot in general be separated, however, using only electrical birefringence measurements. Either the optical factor must be obtained from flow birefringence or depolarization of scattered light experiments, or dielectric dispersion measurements must be made to obtain μ and α_E.

In the present study the dynamic electrical birefringence of two PBLG samples of different molecular weight has been measured. A rotary diffusion coefficient for the high molecular weight sample was obtained, but the exact nature of the orienting electrical couple must await further information.

Experimental

The poly-γ-benzyl-L-glutamate was obtained through the courtesy of Dr. E. R. Blout and Dr. P. Doty. The two samples were: RK 1149-B with a weight average molecular weight (M_w) of 84,000 and RK 1263, M_w = 350,000. Ethylene dichloride (EDC), Union Carbide and Carbon technical grade, was dried with Drierite, then distilled through a 30 plate column at atmospheric pressure. The concentrations of the two stock solutions were determined by dry weight.

The electrical birefringence apparatus has been described before.[7,8] A Teflon cell was used, however, instead of the glass cell described previously. The cell, machined from Teflon rod, has threaded ends for standard polarimeter end plates. Gold electrodes, 0.079 × 0.476 × 8.86 cm., rest on the bottom of the cell and are held 0.249 cm. apart against the sides of the cell by Teflon spacers. Electrical connection to the electrodes is made by platinum wires. The volume of solution necessary to fill the cell is about 2.5 ml.

The performance of the apparatus was checked using nitrobenzene (J. T. Baker, purified grade). A Kerr coefficient ($B = \Delta n/\lambda E^2$) of 4.24×10^{-5} cm./volt^2 was obtained for nitrobenzene at the average effective wave length of 510 mμ. This is in satisfactory agreement with previously obtained values at 546 mμ after correction for the wave length difference. The instrumental relaxation time was also obtained from the nitrobenzene experiments; the molecular relaxation time is of course negligible. A value of 13.7 μsec., in excellent agreement with that obtained by Billick,[8] resulted.

All measurements were made at room temperature; an average value of 298°K. was used in calculations.

The methods for analyzing the primary data have been described previously.[7] It was not necessary to correct the observed rotary diffusion coefficient for the instrumental relaxation time as it was negligible compared to the relaxation time of the high molecular weight PBLG. To calculate the rotary diffusion coefficients for the molecules in water at 20°, the viscosity of the solvent (η = 0.0078 poise)[14] at 25° was used.

Results

The Kerr coefficients and rotary diffusion coefficients for solutions of PBLG in EDC are given in Table I; the Kerr coefficients are plotted *vs.* concentration in Fig. 1.

For the high molecular weight sample the birefringence was studied as a function of field strength

over the range 170–1200 practical[15] volts per cm. The Kerr coefficient was found to be independent of field strength. The number of measurements made at different voltages is given in parentheses to the right of the average value of the Kerr coefficient which is shown in the table.

The slopes of the plots in Fig. 1 give specific Kerr coefficients of $B/c = 0.31$ cm.^{4} volt^2 g. for $M_w = 350{,}000$ and $B/c = 0.057$ cm.^{4}/volt^2 g. for $M_w = 84{,}000$.

The curves for the rise of the birefringence of the high molecular weight sample on application of a rectangular electrical pulse were not symmetrical to the decay curves. The shape of the curves showed that both permanent and induced dipole orientation were important.

Discussion

Kerr Coefficients.—The specific Kerr coefficient for a molecule with a polarizability ellipsoid of revolution and permanent dipole μ_1 along the symmetry axis is related to molecular parameters by the equation[11]

$$B/c = (2\pi/15n_0\rho\lambda_0)(g_1 - g_2)(p_1 + q)$$

The quantities n_0, ρ, λ_0 are the refractive index of the solvent, the density of the solute, and the vacuum wave length of the light, respectively. The anisotropy of the optical polarizability per unit volume of particle is $(g_1 - g_2)$. The electrical orientation parameters are $p_1 = (\mu_1/kT)^2$ and $q = v(g_1^0 - g_2^0)/kT$. The permanent dipole moment is μ_1, and the anisotropy of the electrical polarizability is $(g_1^0 - g_2^0)$.

Although the factors cannot be untangled from the Kerr data alone, we can deduce the following facts. From the definitions of the molecular parameters we see that for different length rods, *e.g.*, different molecular weights of PBLG: (1) $(g_1 - g_2)$ is independent of molecular weight for long rods, (2) p_1 is proportional to the square of the molecular weight, (3) q is proportional to the molecular weight. Therefore, for the two samples studied, if the permanent dipole is the principal orienting factor, then

$$(B/c)_{M_1}/(B/c)_{M_2} = 17.4$$

or, if the induced dipole is primarily responsible

$$(B/c)_{M_1}/(B/c)_{M_2} = 4.2.$$

Experimentally we find $(B/c)_{M_1}/(B/c)_{M_2} = 5.4$; thus indicating that, although both terms are effective, induced dipole orientation is the more important. For example, if we take $p_1 = q/2$ for the high molecular weight sample, $(B/c)_{M_1}/(B/c)_{M_2} = 5.6$.

The orienting torque acting on a rigid ellipsoid of revolution of dielectric constant ϵ in a solvent of dielectric constant ϵ_0 can be calculated from an equation derived by Maxwell.[6] Using this equation a value of q can be calculated for PBLG in EDC if the helices are approximated by ellipsoids of the same length and volume. This q is nearly independent of shape for axial ratios greater than 10, if ϵ is finite.

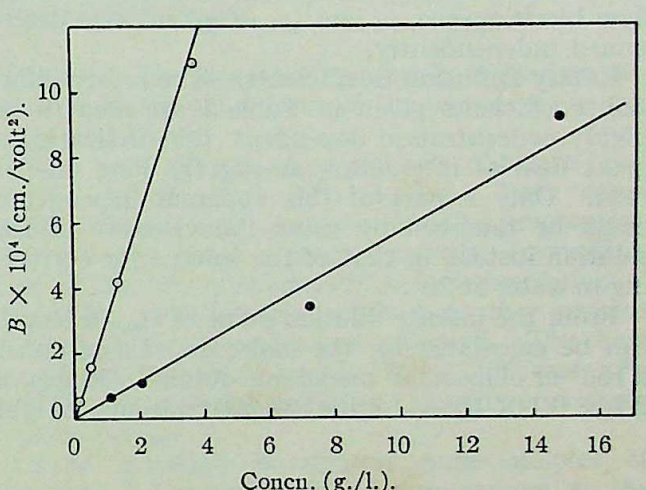

Fig. 1.—The Kerr coefficient of poly-γ-benzyl-L-glutamate in ethylene dichloride *vs.* concentration. The open circles are for $M_w = 350{,}000$; the closed circles are for $M_w = 84{,}000$.

For the calculation a dielectric constant of 2.5 for PBLG was used. This value is based on the assumption that the electrical polarizability of PBLG is completely electronic and thus ϵ is equal to the square of the refractive index obtained from Doty's (dn/dc) measurements.[3] The other parameters used were: $\epsilon_0 = 10.36$,[14] $\rho = 1.32$.[3] The shape of the rise of the birefringence curves and the molecular weight dependence of the Kerr coefficients were consistent with values of p_1 and q of the same order of magnitude for the high molecular weight sample; therefore, p_1 can be set equal to q, and the dipole moment μ_1 and optical factor $(g_1 - g_2)$ also can be estimated. For the calculation of $(g_1 - g_2)$ the following data were used: $n_0 = 1.443$,[14] $\lambda_0 = 510$ mμ. The values thus obtained for the 350,000 molecular weight sample were: $q = 4.1 \times 10^{-6}$ cm.^{3}/erg, $\mu_1 \cong 80$ debye, $(g_1 - g_2) \cong 8.9$. The value of $(g_1 - g_2)$ is very large compared to values found for many proteins in water solution.[16] Furthermore, a value of $\mu_1 = 7{,}200$ D would be estimated for a polyglycine α-helix of the same length.[17] Because of these discrepancies we should examine the assumptions in

(15) Unless designated otherwise voltages are given in practical volts (1 RSU = 300 practical volts).

(16) R. Cerf and H. A. Scheraga, *Chem. Revs.*, **51**, 185 (1952).

(17) Schellman[18] gives $\mu_1 \cong (7.2 + 4.5)n$ debye for a polyglycine α-helix where n is the degree of polymerization. The first term is the contribution to the dipole moment from a charged carboxyl group at one end of the molecule and a charged amino group at the other end. The second term is the contribution from each NH and C=O group in the helix. Obviously, only this second term is present for our system.

(18) J. A. Schellman, *Compt. rend. trav. Lab. Carlsberg, Serie chim.*, **29**, 254 (1955).

Digitized by Arya Samaj Foundation Chennai and eGangotri

our calculation. The critical assumption is that the electrical polarizability of PBLG is purely electronic, *i.e.*, $\epsilon = 2.5$. If instead we consider that the dipolar ester side chains can orient in the electric field and thus give rise to a very large atomic polarizability, the value of ϵ could be much larger than ϵ_0, the dielectric constant of the solvent. To calculate an upper limit for μ_1 we shall let $\epsilon \rightarrow \infty$. The value of q then approaches a limit depending on the axial ratio of the ellipsoid. For an axial ratio of 100, q becomes 1.9×10^{-2} cm.^{3}/erg, $\mu_1 \cong 5{,}400\,D$, $(g_1 - g_2) \cong 1.9 \times 10^{-3}$.

By measurements of dielectric dispersion and flow birefringence, μ_1 and $(g_1 - g_2)$ may be determined independently.

Rotary Diffusion Coefficients.—The rotary diffusion coefficients given in Table I are seen to be highly concentration dependent, thus indicating a great deal of interaction among the long dipolar rods. Only a part of this apparent dependence could be removed by using the viscosity of the solution instead of that of the solvent for correcting to water at 20°.

From the infinite dilution value of $\Theta_{20,w}$ a length can be calculated for the molecule. Using either a rod[9] or ellipsoidal[6] model one obtains a length of $2.7 \pm 0.1 \times 10^3$ Å. for the 350,000 molecular weight PBLG. This value may be compared with a light scattering length of about 2.0×10^3 Å. obtained by Doty, *et al.*,[3] and a calculated α-helix length of 2.4×10^3 Å. (length = 1.5 times degree of polymerization).[4] Doty's light scattering lengths agreed well with the α-helix configuration for the lower molecular weights; for the high molecular weight he attributed the disagreement to a slight flexibility in the longer rods. This flexibility might lower the rotational diffusion of the molecules and cause an apparent longer length. However, O'Konski[9] found a rotational diffusion length for tobacco mosaic virus significantly larger than electron microscope values, thus suggesting that rod-like models for these molecules may not be adequate.

Acknowledgments.—This work was done in Professor John D. Ferry's laboratory; we are very grateful to him for his hospitality and for his helpful suggestions. We also wish to thank Dr. E. R. Blout and Professor P. Doty for the samples of PBLG which made this work possible.

NOTE ADDED IN PROOF.—Professor Doty has kindly supplied a value of $(g_1 - g_2)$ for PBLG in EDC of 4.1×10^{-3} from flow birefringence experiments of J. T. Yang and P. Doty. If one assumes $p_1 = q$, this value leads to $\mu_1 = 3{,}900\,D$. for $M_w = 350{,}000$.

ORGANIC AND BIOLOGICAL CHEMISTRY

[CONTRIBUTION NO. 2190 FROM THE GATES AND CRELLIN LABORATORIES OF CHEMISTRY, CALIFORNIA INSTITUTE OF TECHNOLOGY]

Coördination of Silver Ion with Unsaturated Compounds. IX. Solid Complexes of Silver Salts with Cyclohexene, α-Pinene and β-Pinene[1]

BY ALAN E. COMYNS[2] AND HOWARD J. LUCAS[3]

RECEIVED MARCH 6, 1957

Silver perchlorate with cyclohexene, α-pinene and β-pinene forms crystalline complexes which contain two molecules of hydrocarbon to one of silver perchlorate. Silver nitrate forms a similar complex with cyclohexene but none with the pinenes. By means of silver perchlorate the pinenes can be separated from each other, and both α-pinene and β-pinene can be obtained optically pure from optically impure specimens of the respective hydrocarbons.

The first complexes of silver salts with alkenes to be isolated[4] were those of silver nitrate with cyclopentadiene dimer and of silver perchlorate with biallyl and cyclopentadiene dimer. Many complexes of silver nitrate with cyclic olefins have since been prepared and have been used to purify and characterize the olefins.[5] The melting points of a number of olefin–silver nitrate complexes have been compared by Salomon,[6] and some unusual "liquid complexes" of silver nitrate with propene and 1-butene have been described.[7]

When silver perchlorate is added to cyclohexene, α-pinene and β-pinene finely divided solid compounds are formed in the ratio of one mole of silver perchlorate to two of the hydrocarbon. When the mixture of solid with excess of hydrocarbon (plus acetone in the case of cyclohexene) is cautiously warmed,[8] the solid dissolves and crystallizes on cooling. The cyclohexene complex was prepared for study by X-ray diffraction.[9]

The pinene complexes are of interest because they enable the two pinenes to be separated from each other and to be obtained optically pure. The separations are effected by mixing less than one mole of silver perchlorate with two moles of the pinene mixture, letting them react, removing uncomplexed pinene by high vacuum distillation and recovering pinene from the complex by the addition of water. The separations probably depend on differences in the solubilities of the complexes in the pinene mixtures.

The best sample of α-pinene[10] obtained had $[\alpha]^{25}D$ +52.4° and $n^{25}D$ 1.4632. Two other methods have been described for the preparation of "optically pure" α-pinene, namely, crystallization of the nitrosochloride[10a] and isomerization of "optically pure" β-pinene,[10b] but the present method is easier and more effective. The best sample of β-pinene[11] had $[\alpha]^{25}D$ −22.7° and $n^{25}D$ 1.4764; the rotation is higher than any previously reported value.

It is necessary to employ pure samples of pinenes. α-Pinene which had been exposed to the air for several days gave a sticky black mass with silver perchlorate. Negligible optical fractionation of α-pinene was obtained with a "practical" grade, although the complex was formed as usual.

Experimental

Materials.—Silver perchlorate (anhydrous) was used as purchased from G. F. Smith and Co. The cyclohexene had been prepared from cyclohexanol by Dr. N. Koenig in this Laboratory and had $n^{25}D$ 1.4441. The pinenes, prepared specially for this work by the Glidden Co. and stated to be of better than 99.9% purity, were stored before use under vacuum in sealed ampoules. α-Pinene[10] had $[\alpha]^{25}D$ +30.0° (in 1 dm. tube),[12] $n^{25}D$ 1.4631, and β-pinene[11] had $[\alpha]^{25}D$ −21.0°, $n^{25}D$ 1.4765.

Analyses.—Silver determinations on the cyclohexene complexes were by thiocyanate titration in the presence of the hydrocarbon; other analyses were by A. Elek, Los Angeles, Calif.

Preparation of Silver Perchlorate–Cyclohexene Complex.—An excess of cyclohexene, 12 ml., was added to crystalline silver perchlorate, 2.63 g. A rapid exothermic reaction occurred, and the silver perchlorate was converted into a voluminous white powder which was filtered off; yield 4.28 g.

plex.—Silver perchlorate, 4.05 g., was dissolved in a warm mixture of cyclohexene, 5 ml., with acetone, 5 ml., and the solution was cooled in ice. The complex crystallized in the form of rectangular plates, which were filtered off; yield 5.02 g.

Anal. Found: C, 37.97; H, 5.41; Cl, 9.66; Ag, 29.00, 28.93.

Recovery of Cyclohexene from Silver Perchlorate Complex.—The powdered complex, 3.64 g., was shaken with water, 15 ml., until all the solid had dissolved. The upper liquid layer, 1.6 ml., was separated, dried overnight with sodium and then distilled under vacuum; yield 1.21 g. (75%) of liquid having $n^{25}D$ 1.4438. The lower aqueous layer yielded only a trace of second liquid phase when treated with an excess of ammonium hydroxide.

Solubility of Silver Perchlorate Complex in Cyclohexene.—Silver perchlorate, *ca.* 0.2 g., contained in an ampoule fused to the vacuum system, was dried by pumping for 24 hr. with a mercury-vapor diffusion pump followed by a liquid-air trap. Cyclohexene, 25 ml., over sodium in a flask attached to the vacuum system, was distilled directly onto the silver perchlorate, and the ampoule was then sealed and removed from the apparatus. After having been shaken at 25.0° for 4 days, the ampoule was opened, and a 10-ml. portion of the clear supernatant liquid was withdrawn. This was evaporated. Titration of the silver in the residue against thiosulfate showed the solubility to be 0.003 g. of $AgClO_4$/100 ml. of solution. A similar experiment in which the silver perchlorate had been dried for only 4 hr. gave a solubility of 0.005 g./100 ml.

Preparation of Silver Perchlorate–α-Pinene Complex.—When silver perchlorate was left to stand with α-pinene at 25° for several hours, a voluminous white powder formed. It was not possible to obtain a solid of reproducible silver content by removing adhering liquid by high-vacuum distillation from room temperature to a trap cooled by liquid air. For the preparation of the crystalline complex, silver perchlorate, *ca.* 0.2 g., was left with α-pinene, 10 ml., at room temperature for 3 hr., and the mixture was then warmed[8] to dissolve the complex thus formed. Cooling to room temperature yielded small hexagonal plates; yield 0.1 g.

Anal. Calcd. for $AgClO_4 \cdot 2C_{10}H_{16}$: C, 50.06; H, 6.72; Cl, 7.39; Ag, 22.48. Found: C, 50.36; H, 6.72; Cl, 7.26; Ag, 22.64.

When these crystals were heated in a melting-point tube, they broke up into a liquid and a solid phase at 76 ± 1°, and on further heating this mixture blackened suddenly at 125°. Observation of these processes under a hot-stage microscope showed that at 74° the edges of the crystals started to become etched with the formation of liquid drops and that at 80° the crystalline form had been lost entirely. Again, further heating to 125° caused sudden blackening. When heated in a test-tube, the complex exploded mildly. The crystals were not stable in air at room temperature; a sample that had been kept for 3 days in the dark in a well-corked tube had become gray, and microscopic examination showed liquid drops to be present on the faces of the crystals. No attempt was made at storage in the absence of oxygen.

The crystalline complex was prepared in better yield by the use of acetone. Silver perchlorate, *ca.* 4 g., was dissolved in a mixture of α-pinene, 6 ml., and acetone, 1.4 ml., thereby forming a system of two liquid phases. Most of the acetone was removed by standing in a continuously evacuated desiccator. Filtration yielded crystals 2.3 g., m.p. 77–78°, dec. *ca.* 150°.

Anal. Found: Ag, 22.6, 22.9.

Preparation of Silver Perchlorate–β-Pinene Complex.—Silver perchlorate reacted rapidly with β-pinene at room temperature, the mixture becoming warm and much white powder being produced. As in the case of the α-pinene complex, a pure product could not be obtained using this procedure. The crystalline complex was obtained by allowing silver perchlorate, *ca.* 0.4 g., to stand with β-pinene, 10 ml., for 5 min., heating[8] to dissolve the complex so formed, cooling to room temperature and filtering; yield 0.4 g. of small rectangular plates, m.p. 108–109°. The molten complex underwent violent decomposition at 125°.

Anal. Found: C, 49.00; H, 6.56; Cl, 7.21; Ag, 22.40.

The same complex was obtained in better yield by the addition of acetone to the β-pinene. An excess of silver perchlorate was warmed with a mixture of β-pinene, 3.5 ml., having $[\alpha]^{25}D$ −20.6°, $n^{25}D$ 1.4763, and acetone, 0.5 ml., "reagent" grade. The liquid was decanted and allowed to cool slowly to 4°. Filtration yielded rectangular plates, 0.42 g., m.p. 107–109°, decomposing at 126°.

The crystalline complex, 0.32 g., was decomposed by water, 0.4 ml., the β-pinene phase was separated and dried with a small lump of calcium sulfate and then distilled in the vacuum system. The distillate, *ca.* 0.1 g., had $[\alpha]^{25}D$ −22.4°, $n^{25}D$ 1.4763.

Optically Pure α-Pinene from Optically Impure α-Pinene.—α-Pinene, 12.75 g., having $[\alpha]^{25}D$ +30.0°, $n^{25}D$ 1.4631, and crushed silver perchlorate, 4.83 g., were shaken together in a stoppered flask at 25° for 24 hr. Although less than half the α-pinene had reacted, the product was a semi-solid white mass. Unreacted α-pinene was removed from the mixture by high-vacuum distillation at room temperature into a receiver cooled in liquid air. Pinenes volatilize very slowly from their complexes with silver perchlorate under these conditions, and this quantity of unreacted α-pinene distilled completely in about 1 hr.[13] The distillate was dried over calcium sulfate (the trace of water present probably originated in the silver perchlorate), decanted and redistilled in the same apparatus under the same conditions: yield 6.08 g. (48%) of α-pinene, $[\alpha]^{25}D$ +16.2°, $n^{25}D$ 1.4630. The solid complex was decomposed by water, 10 ml., and the upper layer of α-pinene was separated. This was dried over calcium sulfate and distilled as before: yield 4.52 g. (36%), $[\alpha]^{25}D$ +50.7°, $n^{25}D$ 1.4630.

The sample of α-pinene obtained from the complex was fractionated again by the same procedure: 4.27 g. was shaken with silver perchlorate, 2.33 g., at 25° for 24 hr. In this experiment, however, little reaction occurred in this period, and the mixture was warmed in a water-bath at 95° for 0.5 min. to initiate the reaction. After a further 24 hr. little more reaction had occurred, so the mixture was warmed in a water-bath at 60° for several minutes, and then left to stand at 25° for a further 24 hr., by which time the mixture had become a semi-solid white mass. The products were separated, and the complex decomposed by water, 0.5 ml., as in the previous experiment. The unreacted α-pinene, 2.21 g. (52%), had $[\alpha]^{25}D$ +49.6°, $n^{25}D$ 1.4633; the α-pinene, 1.31 g. (30%), obtained from the solid complex had $[\alpha]^{25}D$ +52.4°, $n^{25}D$ 1.4632. The constancy of the refractive index throughout showed that no chemical change was taking place.

Optically Pure β-Pinene from Optically Impure β-Pinene.—β-Pinene, 8.59 g. having $[\alpha]^{25}D$ −21.0°, $n^{25}D$ 1.4765, reacted exothermally with silver perchlorate, 2.93 g., to produce a semi-solid white mass in several minutes; the mixture was then left at 25° for 18 hr. The product was treated in the same manner as the α-pinene complex. The unreacted β-pinene, 3.34 g. (39%), had $[\alpha]^{25}D$ −20.6°, $n^{25}D$ 1.4763. The β-pinene, 2.93 g. (34%), obtained by treating the solid complex with water, 10 ml., had $[\alpha]^{25}D$ −22.7°, $n^{25}D$ 1.4764.

Separation of α-Pinene from β-Pinene.[14]—The initial mixture was prepared by mixing α-pinene, 1.11 g., $\alpha^{25}D$ +44.7°, $n^{25}D$ 1.4632, with β-pinene, 1.13 g., $\alpha^{25}D$ −19.7°, $n^{25}D$ 1.4764. The mixture had $\alpha^{25}D$ +12.8°, $n^{25}D$ 1.4699. The percentage of α-pinene in this mixture, as calculated from the quantities taken, is 49.6. Assuming linear relations, the measured optical rotation of the mixture corresponds with that of a mixture containing 50.5% α-pinene, and the

(13) On one occasion an attempt was made to hurry this process by warming the reaction mixture in a water-bath at 90°; an explosion occurred which shattered the apparatus.

(14) Mixtures were analyzed by measurement of optical activity and refractive index, the results of these two methods agreeing within the limits of accuracy of the refractive index measurements. In this experiment the optical activities are expressed as measured rotations in a 1-dm. tube, the measured rotations of mixtures of α-pinene and β-pinene being approximately linear functions of relative concentration. The error involved in assuming refractive indices to be linear functions of concentration is only 1.5% at equal concentrations; the accuracy of our measurements did not warrant the more accurate treatment given by Fuguitt, *et al.*[10] Optically pure pinenes, prepared by the methods described in the preceding two sections, were employed in order to avoid simultaneous fractionation of optical isomers which would vitiate the simple optical method of analysis. Other experiments in which optically pure pinenes were not employed gave similar results, as shown by the refractive index method.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

refractive index corresponds with that of a mixture containing 51.1% α-pinene.

The mixture, 2.05 g., was treated with silver perchlorate, 0.75 g., and left to stand at 25° for 7 hr., when the products were separated by the method described above. The liquid, 1.00 g. (49%), distilled from the mixture had $\alpha^{25}D$ +30.7°, $n^{25}D$ 1.4662. These figures correspond with those of a mixture of α-pinene with β-pinene containing 78.3 and 78.2% α-pinene, respectively. The liquid, 0.60 g. (29%), obtained by treating the solid phase with water, 2 ml., had $\alpha^{25}D$ −14.7°, $n^{25}D$ 1.4756. These figures correspond with those of a mixture containing 92.2 and 93.1% β-pinene, respectively. The agreement between the two methods of analysis for both fractions confirms that no chemical change had occurred and that the recovered liquids consisted of only the mixed pinenes.

Behavior of α-Pinene and β-Pinene toward Aqueous Silver Perchlorate.—A solution of silver perchlorate, 6 g., in water, 5 ml., was shaken with β-pinene, 0.5 ml., for several minutes at 25°. The β-pinene was thereby completely converted to a white solid, which was not analyzed but was probably the same complex as that formed in the absence of water. An identical experiment in which α-pinene was substituted for the β-pinene did not produce any solid, the α-pinene remaining instead as a separate liquid phase. A further experiment, in which a mixture, 0.5 ml., of equal volumes of the two pinenes was taken, gave a mixture of solid and two liquid phases. This might be a promising method for the separation of α-pinene and β-pinene from each other.

Preparation of Silver Nitrate–Cyclohexene Complex.[15]—Silver nitrate, 3.6 g., was dissolved in a warm mixture of cyclohexene, 15 ml., and ethanol, 2 ml. At room temperature a system of two colorless phases was formed, and at 0° the lower phase gave a mass of needle-shaped crystals. Filtration at *ca.* 4° gave 4.6 g. of product, m.p. 24–32°.

Anal. Calcd. for $AgNO_3 \cdot 2C_6H_{10}$: Ag, 32.3. Found: Ag, 33.2, 33.3.

Pinenes and Silver Nitrate.—Attempts to obtain a solid complex were unsuccessful with pinene (practical) or pinene diluted with a solvent, for example, acetone, methanol or ethanol.

Miscellaneous Observations.—Silver perchlorate dissolves readily in 2-pentene, in 1-hexene and in 4-methyl-2-pentene to form systems consisting of two colorless liquid phases.[16] Crystals form when the 2-pentene system is cooled below room temperature. Silver nitrate dissolves to some extent in 2-pentene and in 4-methyl-2-pentene, but no second liquid phase results.

(15) The complex, but not its preparation, has previously been described by Salomon.[6]

(16) Francis[7] found that silver nitrate gave two liquid phases with propene and 1-butene but not with mixed pentenes.

Coördination of Silver Ion with Unsaturated Compounds. X. Complexes of Silver Perchlorate and Silver Nitrate with Alkynes[1]

BY ALAN E. COMYNS[2] AND HOWARD J. LUCAS[3]

RECEIVED MARCH 6, 1957

Systems of silver nitrate and silver perchlorate with 2-butyne, 2-pentyne and 3-hexyne have been studied. Solid complexes are formed, and their solubilities in the alkynes have been measured at 25°.

Previous investigations in this series[4,5] of the coordination[6] of alkynes with silver ion were devoted to measuring equilibrium constants in aqueous solution. We now report studies on systems formed in the absence of added solvent. As before, only dialkylacetylenes have been studied in order to obviate complications from the presence of acidic hydrogen atoms on 1-alkynes.

Silver perchlorate and silver nitrate differ markedly in their solubilities in the three alkynes, as shown in Table I. Except in the case of the silver perchlorate–2–butyne system, where a solid complex is rapidly and quantitatively formed, the solids in contact with the "saturated" solutions were mixtures of unreacted silver salt with solid complexes. This was due to the slowness with which solid complexes were formed, and in consequence the solubilities given in Table I are not true equilibrium values.

TABLE I

SOLUBILITIES OF $AgClO_4$ AND $AgNO_3$ COMPLEXES IN ALKYNES AT 25°

	2-Butyne	2-Pentyne	3-Hexyne
$AgClO_4$[a]	0.10	68	65
$AgClO_4$[b]	.10	211	185
$AgNO_3$[a]	.28	0.22	0.24

[a] Grams of $AgClO_4$ or $AgNO_3$ per 100 g. of solution. [b] Grams of $AgClO_4$ per 100 g. of solvent.

Silver Perchlorate Complexes.—The solubility of silver perchlorate in 2-pentyne and 3-hexyne is about two thousand times that in 2-butyne. This is probably a consequence of the symmetry of the 2-butyne molecule, which favors packing into a crystal lattice, rather than the formation of concentrated solutions. Similar behavior is found in related systems: thus silver perchlorate is insoluble in dioxane[7] but very soluble in tetrahydropyran[8] and is sparingly soluble in cyclohexene but very soluble in 1-hexene.[9] In each of these systems the solvents of more symmetrical structure readily form solid complexes with silver perchlorate but are poor solvents for these complexes.

The compositions of the "saturated" solutions of silver perchlorate in 2-pentyne and 3-hexyne at 25° correspond with molal ratios of alkyne to silver perchlorate of 1.4:1. Partial evaporation of the

alkyne gives in each case a solid in which this ratio is approximately 1:3.

Solutions of 7.2 to 41% silver perchlorate in 2-pentyne (molal ratios of alkyne to silver perchlorate between 39:1 and 4.3:1) exist at 25° as two conjugate liquid phases of these compositions. Solutions containing less than 7.2% and between 41 and 68% of silver perchlorate in 2-pentyne consist of one liquid phase. The more concentrated solutions are viscous and become pale brown after standing for several days.

Solutions of silver perchlorate in alkynes silver-plate metallic copper, as do solutions of silver salts of fluoro acids in aromatic hydrocarbons.[10] Concentrated solutions in 2-pentyne and 3-hexyne explode on contact with mercury.

Vapor pressure data obtained on the system silver perchlorate–2-butyne, are plotted in Fig. 1. Systems containing 2-butyne in excess of the formula $AgClO_4 \cdot 3C_4H_6$ exert a pressure equal to that of 2-butyne (254 mm. at 0°), and those containing between 3 and 2.5 moles[11] of 2-butyne to 1 of silver perchlorate have a vapor pressure of 46 mm. at 0°.

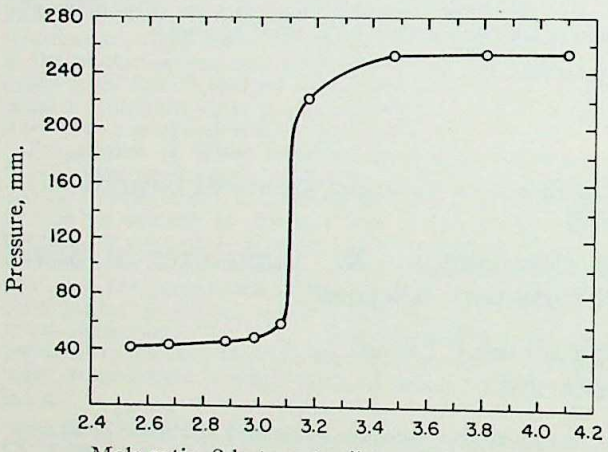

Fig. 1.—Vapor pressure of 2-butyne in the silver perchlorate–2-butyne system.

Silver Nitrate Complexes.—The solubility of silver nitrate is about the same in 2-butyne, 2-pentyne and 3-hexyne (Table I). 2-Pentyne reacts the most rapidly, for within a few minutes of adding powdered silver nitrate a fluffy white powdery complex is noticed. In the presence of a trace of moisture, introduced for example by working in an open test-tube, a second liquid phase forms, but even when the anhydrous reactants are heated to 90° in a sealed tube, no second liquid phase is observed. Evaporation of a saturated solution of silver nitrate gave a small amount of a flaky crystalline solid, $AgNO_3 \cdot 3C_5H_8$. This lost 2-pentyne rapidly on exposure to the atmosphere, and the resulting white powder had the approximate composition $AgNO_3 \cdot C_5H_8$.

When 2-butyne and 2-pentyne were shaken with silver nitrate at 25° for five days, some silver nitrate remained unchanged. 2-Butyne became yellow and a silver mirror was deposited on the walls of the vessel. When a mixture of 2-butyne and silver nitrate was warmed gently to 65°, the crystals of silver nitrate dissolved and a second, denser, initially yellow liquid phase appeared. This rapidly became dark brown and a silver mirror was deposited. Because of this side reaction, no satisfactory complex was isolated.

Powdered silver nitrate reacted quantitatively with 3-hexyne in 8 weeks to give the colorless crystalline complex, $AgNO_3 \cdot C_6H_{10}$.[12]

Experimental

Materials.—Silver perchlorate and silver nitrate were of reagent grade, the former from the G. F. Smith Co. The alkynes were all purchased from the Farchan Research Laboratories and purified by standing over sodium for 24 hr., followed by fractionation through a series of U-tubes in the vacuum system. The purified 2-butyne had v.p. 253 mm. at 0°, in agreement with that calculated from the formula given by Heisig and Davis.[13] The vapor density at 321 mm. and 24.5° was 2.46 g./l., which corresponds to a mol. wt. of 55.2 (calcd., 54.1). 2-Pentyne had d^{25}_4 0.705, $n^{25}D$ 1.4005. The vapor pressure of 2-pentyne was measured between −33° and +26° and obeyed the relation $\log_{10} P_{mm} = 8.067 - (1695/T_{abs})$. 3-Hexyne had $n^{25}D$ 1.4091.

Analyses.—The complexes of silver perchlorate with 2-butyne and of silver nitrate with 3-hexyne were analyzed by Dr. A. Elek. Other silver analyses were by thiocyanate titration using ferric alum indicator.

Solubility Measurements.—The solubility measurements for silver perchlorate in 2-pentyne and 3-hexyne are described in their respective sections below. The solubilities of silver perchlorate in 2-butyne and of silver nitrate in 2-butyne, 2-pentyne and 3-hexyne were measured by the following technique. A small quantity of the salt, contained in a glass ampoule fused to the vacuum system, was dried by pumping for at least 24 hr. with a mercury-vapor diffusion pump followed by a liquid-air trap. The alkyne, dried over sodium, was distilled directly into the ampoule which was then sealed off from the vacuum system and left to shake in a thermostat at 25.0° for several days. By this time the silver perchlorate with 2-butyne had been completely converted to a white powder: in the three silver nitrate systems the salt had been partially converted to solid complexes, which had the form of exceedingly thin, transparent flakes. Aliquots of the solutions were transferred to small flasks by pipets which had previously been warmed to 25°. The solutions were evaporated to dryness, and the residues were dissolved in 3 *N* nitric acid and titrated with 0.1 *N* potassium thiocyanate solution.

Silver Perchlorate–2-Butyne.—2-Butyne, 2.8 ml. at 0°, was distilled onto finely crystalline silver perchlorate, 0.90 g., contained in a graduated tube closed by a mercury float valve. In 15 minutes the solid, which had previously occupied 0.6 ml., had become transformed into a white, powdery mass which occupied 2.0 ml. An excess of liquid 2-butyne was present. The solid underwent no further volume change in 15 hr. All volatile constituents were then distilled from the mixture into a trap cooled in liquid air, 2 hr. being required. The distillate consisted of unchanged 2-butyne, 2.8 ml. at 0°, v.p. 254 mm. at 0°. The residual silver perchlorate, now in the form of a fine, white powder, occupied 1.8 ml.; it was completely soluble in water.

The complex was prepared on a sintered-glass disk fused into the middle of a centrifuge tube, the latter initially fused to the vacuum system. After the complex had formed on the disk, the contents of the tube were frozen, and the tube was sealed off from the vacuum system. The excess of liquid 2-butyne was then removed from the solid complex by centrifuging; by this means the solid was in

(10) D. W. A. Sharp and A. G. Sharpe, *J. Chem. Soc.*, 1858 (1956).

(11) Systems containing less butyne than this were not examined owing to the long time necessary for them to reach equilibrium. The experiment illustrated in Fig. 1 took ten weeks. For this reason it is not possible to deduce the nature of the second solid phase in equilibrium with the complex when less than 3 moles of 2-butyne is present. It may be silver perchlorate or another complex. Solid solutions are precluded by the shape of the vapor pressure curve.

(12) The formation of a solid complex of silver nitrate with 3-hexyne was first observed by F. L. Carter in these Laboratories.

contact with saturated 2-butyne vapor until finally it was removed and sealed in a small glass tube for analysis.

Anal. Calcd. for $AgClO_4 \cdot 3C_4H_6$: C, 39.0; H, 4.91; Cl, 9.59; Ag, 29.2. Found: C, 38.7; H, 5.02; Cl, 8.98; Ag, 29.4.

For the vapor pressure measurements, Fig. 1, silver perchlorate (1.049 g., 0.0051 mole) was contained in a small bulb which was maintained at 0° throughout the experiment. This bulb was connected to a manometer, and, *via* a mercury float valve, to a bulb of known volume, 147 ml., provided with a manometer of known volume per unit length. This larger bulb was in turn connected to the main line of the vacuum system by another mercury float valve. 2-Butyne (1.121 g., 0.0207 mole) was distilled onto the silver perchlorate, the valve was closed, and the mixture was left to equilibrate for 24 hr.; the vapor pressure remained at 254 mm., showing free liquid 2-butyne to have been present. Successive samples of 2-butyne vapor were removed from the small bulb, their masses being determined by measurement of the pressures exerted in the calibrated bulb. The pressures exerted by the complex were recorded as a function of time in order to find when equilibrium was established. Systems in the region of the inflection of the curve, Fig. 1, came to equilibrium in about 2 days, but the system of composition $AgClO_4 \cdot 2.6C_4H_8$ took approximately 30 days. At the conclusion of the experiment (after 10 weeks) the combined samples of removed vapors, 0.276 g., were shown to consist of pure 2-butyne (v.p. 254 mm. at 0°; v.d. 2.45 g./l.) and to account for 65% of the quantity expected on the basis of the separate pressure measurements. The remainder probably was lost through the stopcock grease of the storage flask during the experiment. At the conclusion of the experiment 1.0 ml. of water was admitted to the complex to release the remaining 2-butyne.[14] The liquids were distilled into a trap on the vacuum line and roughly fractionated by allowing the 2-butyne to distil out of the mixture into a second trap containing sodium. The 2-butyne, 0.451 g. (0.0083 mole), thus obtained had v.p. 254 mm. at 0°.

Silver Perchlorate–2-Pentyne.—Silver perchlorate, 4.75 g., and 2-pentyne, 17 ml., were shaken together in a stoppered test-tube in a thermostat at 25.0° for 24 hr. The solid dissolved, forming approximately equal volumes of two colorless liquid phases. The densities of the phases were determined using a pycnometer of 1.7-ml. volume. The concentrations of silver ion in the two phases were measured by shaking known weights with 3 *N* nitric acid and titrating with 0.1 *N* potassium thiocyanate. They are expressed as g. of $AgClO_4$ per 100 g. of solution. The upper phase had d^{25}_4 0.752; $AgClO_4$, 7.22, 7.24%. The lower phase had d^{25}_4 1.136; $AgClO_4$, 41.1, 41.2%.

The liquids remaining after the measurements had been made were treated with an excess of silver perchlorate, and the mixture was stirred intermittently at 25.0° during 48 hr., using a Trubore stirrer fitted in a test-tube. An orange, viscous solution was formed having d^{25}_4 1.748; $AgClO_4$, 67.8, 67.9%. The solid phase filtered from this solution appeared to contain unchanged silver perchlorate, contaminated with a small amount of a dark powder: analyses gave $AgClO_4$, 96.3, 95.7%. The viscous solution was evaporated under vacuum to approximately half-volume and the resulting white powder was filtered off.

Anal. Calcd. for $(AgClO_4)_3 \cdot C_5H_8$: Ag, 46.9. Found: Ag, 47.7, 46.4, 47.3.

Silver Perchlorate–3-Hexyne.—A mixture of silver perchlorate, 16.1 g., and 3-hexyne, 10 ml., was stirred intermittently for four days at 25.0° using the same apparatus as was used for the system with 2-pentyne. Here also a viscous, orange solution was formed. It had d^{25}_4 1.654; $AgClO_4$, 64.8, 64.9%. The solid phase which was filtered from this solution had a pale, creamy color and was more powdery than the silver perchlorate taken initially. Analyses gave $AgClO_4$, 95.9, 95.1%. Partial evaporation of the saturated solution yielded a cream-colored powder which was filtered off and freed from excess of 3-hexyne by exposure in the vacuum system for 4 min.

Anal. Calcd. for $(AgClO_4)_3 \cdot C_6H_{10}$: Ag, 46.0. Found: Ag, 45.6, 45.7.

(14) It was later found that distillation into a trap cooled in liquid air would have been more effective.

Silver Nitrate–2-Butyne.—The solid complex taken for analysis was that removed from a mixture which had been used for a solubility determination. This mixture had been shaken at 25° for 5 days and a pale yellow color had developed in the liquid phase. The solid phase, which was separated from this solution by centrifuging in a stoppered tube fitted with a sintered disk, contained small crystals of unchanged silver nitrate.

Anal. Found: Ag, 41.0, 40.5; ratios of $AgNO_3$ to C_4H_6 calcd. from these figures are 1 to 1.72 and 1.78, resp.

Silver Nitrate–2-Pentyne.—The solid phase formed during a solubility experiment was analyzed; the mixture had been shaken in a sealed tube at 25° for 4 days and had remained colorless.

Anal. Calcd. for $AgNO_3$: Ag, 63.5. Found: Ag, 64.0, 63.1.

The yield of crystals formed by evaporating a saturated solution of silver nitrate in 2-pentyne is very small. An apparatus, Fig. 2, was designed in order to repeat the process any desired number of times on the same mixture. Bulb A, 100 ml., contained silver nitrate. 2-Pentyne was distilled

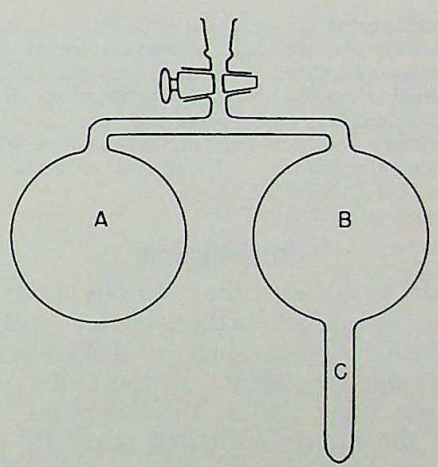

Fig. 2.—Apparatus for the preparation of the silver nitrate–2-pentyne complex.

onto it from the vacuum system, after which the stopcock was closed and the apparatus was detached from the system. The apparatus was shaken at room temperature for several hours for solution to occur, and then it was carefully tilted in order to decant the solution into bulb B, also 100 ml. With the apparatus in the vertical position again, bulb A was cooled by solid carbon dioxide thus causing 2-pentyne to distil back into bulb A and, by evaporation, to deposit crystals in bulb B which settled in tube C, 5 cm. × 1 cm. When all the 2-pentyne except that in tube C had distilled, bulb A was warmed to room temperature whereupon the whole process was repeated several times. When sufficient crystals had been formed, air was admitted through the stopcock and tube C was cut off. The contents were rapidly filtered and analyzed.

Anal. Calcd. for $AgNO_3 \cdot 3C_5H_8$: Ag, 28.8. Found: Ag, 30.66, 30.39; ratios of $AgNO_3$ to C_5H_8 calcd. from these figures are 1 to 2.67 and 2.72, resp.

The remainder of the crystals were left in a conical flask, 25 ml., open to the atmosphere, and the rate of loss in weight found, Table II.

TABLE II

CHANGE IN WEIGHT OF $AgNO_3 \cdot 3C_5H_8$ WHEN EXPOSED TO AIR

Time, min.	0	1	2	3	5	9	17	33	46	217
Weight, mg.	70	66	63	61	58	56	53	51	50	50

The very rapid initial loss shows that the samples which had been analyzed must have lost some 2-pentyne prior to analysis, and the initial composition was probably $AgNO_3 \cdot 3C_5H_8$. The powder which had come to constant weight in the atmosphere was analyzed

Anal. Calcd. for $AgNO_3 \cdot C_5H_8$: Ag, 45.3. Found: Ag, 46.5.

Silver Nitrate–3-Hexyne.—A mixture of silver nitrate with an excess of 3-hexyne was prepared following the same technique as in the solubility experiments, and it was left to stand at room temperature for 8 weeks. The tube was then opened and the resulting crystalline mass was freed from liquid by centrifuging in a tube fitted with a sintered-glass disk.

Anal. Calcd. for $AgNO_3 \cdot C_6H_{10}$: C, 28.6; H, 4.00; N, 5.56; Ag, 42.8. Found: C, 28.4; H, 3.92; N, 5.47; Ag, 43.5.

This solid evolved 3-hexyne readily when warmed, and it burned with a smoky flame leaving a residue which contained free silver and also some water-soluble silver compound, presumably silver nitrate.

Structures of the Reaction Products of Tetraalkoxytitanium with Acetylacetone and Ethyl Acetoacetate

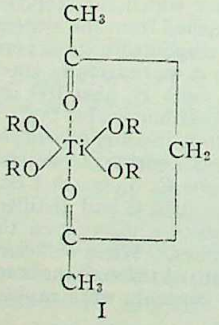
BY AKIO YAMAMOTO AND SHU KAMBARA

RECEIVED APRIL 1, 1957

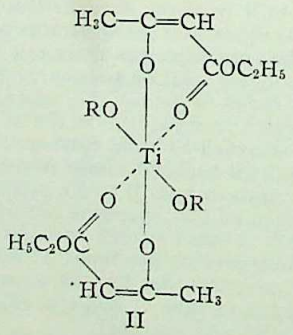
The structures of the reaction products of a series of tetraalkoxytitaniums with acetylacetone and ethyl acetoacetate were studied by chemical and physical analysis of the isolated pure compounds. In contrast to the previously published paper, penta-coördinated titanium complexes (III and IV) with three alkoxy groups and one bidentate chelating group were obtained when equimolecular proportions of these chelating agents and tetraalkoxytitaniums were used. When two moles of the chelating agents were used per mole of tetraalkoxytitaniums, hexa-coördinated titanium complexes (V and VI) with two alkoxy and two chelating groups were formed. The compounds obtained were found to be present as monomers in dilute benzene solutions. Hydrolysis of dialkoxy-titanium-bis-(acetylacetonate) (V) gave a new type of titanium complex, $[TiO-(CH_3COCHCOCH_3)_2]_2$.

Introduction

Schmidt[1] has studied the reactions of tetraalkoxytitanium (tetraalkyl orthotitanate) with bidentate chelating agents such as diacetone alcohol, acetylacetone and ethyl acetoacetate with the aim of obtaining stable titanic esters. He has proposed the hexa-coördinated structure I for the reaction product of one mole of tetraalkoxytitanium with one mole of acetylacetone and structure II for the product of one mole of tetraalkoxytitanium with two moles of ethyl acetoacetate.



I



II

A similar study has been carried out cryoscopically by Reeves and Mazzeno,[2] recently. They have measured the freezing points of *t*-butyl alcohol solutions containing tetra-*t*-butoxytitanium (tetra-*t*-butyl titanate) and ethyl acetoacetate in various ratios and obtained evidence that tetra-*t*-butoxytitanium reacts with ethyl acetoacetate with the formation of 1:1 and 1:2 compounds.

The reaction products have been neither isolated as pure compounds nor analyzed in these two studies. The purpose of the present work was to determine the structures of the reaction products of a series of tetraalkoxytitaniums with bidentate ligands and also to study the physical and chemical properties of the titanium compounds having both alkoxy groups and chelate rings.

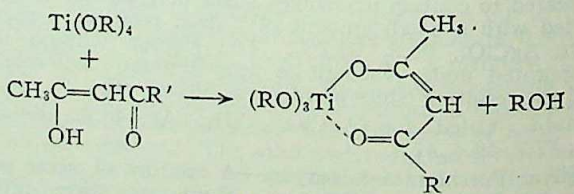
Results and Discussions

(a) **Reaction of Tetraalkoxytitaniums with Acetylacetone and Ethyl Acetoacetate in a Molar Ratio 1:1.**—When one mole of acetylacetone was mixed with one mole of tetraalkoxytitaniums (tetraethoxy-, tetrapropoxy- and tetrabutoxy-titanium), crystalline or liquid complex products and one mole of alcohols (ethyl, propyl and butyl alcohol) were obtained. Physical constants and analytical data of the complexes obtained are summarized in Table I (nos. 1, 3 and 5.)

The results of the chemical analyses of the compounds formed lead to structure III, which is considered to be formed by an exchange reaction of an alkoxy group of each tetraalkoxytitanium with bidentate ligand.



III, $R' = CH_3$
IV, $R' = OC_2H_5$
$R = C_2H_5$, n-C_3H_7, n-C_4H_9.

A similar experiment on the reaction of tetraalkoxytitanium with ethyl acetoacetate indicated the formation of one mole of trialkoxy-titanium-(ethyl acetoacetate) (IV) (nos. 2, 4 and 6 in Table I) and one mole of alcohols.

These results disagree with Schmidt's proposal for the hexa-coördinated structure I with four alkoxy groups and one chelating group in keto-form bound to central titanium. In order to confirm the structures III and IV, infrared absorption spec-

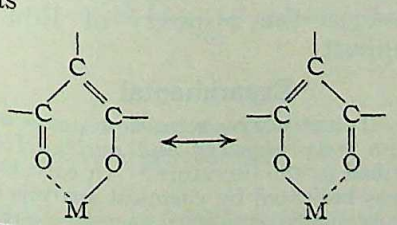
[a] See references, Table I.

tra of the products were observed. The results are shown in Fig. 1.

The infrared absorption spectrum of tetrabutoxytitanium (Fig. 1-A) has strong absorption bands at 1080 and 1120 cm.$^{-1}$. Tributoxytitanium-(acetylacetonate) (III) (Fig. 1-B) also has two strong bands at exactly the same positions. The positions of these two peaks agree well with the positions of C–O stretching bands of aliphatic ethers at 1050 and 1150 cm.$^{-1}$. No band was found in the same range of the spectrum of the hydrolysis product of dialkoxy-titanium-bis-(acetylacetonate) (Fig. 1-D), which was prepared by hydrolysis of alkoxy groups of dialkoxytitanium-bis-(acetylacetonate) as is described later. These facts prove that the strong bands are due to C–O stretching vibrations of alkoxy groups bound to a titanium atom.

The spectrum of III (Fig. 1-B) indicates two strong bands at 1376 and 1577 cm.$^{-1}$ with nearly equal intensity and a strong band at 1523 cm.$^{-1}$. On the other hand, there is no band observed in the region of unperturbed carbonyl vibrations between 1700 and 1750 cm.$^{-1}$. These results agree well with the results of Lecomte[3] and Bellamy, *et al.*,[4] who have observed two strong bands of nearly equal intensity near 1560 cm.$^{-1}$ and between 1310 and 1410 cm.$^{-1}$ in the spectra of various metal chelate compounds of acetylacetone. They have assigned these bands to the assymmetric and symmetric vibrations of two CO links in the resonating structure as



(3) J. Lecomte, *Disc. Faraday Soc.*, **9**, 125 (1950).
(4) L. J. Bellamy and L. Beecher, *J. Chem. Soc.*, 4489 (1954).

The other strong band in the region between 1500 and 1534 cm.$^{-1}$ has been assigned by Lecomte to the vibration of perturbed C=C bonds of the enolic form.

The absorption spectrum of tributoxy-titanium-(ethyl acetoacetate) (IV) (Fig. 1-C) is similar to that of tributoxytitanium-(acetylacetonate) (III) (Fig. 1-B), except that the band at 1577 cm.$^{-1}$ of acetylacetone chelate is shifted to higher frequency, 1628 cm.$^{-1}$, in the spectrum of ethyl acetoacetate chelate. The shift is considered to indicate an influence of the substitution of the ethoxy group in place of the methyl group of acetylacetone. The electron-attracting tendency of the ethoxy group may interfere with the resonance.

Titanium exhibits an apparent coördination number of five in these complexes with three alkoxy groups and one bidentate ligand. However, there exist the alternative possibilities that the compounds may actually be di- or trititanium compounds having the favored coördination number of six. The values of molecular weight determined cryoscopically in benzene solutions are shown in Table III. The observed values roughly correspond to monomer in the molality range between 0.01 and 0.04 mole per 1000 g. of solvent and tend to increase with the solute concentration, suggesting that association might occur to some extent.

(b) Reaction of Tetraalkoxytitaniums with Acetylacetone and Ethyl Acetoacetate in a Molar Ratio 1:2.—In case of the reaction of the series of tetraalkoxytitaniums with acetylacetone or ethyl acetoacetate in a molar ratio 1:2, crystalline or liquid complex products and two moles of alcohols were formed. Physical constants and analytical data of the complexes formed are listed in Table II, and the molecular weights are summarized in Table III (nos. 1′ to 4′).

From these results, the reaction is considered to proceed according to the following equation in agreement with Schmidt's proposal, forming hexa-

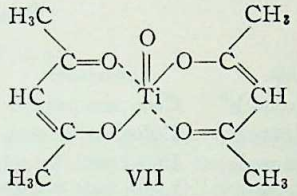
Infrared spectra of these compounds are essentially the same as those of trialkoxy chelate compounds, indicating the presence of alkoxy and chelating groups.

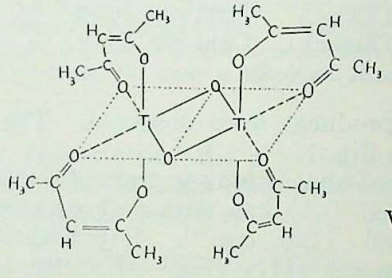
When more than two moles of the chelating agents were used per mole of tetraalkoxytitanium, the same compounds as structure V or VI were obtained. It seems, therefore, that no further substitution of the alkoxy groups with the chelating agents occurs under the condition employed.

Hydrolyses.—These complexes (III, IV and VI) with the alkoxy and the chelating groups, except dialkoxy-titanium-bis-(acetylacetonate)s (V), turn to gel-like substances, gradually in moist air and rapidly with the addition of water. The change may be ascribed to the hydrolysis of unstable alkoxy groups and subsequent condensation with the formation of polymeric substances with Ti–O–Ti bonds.

In the cases of diethoxy-, dipropoxy- and dibutoxy-titanium-bis-(acetylacetonate)s, on the other hand, pale yellow needles were produced by addition of water. The crystals were stable in the organic solvents from which the compound was recrystallized. When the solvents were removed, the crystals readily lost their crystalline form.[5] The infrared spectrum of the hydrolysis product of V, shown in Fig. 1-D, indicates the complete absence of the absorption bands due to alkoxy groups in the region between 1080 and 1150 cm.$^{-1}$. The other bands due to the chelate rings, near 1370, 1520 and 1570 cm.$^{-1}$, are essentially the same as the bands of dialkoxy-titanium-bis-(acetylacetonate) (V). This fact together with the results of the chemical analyses leads to the formula $Ti(CH_3COCHCOCH_3)_2$. Two structures can be considered for this formula, namely, (a) titanyl structure VII and (b) cyclic polymer structure, in which titanium achieves a coördination number of six by the sharing of the oxygen atom between titanium atoms.



VII



VIII

Molecular weight determination in benzene solution gave a value of 490, suggesting the dimeric structure VIII, the theoretical value for the monomer being 262.

Photochemical Reaction.—The color of titanium acetylacetonates (III, V and VIII) in hermetically sealed glass cells turns to blue when irradiated with a high-pressure mercury lamp or with sunlight. The change in color occurs rapidly in the absence of air, and the development of the blue color is retarded by the air in the cell. When the compounds are exposed to the open air, the blue color disappears rapidly. The blue color could be due to trivalent titanium which is produced by the fission of the Ti–O bond with the action of light. The trivalent titanium thus formed would be oxidized to quadrivalent titanium by oxygen when exposed to the open air. The further investigation of the photochemical reaction will clarify the detailed mechanisms of this reaction.

Acknowledgment.—The authors would like to express their sincere thanks to Professor K. Kojima for the infrared spectra and to Professor Y. Inamura for visible and ultraviolet spectra, and to Mr. Y. Takahashi for his assistance. The authors are indebted to the Ministry of Education for financial support.

Experimental

Materials.—Tetraethoxy-, tetra-*n*-propoxy- and tetra-*n*-butoxytitanium were prepared and purified following the method described in the literature.[6] In each case satisfactory purity was indicated by chemical analysis of the compound. Commercially available acetylacetone and ethyl acetoacetate were purified by fractional distillation and the

(5) Similar behavior has been observed by Jones, Pfeiffer and Werner in cases of vanadyl and platinum complexes with acetylacetone and salicylaldehyde diimine; M. M. Jones, THIS JOURNAL, 76, 5975 (1954); Pfeiffer, *et al.*, *J. prakt. Chem. N. F.*, 149, 217 (1937); A. Werner, *et al.*, *Ber.*, 34, 2584 (1901).

acetoacetate. Reaction took place with the evolution of heat and ended within several minutes. The reaction mixture was fractionated under reduced pressure. The volatile liquid distillates were shown to be alcohols by measurements of the refractive indices and boiling points. The quantity of alcohol was 0.010 mole. An equivalent amount (0.010 mole) of compounds III or IV remained as the residue. When the products were solid (see Table I), they were purified using diethyl ether or petroleum ether as solvent. The liquid products were distilled at 10^{-4} mm. with a pot-still or "falling-film" type molecular still, maintaining the temperature under 70° to prevent heat decomposition. These products are soluble in most organic solvents.

(b) **Reaction of Tetraalkoxytitaniums with Acetylacetone and Ethyl Acetoacetate in a Molar Ratio 1:2.**—To 0.010 mole of each tetraalkoxytitanium was added 0.020 mole of acetylacetone or ethyl acetoacetate. Reaction took place with the evolution of heat and ended within several minutes. From the reaction mixtures, 0.020 mole of alcohols were removed under reduced pressure. The theoretical amount (0.010 mole) of compounds V or VI remained as the residue. When the products were solid (see Table II), they were purified using diethyl ether or petroleum ether as solvents. The liquid products were distilled with the molecular still. These compounds are soluble in most organic solvents.

Molecular Refraction.—*MR* values for $(PrO)_2Ti(acac)_2$, $(PrO)_2Ti(etac)_2$, $(BuO)_2Ti(acac)_2$ and $(BuO)_2Ti(etac)_2$ were 103.8, 116.6, 113.4 and 125.9, respectively. Since there are no atomic refraction data for hexa-coördinated titanium in the literature, calculation of the molecular refractions was impossible. Instead, the atomic refraction was calculated from observed molecular refractions, and the values of 19.9, 20.1, 20.2 and 20.2, respectively, were obtained for hexa-coördinated titanium from these four *MR* values.

Hydrolyses of the Compounds and Isolation of VIII.—The compounds III, IV and VI were hydrolyzed readily by moisture. Gel-like substances were formed after standing several hours in moist air or instantly by addition of water. In case of dialkoxytitanium-bis-(acetylacetonate)s (V), addition of water gave light-yellow needles. To 1.62 g. of $(BuO)_2Ti(acac)_2$ was added 5 ml. of water. The crystals obtained were filtered and dried to give 0.74 g. of pale-yellow amorphous powder. The powder was recrystallized from chloroform or benzene solution, and again light yellow crystals were obtained. The crystals (plate form) were stable in chloroform or benzene solutions, but they lost their crystalline form and turned to a light yellow amorphous substance, gradually in air and rapidly in a vacuum desiccator. The color gradually turned to brown over 200° and the compound decomposed to a dark-red liquid at 235°.

Anal. Calcd. for $TiC_{10}H_{14}O_5$: Ti, 18.3; C, 45.9; H, 5.38. Found: Ti, 18.2; C, 45.6; H, 5.57.

Hydrolyses of dipropoxy- and diethoxy-titanium-bis-(acetylacetonate) were carried out analogously with the butoxy-compound, and the products obtained were confirmed to be identical with the hydrolysis product of the dibutoxy-compound by chemical analyses.

The aqueous solution of VIII gave transparent gel-like substance after standing several days at room temperature. When heated over 40°, the solution decomposed to an opalescent substance.

Molecular Weight Determinations.—Molecular weights were measured cryoscopically in completely dried benzene. The measurements were carried out in a shielded cryoscopic cell with an electromagnetic stirring device after exclusion of air with a stream of dry nitrogen. Freezing points of benzene solutions of some compounds showed a tendency to decrease with time.

Measurements of Absorption Spectra in the Visible and Ultraviolet Regions.—Ultraviolet absorption measurements were made with a Beckman DU spectrophotometer using 1.0-cm. silica cells. The absorption spectra of III and V measured in appropriate alcohols showed similar curves having a maximum at 325 mμ (log ε 3.5). The absorption spectrum of irradiated $(BuO)_2Ti(acac)_2$ in the visible region was measured in *n*-hexane and showed a maximum at 600 mμ and a shoulder near 650 mμ.

The infrared absorption measurements were carried out with a Perkin–Elmer recording spectrophotometer model 112. Liquid samples were measured in thin films and the solid sample was measured using Nujol.

The Kinetics of Aromatic Hydrocarbon Chlorination in Acetic Acid. The Use of Zinc Chloride as a Catalyst and of Iodobenzene Dichloride as a Halogen Source

BY R. M. KEEFER AND L. J. ANDREWS

RECEIVED FEBRUARY 4, 1957

In acetic acid methylbenzenes undergo chlorination by a reaction which is first order in halogen. The reactions are not inhibited by hydrogen chloride and are subject to relatively mild catalysis by zinc chloride. Bromination and iodination reactions in this solvent are of higher order than first in halogen in the absence of catalyst. The reactions are accelerated by zinc chloride and in some cases are complicated by trihalide formation. These differences may be explained in part through consideration of the relative stabilities of trihalide ions in acetic acid and of the role of acetic acid in the substitution reaction. Polymethylbenzenes chlorinate too rapidly in acetic acid for kinetic measurement. To investigate possible steric complications in the reactions of these hydrocarbons, iodobenzene dichloride has been tested as a potentially less reactive chlorinating agent than the free halogens. In this sense it has proved to be unsuitable. It dissociates slowly and comes to equilibrium with its components in dilute solutions in acetic acid. Its rate of reaction with mesitylene and pentamethylbenzene in acetic acid is identical with its rate of dissociation.

The investigation of the relative susceptibilities of a series of polymethylbenzenes to nuclear halogenation with bromine and with iodine monochloride in acetic acid has been simplified by the use of zinc chloride as a catalyst.[1,2] In the presence of this salt the orders of reactions with respect to these halogens reduce to unity and the kinetic complication of trihalide formation[2] is eliminated. In addition, by varying the catalyst concentration, relative halogenation rates for hydrocarbons of widely different reactivities can be established without changing the halogenating agent. With these observations in mind the effects of zinc chloride on the kinetics of chlorination of various methylbenzenes in acetic acid have been studied, and the results are presented in this paper.

One of the original objectives of this investigation was to determine whether the methyl group steric effect, which so markedly influences the susceptibility of polymethylbenzenes to bromination or iodination,[1,2] is less apparent in chlorination reactions. However, the higher molecular weight hydrocarbons, even in the absence of catalyst, react

too rapidly with chlorine for kinetic measurement. The possibility, therefore, has been considered that iodobenzene dichloride might serve as a less reactive chlorinating agent for use in a comparative rate study of the more reactive hydrocarbons. Although in this sense iodobenzene dichloride has proved to be an unsuitable reagent in acetic acid, the results of kinetic investigations concerning its function in aromatic chlorination are sufficiently interesting that they are included in this report.

Experimental

Materials.—The procedures used in preparing pure acetic acid, the aromatic hydrocarbons and dry zinc chloride have been described previously.[3,4] Eastman Organic Chemicals cyclohexene and iodobenzene were used without further treatment except for distillation of the latter.

Solutions of chlorine in acetic acid were prepared by passing cylinder gas (Ohio Chemical) directly into the solvent. Halogen analyses of the solutions were made iodometrically. In determining the extinction coefficients of chlorine solutions, the spectrum measurements were made first, and samples for iodometric analysis were then removed by pipet directly from the ground glass stoppered absorption cells to avoid volatility losses. Solutions of hydrogen chloride in acetic acid were prepared and analyzed as described elsewhere.[2]

Iodobenzene dichloride was made in small lots which were used immediately. The standard synthetic method[5] was used with the substitution of carbon tetrachloride for chloroform as the solvent. Iodometric analyses of weighed samples of the fresh product in acetic acid solution were generally within 1% of the theoretical value.

The Spectrum of Chlorine in Acetic Acid and in Solutions Containing Hydrogen Chloride and Zinc Chloride.—Contrary to what was found for solutions of hydrogen bromide and bromine[1] and of hydrogen chloride and iodine monochloride[2] in acetic acid, the ultraviolet spectra (Table I) of solutions of hydrogen chloride and chlorine in acetic acid do not offer positive evidence of the formation of trihalide ion (or HCl_3). The spectrum of a chlorine solution containing zinc chloride, at a concentration typical of that used in the rate runs, and hydrogen chloride is included in Table I.

TABLE I

THE EFFECT OF HYDROGEN CHLORIDE AND ZINC CHLORIDE ON THE SPECTRUM OF CHLORINE IN ACETIC ACID[a]

300	40.4	42.2	44.0
310	61.6	62.6	64.8
320	74.6	75.6	77.7
330	76.0	76.6	77.9
340	66.5	66.5	68.7
350	50.5	51.0	53.2
360	34.5	35.3	37.2
380	12.9	13.9	15.3

[a] The ε values are the molecular extinction coefficients of chlorine.

It is apparent that the salt also has no marked effect on the halogen spectrum.

The Rates of Chlorinations of the Hydrocarbons.—A single batch of purified acetic acid was used in carrying out the kinetic experiments. Stock solutions of the hydrocarbons and of zinc chloride in acetic acid were prepared from weighed samples of the reagents. Known volumes of these and of stock solutions of chlorine and hydrogen chloride were mixed at the temperature of the rate measurement. Samples of these mixtures, in silica absorption cells (10 cm., 2 cm. or 1 cm., depending on the initial concentration of chlorine), were placed in the housing of the Beckman spectrophotometer. Details concerning temperature control are given elsewhere.[2]

The changes in chlorine concentration were followed, generally to more than 75% of completion, by measuring optical densities of the rate samples (against an acetic acid blank) at a fixed wave length in the 340–370 mμ region. The wave lengths were chosen to provide initial readings, somewhere between 1.0–0.4. The data were, in certain cases, corrected for slight absorption by zinc chloride in the solutions.

The optical densities of dilute solutions of chlorine in acetic acid were observed to change negligibly during the time interval of even the longest rate runs. In other words errors resulting from the volatilization of chlorine were negligible.

The Dissociation of Iodobenzene Dichloride in Acetic Acid.—Qualitative experiments showed that the absorption in the near ultraviolet region of freshly prepared solutions of iodobenzene and chlorine in acetic acid were found to increase slowly with time. These changes were attributed to slow equilibration between iodobenzene dichloride and its components in acetic acid. It was found that the spectrum of an acetic acid solution which was 5.55×10^{-4} M in iodobenzene dichloride and 0.0989 M in iodobenzene did not change with time. The increases in absorption of solutions of chlorine and iodobenzene occurred more rapidly as the iodobenzene concentrations of the media were raised.

The optical density readings at equilibrium for two solutions, initially 2.39×10^{-3} M in chlorine and 0.164 and 0.0164 M in iodobenzene, were (after correction for the absorption of iodobenzene) nearly the same. It was assumed, therefore, that in acetic acid solutions in which the free iodobenzene concentration is of the order of 0.1 M, the conversion of chlorine to dichloride is essentially complete.

Extinction coefficients for iodobenzene dichloride over a short wave length range were calculated from equilibrium optical density readings of two of the solutions described above. These are recorded in Table II. Details of further experiments to determine the forward and reverse rate constants for dissociation of iodobenzene dichloride are included with the results.

TABLE II

THE SPECTRUM OF IODOBENZENE DICHLORIDE IN ACETIC ACID[a]

λ, mμ	350	360	370	380	390
ε of soln. I[b]	309	233	147	85.6	...
ε of soln. II[c]	312	224	144	86.0	45.6

[a] Based on optical densities after attainment of equilibrium. The optical densities were corrected for iodobenzene absorption. [b] Soln. I was originally 5.55×10^{-4} M in $C_6H_5ICl_2$ and 0.0989 M in C_6H_5I. [c] Soln. II was originally 2.39×10^{-3} M in Cl_2 and 0.164 M in C_6H_5I.

The Kinetics of Reaction of Iodobenzene Dichloride with Mesitylene and Pentamethylbenzene.—All rate measurements were carried out spectrophotometrically using 1-cm. absorption cells and an acetic acid blank. The changes in optical density with time recorded during a run were corrected for any small absorption which was observed at infinite reaction time.

Several hours prior to starting rate runs, a stock acetic acid solution of chlorine containing more than an equivalent amount of iodobenzene was prepared. The rate samples were prepared by mixing known volumes of this solution with known volumes of solutions of the hydrocarbon and, in some cases, of iodobenzene. A single batch of purified acetic acid was used in studying both kinetics of dissociation of iodobenzene dichloride and of chlorinations with iodobenzene dichloride.

The Product of Reaction of Pentamethylbenzene with Iodobenzene Dichloride in Acetic Acid.—To a freshly prepared solution of 0.65 g. (0.0024 mole) of iodobenzene dichloride in 80 ml. of acetic acid was added 0.300 g. (0.00202 mole) of pentamethylbenzene. This solution was allowed to

stand in the dark overnight. It was then poured into 250 ml. of water. The slightly gummy precipitated solid, after washing with water and air drying, weighed 0.250 g. This material was recrystallized from ethanol to provide 90 mg. of fine white crystals of m.p. 153–155° (reported[6] m.p. for 6-chloro-1,2,3,4,5-pentamethylbenzene, 155°). The yield, based on crude product, was 67%. The purified product gave no precipitate when it was boiled with alcoholic silver nitrate.

Results

Zinc Chloride Catalyzed Chlorination.—The results of earlier investigations indicate that chlorination of methylbenzenes in acetic acid leads to high yields of nuclear substituted products[7] by processes which appear, on the basis of rather limited experimental detail, to be first order in hydrocarbon and in halogen.[8–10]

To assess the effects of zinc chloride on the chlorination rates of several methylbenzenes a more detailed investigation of the kinetics of the uncatalyzed reactions has now been conducted. In agreement with de la Mare and Robertson[9] these new data have been found to conform to the rate law

$$-d(Cl_2)/dt = k(ArH)(Cl_2) \qquad (1)$$

Retardation of the reactions through the accumulation of hydrogen chloride in the medium has not been encountered with any of the hydrocarbons under investigation, and this observation is in accord with the negative spectrophotometric evidence (see Experimental section) for interaction between hydrogen chloride and chlorine in acetic acid solution. Actually for several runs with *p*-xylene in which excesses of hydrogen chloride (as compared to chlorine) were added to the reaction mixtures, a slight enhancement in rates was observed, as was reported previously by de la Mare and Robertson.[9] For those runs in which the initial *p*-xylene to chlorine ratio was large the initial phase of the reaction was abnormally fast, probably because of a trace of *m*-xylene impurity in the hydrocarbon sample.

Table III summarizes the results of the runs, both at 25.2 and 45.3°, on the several hydrocarbons under investigation. Where the variation in hydrocarbon concentration was small, values of k(ArH) were calculated from the slopes of plots of logarithms of the measured optical densities (see Experimental section) *vs.* time. In general the fit of the data to linear plots was excellent except as noted for *p*-xylene. For the few runs in which the hydrocarbon concentration dropped appreciably as reaction occurred, k values were evaluated graphically by the usual procedure for bimolecular reactions.[11]

(9) P. B. D. de la Mare and P. W. Robertson, *J. Chem. Soc.*, 279 (1943).

(10) Chlorinations of phenolic ethers and of anilides in acetic acid have been shown to be second order over-all; see, for example, A. E. Bradfield and B. Jones, *J. Chem. Soc.*, 3073 (1928); B. Jones, *ibid.*, 418, 676 (1942).

(11) The relative values found for k at 25.2° for toluene, *p*-xylene and *o*-xylene are in the ratio 1/6.7/10. These values compare favorably with those (1/6.3/13.4) calculated from the times of 20% reaction at 24° in 99% acetic acid reported by de la Mare and Robertson[9] for reaction mixtures containing equal concentrations of chlorine and hydrocarbon. The rate constants at 25.2° reported in Table III for toluene, and the xylenes are about 1.3 times as large as those which can be estimated from the results reported by de la Mare and Robertson for 24°.

.097	7.7	4.3	0.00188	1.78	4640
.049	7.7	3.9	0.00188	0.90	3740

[a] Average of two runs of which values of 10^3k were 0.73 and 0.745. [b] Temperature for this run was 45.3°. [c] Average of two runs of which values of 10^3k were 335 and 341. [d] Average of two runs of which values of 10^3k were 4.5 and 4.5. [e] The initial concentration of HCl in the reaction mixture was 0.0112 *M*. [f] The initial concentration of HCl in the reaction mixture was 0.112 *M*.

As zinc chloride is added to the reaction medium, an acceleration of the aromatic hydrocarbon chlorination rate is observed. Equation 2 has been used in interpreting rate runs in the presence of this salt.

$$-d(Cl_2)/dt = k'(ArH)(Cl_2) = [k + k_c(ZnCl_2)][(ArH)(Cl_2)] \qquad (2)$$

Rate constants, k', have been determined for individual runs in the same way as were the constants, k, for the uncatalyzed reaction. These values and the k_c values for the third-order catalytic reactions at 25.2 and 45.3° of the several aromatic hydrocarbons which have been investigated are given in Table IV. Average values of k from Table III have been used in calculating the k_c values.

From the results reported in Tables III and IV it is clear that there are several marked differences in the kinetics of reaction of aromatic hydrocarbons with chlorine and with bromine or iodine monochloride in acetic acid. In discussing these differences the generalized mechanism for aromatic halogenation[1,2,12,13] in solvents of low polarity, which is given in equations 3–5, is useful.

$$ArH + X_2 \rightleftharpoons ArH\cdot X_2 \qquad (3)$$

$$ArH\cdot X_2 + E \longrightarrow ArH\cdot X^+ + EX^- \qquad (4)$$

$$ArHX^+ \longrightarrow ArX + H^+ \qquad (5)$$

Equation 4, in which the halogen–halogen bond of an aromatic–halogen π-complex is severed by attack of an electrophilic reagent, E, represents the rate-determining step.

In the absence of a catalyst the solvent alone may function as the reagent E, in which case the reaction should show first-order dependence on halogen. The reactions of toluene and *p*-xylene with iodine monochloride in trifluoroacetic acid behave kineti-

cally in this way.[14] In acetic acid the uncatalyzed iodination reactions are second order in iodine monochloride,[2] and bromination reactions are second order in halogen, although a small contribution from a first-order process may be detected at low bromine concentrations.[12] Apparently in these cases a second halogen molecule serves as the electrophilic reagent. The superiority of trifluoroacetic acid as compared to acetic acid in promoting halogenation by the first-order process has been ascribed to the importance of proton sharing by the solvent when it participates in the abstraction of halide ion from the complex in the rate determining step.[14]

[a] Average of two runs of which values of $10^3 k'$ were 3.52 and 3.61. [b] Temperature for this run was 45.3°. [c] The initial concentration of HCl in the reaction mixture was 0.112 *M*. [d] The k_c value for durene is not reported since the k value required for its calculation is somewhat uncertain (see Table III). The error resulting from this uncertainty might have been minimized were not durene too reactive to permit the determination of k' values at zinc chloride concentrations higher than 0.1 *M*.

In chlorination reactions in acetic acid the solvent again appears to serve satisfactorily as the reagent E. The likelihood that a second molecule of chlorine should fill this role seems minimal since, unlike iodine monochloride, chlorine shows no tendency to coördinate with chloride ion in acetic acid. Actually the rate of first-order bromination of mesitylene in acetic acid is relatively slow,[12] but the hydrocarbon chlorinates virtually instantaneously in this medium even at low (0.01 *M* or less) initial reactant concentrations.

The rate superiority of chlorine over bromine and iodine monochloride in the first order (in halogen) substitution reactions may be explained in part by consideration of the solvation energies of the halogens. Acetic acid functions as a donor in interacting with iodine monochloride and with bromine.[15] The extent of this interaction is smaller for bromine than for iodine monochloride and must be even smaller[16] in solutions of chlorine in acetic acid, and the solvation energies for the halogens probably fall off in this same order.[2] In forming a complex with the aromatic hydrocarbon (equation 3) the halogen must undergo some desolvation, and the desolvation energy must make a direct contribution (smaller for chlorine than for the heavier halogens) to the activation energy of the substitution reaction.

It appears, furthermore, that acetic acid is considerably more effective in the transition state of the chlorination reaction as a solvating agent for halide ion which is separating from the aromatic–halogen complex than it is in bromination and iodination reactions. Zinc chloride has a relatively small influence on the kinetics of hydrocarbon chlorination. At concentration levels of zinc chloride at which bromination and iodination reactions are first order with respect to the two reactants and to the catalyst,[1,2] a significant fraction of the chlorination reaction still appears to take place by a catalyst-independent process. Whereas the ratio of k_c/k values for the chlorination reactions studied in this investigation range from 23 for benzene to 8 for *m*-xylene, the corresponding ratio of rate constants[1,4] for mesitylene bromination by reactions which are first order in halogen is of the order of magnitude of 3×10^5.

A comparison of the activation energies for the halogenation reactions also indicates that the influence of zinc chloride is small in chlorinations. For mesitylene bromination the activation energy for the first-order (in bromine) uncatalyzed reaction[4] is 15 kcal./mole and that for the reaction in the presence of zinc chloride[1] is only 7 kcal./mole. Activation energies for the zinc chloride catalyzed iodination reaction of several aromatic hydrocarbons[2] range around 17 kcal./mole, and those for uncatalyzed first-order reactions in iodine monochloride, if measurable, would probably be much higher. The corresponding activation energies for the uncatalyzed and catalyzed chlorination of toluene (calculated from the k and k_c values at 25.2 and 45.3° given in Tables III and IV) are both 13.4 kcal./mole. In view of the identity of these two experimental values, one is inclined to wonder whether the favorable influence of zinc chloride on the chlorination rate might better be classified as a salt effect rather than as true catalysis. It is evident from previous studies of the influences of zinc chloride on the rates of hydrocarbon bromination and iodination reactions that catalytic and environmental effects of this salt cannot be measured separately.

The Relative Halogenation Rates of the Methylbenzenes.—As noted in the introduction, the results of the earlier investigations of the kinetics of zinc chloride catalyzed halogenations indicate that the reactions of highly methylated benzenes are subject to marked steric retardation.[1,2] The steric problem seems to be much more pronounced in iodination than in bromination reactions. Presumably the attack of chlorine on the aromatic nucleus should be less subject to hindrance than that of the larger halogens. The present results provide limited information on this point.

Partial rate factors for halogenation at positions *ortho*, *meta* and *para* to methyl groups relative to that at one position in benzene[17] have been calculated from the chlorination rate constants at 25.2° for benzene, toluene and *o*- and *p*-xylene. For the uncatalyzed reaction they are $o_f = 95$, $m_f = 7.9$ and $p_f = 304$; and for the catalyzed reaction they are $o_f = 130$, $m_f = 6.4$ and $p_f = 235$. These values for the catalyzed reaction may be used to predict a reactivity ratio of 1.3×10^4 for *m*-xylene and benzene as compared with an experimental value of 1.7×10^4. The partial rate factors for the uncatalyzed reaction lead to predicted *m*-xylene/benzene and durene/benzene rate ratios of 1.1×10^4 and 1.9×10^5, respectively. The experimental values are 4.8×10^4 and 5.7×10^5, respectively. In situations in which extreme steric hindrance to halogenation appears to exist, observed polymethylbenzene reactivities are considerably less than those predicted from the partial rate factors.[1,2] In other words, the available data suggest that methylbenzene chlorinations are not unusually sensitive to the methyl group steric effect.

Reactions with Iodobenzene Dichloride.—An attempt has been made to determine the rate constant, k, for chlorination of the higher molecular weight methylbenzenes through inclusion of iodobenzene in the reaction mixtures. If an equilibrium were established rapidly and reversibly with respect to formation of iodobenzene dichloride, one might, by adjustment of the iodobenzene concentration, lower the concentration of free chlorine sufficiently to permit rate measurements on the more reactive hydrocarbons.

Investigation has shown, however, that while an equilibrium is indeed established between iodobenzene dichloride and its components in acetic acid solution, the equilibration process is relatively slow. When mesitylene or pentamethylbenzene are chlorinated in solutions containing iodobenzene, the chlorination rate is independent of the aromatic hydrocarbon and iodobenzene concentrations and is controlled by the rate of decomposition of iodobenzene dichloride into its components (see equations 6 and 7).

$$C_6H_5ICl_2 \underset{k_2}{\overset{k_1}{\rightleftharpoons}} C_6H_5I + Cl_2$$

$$k_1/k_2 = K = \frac{(C_6H_5I)(Cl_2)}{(C_6H_5ICl_2)} \qquad (6)$$

$$ArH + Cl_2 \xrightarrow{k_3} ArCl + HCl \qquad (7)$$

In other words, for the reactions of pentamethylbenzene and mesitylene the condition that $k_3(ArH) >> k_2(C_6H_5I)$ must hold.

In Table V rate constants k_1 for the reactions of these two hydrocarbons with iodobenzene in acetic acid are summarized. These were calculated on the assumption that the rate law for chlorination is

$$-d(ArH)/dt = -d(C_6H_5ICl_2)/dt = k_1(C_6H_5ICl_2) \qquad (8)$$

Cyclohexene				.0100	2.77	2.97	0.206
0.102	18.8	18.8	0.232[a]				

[a] Crystalline $C_6H_5ICl_2$ was used in preparing rate samples. [b] Temperature for these two runs was 45.6°. Rate constants for these two runs and for the runs just above them in the table were used in calculating the reported activation energy. These runs were all made on the same day using the same batches of stock solutions.

As the disappearance of iodobenzene dichloride was followed spectrophotometrically (see Experimental section), k_1 values for each run were actually determined from the slopes of linear plots of the logarithms of measured optical densities *versus* time. The reactions were in general followed to at least 74% completion.

In most cases the initial iodobenzene dichloride concentrations of the reaction mixtures were established through dilution of relatively concentrated solutions of iodobenzene and chlorine in acetic acid, which had been prepared sufficiently well in advance so that the chlorine was largely converted to the dichloride. When solid iodobenzene dichloride itself was used as the dihalide source, the rate samples were made up using freshly prepared solutions of the solid in acetic acid. In all reported runs, therefore, the initial iodobenzene dichloride concentrations are approximated by the values of $(Cl_2)_i$ given in Table V. It may be assumed that any free chlorine initially present in the reaction mixtures disappeared immediately by reaction with the aromatic hydrocarbon.

The rate constants for runs of widely varying concentrations of the various reactants are all of the order of magnitude of 0.2×10^{-3} sec.$^{-1}$ at 25.2° for both pentamethylbenzene and mesitylene and are in close agreement with the rate constant measured for one run in which the aromatic hydrocarbon was replaced by cyclohexene, a substance which consumes free chlorine rapidly.

The constant k_1 was evaluated independently by studying the rate of equilibration of iodobenzene dichloride with its components in acetic acid. Solutions of the solid dichloride in acetic acid were prepared and standardized iodometrically. The changes in optical density of these solutions at an

appropriate wave length in the 340–380 mμ region were followed to the time of equilibration. The concentrations of free chlorine and of iodobenzene dichloride throughout the runs were calculated from measured optical densities using the extinction coefficients given in Tables I and II.

The equilibrium constants, $K = k_1/k_2$, for each run were calculated from equilibrium readings. The individual rate constants for the forward and reverse reaction are also related by differential equation 9.

$$-d(C_6H_5ICl_2)/dt = k_1(C_6H_5ICl_2) - k_2(C_6H_5I)(Cl_2) \quad (9)$$

A useful integrated form of equation 9 is given in equation 10, in which $a = (C_6H_5ICl_2)_i$, $b = -2(C_6H_5ICl_2)_i - K$ and $A = (C_6H_5ICl_2)$. The

$$\ln \frac{2A + b - \sqrt{b^2 - 4a}}{2A + b + \sqrt{b^2 - 4a}} - \ln \frac{2a + b - \sqrt{b^2 - 4a}}{2a + b + \sqrt{b^2 - 4a}} = k_2 t \sqrt{b^2 - 4a} \quad (10)$$

constants k_2 were determined from the slopes of the linear plots of the left-hand term of equation 10 *vs.* time. The results of these runs are summarized in Table VI, in which the values of k_1 and K for the several runs at 25.2 and 45.6° are listed along with equilibrium values of the optical densities of the reaction mixtures.

Table VI

Rate Constants and Equilibrium Constants for the Decomposition of Iodobenzene Dichloride

1.37	360	.100	1.30	4.3	45.6

[a] Wave length at which runs were made; 1-cm. absorption cells and an acetic blank were used. [b] Value of $\Delta H^0 = 9.9$ kcal./mole is calculated from average K values at the two temperatures.

One run also was made at 25.2° in which the change in optical density at 380 mμ of an acetic acid solution originally 2.97×10^{-3} M in iodobenzene and 3.23×10^{-3} M in chlorine was followed to the equilibrium point. An equilibrium constant ($K = 2.0 \times 10^{-3}$ mole/l.), calculated from the equilibrium data for this run, compares favorably with an average value of 1.5×10^{-3} mole/l. for the runs reported in Table VI. Rate constants for this run were evaluated graphically according to equation 10 with, in this case, $a = (C_6H_5I)_i(Cl_2)_i$ and $b = -(C_6H_5I)_i - (Cl_2)_i - K$. The resultant k_1 value, 0.16×10^{-3} sec.$^{-1}$, was also in good agreement with the values listed in Table VI.

Although the values of k_1 reported in Table V are on the average somewhat higher than those in Table VI, the agreement is sufficiently good to support the proposed mechanism for the aromatic chlorinations by iodobenzene dichloride. It is particularly gratifying that the activation energy calculated from rate constants k_1 for the reaction of pentamethylbenzene with iodobenzene at 25.2 and 45.6° ($E_a = 20.1$ kcal./mole) is almost identical with that calculated from the averages of rate constants for the dissociation of iodobenzene dichloride which are given in Table VI ($E_a = 20.2$ kcal./mole.)

A few qualitative tests were made to determine the behavior of iodobenzene dichloride in non-polar solvents. Dilute solutions of the dihalide in benzene and in carbon tetrachloride showed no changes in spectra over a several-hour period, an indication that dissociation to form the component materials did not occur. Similarly the ultraviolet spectrum of a benzene solution of the dichloride which contained an excess of cyclohexene remained invariant for several hours, and then the dichloride suddenly disappeared completely from the solution.

The reaction which occurred may well have been radical induced. Certainly, further work on the function of the dihalide as a halogen source in non-polar media is required to rationalize the results of earlier investigators.[18–20]

Nature of Aliphatic C-Nitroso Compounds. I. Study of the Rate of Dissociation of the Aliphatic C-Nitroso Dimer in Various Solvents

By Joseph R. Schwartz

Received March 27, 1957

The rate of dissociation of two aliphatic nitroso dimers, $(CH_3)_2C(NO)CH_2R$, with R = CH_3 and R = OAc in a series of solvents at several temperatures is reported. From the activation parameters, it is concluded that the inductive effect is mainly responsible for rate trends and solvent effects observed.

Introduction

It has been known for some time that many aliphatic C-nitroso compounds exist in the solid state as dimers and, when dissolved in various solvents, dissociate into blue monomers at a measurable slow rate.[1,2] Crystal studies on the dimer show that the N–N distance is between the single- and

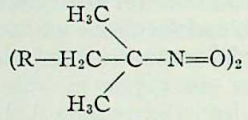
double-bonded values.[3] Recent spectral evidence on some substituted aromatic C-nitroso compounds has yielded information on the effect of substitution on the monomer–dimer equilibrium in the dissolved state and in the solid state. The ground and excited electronic states for both the monomer and dimer were identified from absorption spectra.[4]

It is of interest to determine more specifically the nature of the bonding forces in the dimer and to gain further insight into the rate of monomer formation. Reported herein is a preliminary investigation of these questions. The rate of monomer formation of the tertiary aliphatic nitroso compounds in a series of solvents of varying dielectric



I, R = CH_3COO-

II, R = H_3C-

constant and hydrogen bonding ability and at various temperatures has been measured.

Experimental

Preparations. I. 2-Methyl-2-nitroso-1-acetoxy-propane.—One hundred and seven grams of 2-methyl-2-nitro-1-propanol (Matheson, Coleman and Bell P1242), m.p. 93–95°, was added to 98 g. of acetic anhydride and the mixture was refluxed for 0.5 hr. One hundred and forty-eight grams of the acetate (81% yield, b.p. 125–127° (30 mm.)) was reduced with 130 g. of zinc dust added portionwise to the acetate in 500 ml. of water containing 200 g. of ammonium chloride. The reduction mixture was cooled, filtered free of solids and 93 g. of potassium dichromate in 200 ml. of 2 *N* sulfuric acid was added, whereupon oxidation of the hydroxylamine to the nitroso compound occurred,[5] as indicated by the presence of the blue color of the I monomer. The solution was extracted with two 250-ml. portions of ether. The ether layer was washed several times with water and dried over anhyd. sodium sulfate. The ether was removed with aspirator vacuum at room temperature. The nitroso acetate I was recrystallized twice from 60–90° boiling range petroleum ether: m.p. 67–69°. *Anal.* Calcd. for $C_6H_{11}NO_3$: C, 49.63; H, 7.64. Found: C, 49.32; H, 7.48. The absorption maximum at 674 mμ, $\epsilon(C_6H_6)$ = 13.9, of the monomer was used to follow the rate of dissociation, since the dimer does not absorb at this wave length.

II. 2-Ethyl-2-nitrosopropane.—*t*-Amylurea (Matheson, Coleman and Bell P5547) was hydrolyzed in diethylene glycol with sodium hydroxide,[6] and the *t*-amylamine so obtained was oxidized to the nitro compound following the directions of Kornblum and Clutter.[7] The nitro compound was reduced to the hydroxylamine and oxidized to the nitroso compound II, using the procedure described under the preparation of I above. Due to the great volatility of the nitroso compound, the ether solution extract of I was evaporated slowly at room temperature under a 20-plate column. A blue-white residue remained. This (approx. 1 g.) was taken up in 8 ml. of isopentane and cooled to −80°, whereupon a white solid precipitated out in a few seconds. This was filtered off and air-dried. Recrystallization from the same solvent yielded a material of m.p. 50.3–51.2°; Bamberger and Seligmann[1] report 50.0–50.5°. In no case was better than 10% yield obtained. Note: several attempts to prepare these aliphatic nitroso compounds in any recoverable yield by method of Bamberger and Seligmann[1] were unsuccessful for 2-methyl-2-nitrosopropane and 2-methyl-2-acetonyl-nitrosopropane (oxidation of the corresponding amine with Caro acid). The absorption maximum at 680 mμ, $\epsilon(C_6H_6)$ 20.4, of the monomer was used to follow the rate of dissociation since here, also, the dimer does not absorb at this wave length.

Measurement of the Dissociation Rate.—A Beckman DU model spectrophotometer was fitted with a special water-tight, pitch-lined compartment, having soft glass windows, so as to function as part of the instrument, and constant temperature water was circulated through this compartment. The temperature was maintained constant to within a variation of 0.01°. Samples of solvent of approximately 3 ml. each were placed in 3 test-tubes, tightly stoppered and allowed to thermally equilibrate. Approximately a 10-mg. sample of the finely powdered nitroso compound was added to the first test-tube, the tube then being stoppered, covered with a cloth to insulate thermally and shaken violently to dissolve the nitroso compound rapidly and transferred to a 1.00-cm. path length Corex cell already in the compartment and at thermal equilibrium. The cell was stoppered. The $t = 0$ for the dissociation was taken as 1 second after the solid was added to the tube, it having previously been determined that approximately this time was necessary for solution of the substance. In exactly the same manner, the other two cells were filled at exactly 1-minute intervals, with successively increasing sample sizes to furnish multiplicate determinations.

The reaction showed good first-order behavior, within experimental error. The reaction was followed for 2 half-lives or more, except where indicated in parentheses in the figures for the rate constants in Tables I and II. Attempts to follow the reaction in acetic acid were unsuccessful, because no clear first-order plot was obtained: the earlier part of the run was first-order, followed by a break in slope and a curving off from linearity. Redetermination of several of the rate constants on other occasions under the same conditions gave the reproducibility indicated in the table; k and the activation parameters were calculated from the data: k by the least squares method, ΔH^* by the Arrhenius plot of log k *vs.* $1/T$, and ΔS^* fron the Eyring absolute rate equation, using k at a given T and ΔH^*.

C_6H_6	23.5	17.2	C_6H_6	24.9	20.6

Discussion

It may be noted that there is definitely smaller entropy of activation for I in the polar solvents methanol and acetone, indicating that solvent is effectively associated with the bond about to break in the dissociation. Nitrobenzene seems to be particularly effective in assisting the bond to break in the case of II. It may be noted that the solvents have been ordered according to decreasing dielectric constant. No trend seems evident here. Figure 1 shows that for I, ΔH^* is a good linear function of ΔS^*, but this relationship shows a good deal of scatter for II. Figure 2 shows the plot of k_1 for I *vs.* k_1 for II at 25° in various solvents and indicates a fairly linear relationship, with slope = 0.270 ± 0.116 (95% confidence interval), for the straight line through the origin. The line was made to pass through the origin, since, if the Eyring equation is assumed to hold

$$k_1 = \frac{kT}{h} \exp(-\Delta F^*/RT), \text{ then}$$

$$k_1(\mathrm{I})/k_1(\mathrm{II}) = \exp(-\Delta\Delta F^*/RT)$$

which means that the k_1's are linear functions of one another at a given temperature and that the intercept is 0. On the basis of this line, r, the coefficient of correlation = 0.575, and $\Delta\Delta F^*$ was calculated from the mean slope to be 0.78 kcal./mole. Thus, in all the solvents studied, ΔF^* for I is greater by this amount than ΔF^* for II. This is taken to mean that less organized-energy is needed in the dimer to break the N–N bond in dissociating partially to the transition state and that this must be mainly related to the inductive pull of electrons in the acetoxy group, and perhaps it may be stated that this inductive pull contributes a definite amount of energy to the organized states (organized along the direction in which the bond breaks).

If there were any steric effects involving solvents, then some of the solvents might be expected to deviate from this line markedly. Since no strong deviation is observed, it suggests that no steric effects seem to enter the picture. Preliminary work is in

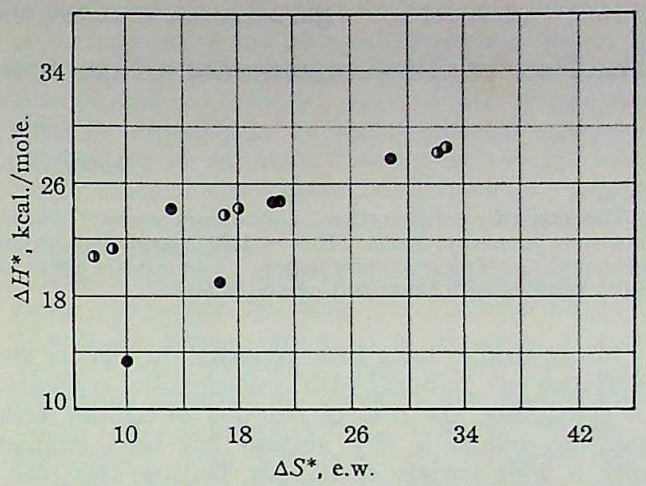

Fig. 1.—Correlation of ΔH^* and ΔS^*: ◐, I; ●, II.

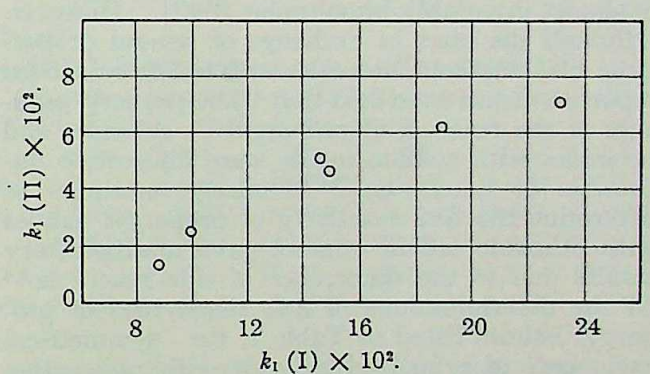

Fig. 2.—Correlation of k_1 of I with k_1 of II in various solvents, at 25.00°.

progress to determine the extent of this factor using R = *t*-butyl.

Nakamoto and Rundle[4] suggest that electron-donating groups stabilize the monomer of aromatic nitroso compounds through a resonance mechanism. In the two compounds studied here, only inductive effects are possible between the substituent and the reaction center and, since no equilibrium constants were determined, it can only be concluded that electronegative groups would make the unshared pair of electrons on the nitrogen atom less available for dimer formation, and hence there might be a contribution from this source to lower the activation energy for monomer formation. The fact that N–N–O compounds do not dimerize, however, is in keeping with these ideas, since nitrogen is quite strongly electronegative and probably would keep the unshared pair on the nitroso-nitrogen unavailable for dimer-bonding.

In a preliminary experiment the rate of dissociation of the pseudonitrole, $(CH_3)_2(NO)(NO_2)$, and nitrosobenzene in benzene were found to be too rapid to measure. This probably indicates that the N–N dimer bond is quite weak. It is a well known fact that negative substituents decrease the stability of these dimers. For example, $(CH_3)_2$-$CCl(NO)$[5] and $(CF_3)_2C(F)(NO)$[6] are both known only as the blue monomer.

The Rate of Quaternization of a Piperazine by Some Propargylic and Allylic Bromides[1]

BY M. HARFENIST

RECEIVED JANUARY 28, 1957

The rate of quaternization of a tertiary amine, 1-carbethoxy-4-methylpiperazine, with allyl bromide ($10k$ = 2.25 l./mole-min.), methyl iodide ($10k$ = 1.22), propargyl bromide ($10k$ = 0.892) and 1-bromo-2-heptyne ($10k$ = 3.50) was measured in acetone–water solution. The order of these rate constants is somewhat different from that reported for other SN2 reactions with these and related halides.

Many studies have been reported on relative reactivities of halides with nucleophilic reagents. In particular, the rate of reaction of halides with metallic iodides in dry acetone has been studied with a wide variety of halides, because this reaction is normally relatively free of side reactions and is almost invariably bimolecular (SN2). However, although the rates of exchange of several propargylic chlorides and bromides with iodide have been reported, it has been said that "The primary products of the reaction of propargyl. . . chlorides and bromides with sodium iodide were difficult or impossible to determine."[2] Similarly, attempts to determine the SN2 reactivity of propargyl halides with ethoxide ion in ethanol gave unsatisfactory results due to the occurrence of side reactions.[3,4] Of the determinations of SN2 reactivities of propargyl halides listed in Table I, the "symmetrical exchange" of propargyl chloride with radioactive chloride in acetone seems most likely to be free of side reactions.

TABLE I

RATES OF SOME BIMOLECULAR REACTIONS OF ALLYL AND PROPARGYL HALIDES

Halide	k, l./mole-min.
A. With inorganic iodide in acetone at 25°[a]	
$CH_2{=}CHCH_2Cl$	0.0111[2]

[a] Recalculated to 25° where indicated, using the formula: $\log \frac{k_2}{k_1} = 4000\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$ [J. B. Conant, W. R. Kirner and R. E. Hussey, THIS JOURNAL, 47, 488 (1925)]. [b] P. D. Bartlett and L. J. Rosen, *ibid.*, 64, 543 (1942). [c] M. J. Murray, *ibid.*, 60, 2662 (1938). [d] Multiplied by 2.303 since $\log_{10}$ appears to have been used.

The author had occasion to quaternize 1-carbethoxy-4-methylpiperazine with a variety of halides.[5] In the course of these syntheses it was observed that the rates of the reactions with the propargylic halides appeared to be in a somewhat different order from those anticipated from the previous work. Since substantially quantitative yields of pure quaternary salts were readily obtained from these reactions, it was felt that a more precise determination of the rate constants of some representative quaternizations would be of value. Rates were therefore determined for the reaction of 1-carbethoxy-4-methylpiperazine with propargyl bromide, allyl bromide, 1-bromo-2-heptyne and with methyl iodide. The last might serve as a reference halide to allow the data reported here to be used to anticipate results with other amines for which methyl iodide quaternization rates are known. The solvent used was a mixture of equal volumes of acetone and water ("50% acetone") which was found to dissolve the reactants and the products.

Experimental

Materials.—Allyl bromide (Matheson–Coleman and Bell), propargyl bromide (General Aniline and Film Corp.), and methyl iodide (R.S.A. Corp.) were distilled within one week of each use, retaining an arbitary center cut, and were stored in the dark.[6] The 1-bromo-2-heptyne[7a,b] made from hept-2-yne-1-ol (Farchan Research Laboratories) was redistilled *in vacuo* within two days of each use, since it darkened quite rapidly. This bromoheptyne gave 101% of the theoretical amount of halide after hydrolysis with excess of hot alcoholic sodium hydroxide. The 1-carbethoxy-4-methylpiperazine was an arbitrary center cut of material[8] with acceptable values for the boiling point, made from hydrochloride of proper m.p.

Method.—Rates were measured by adding an equimolar amount of the halide to a solution of the amine in "50% acetone"[9] contained in a glass-stoppered 250-ml. volumetric flask thermostated at 25 ± 0.15°. Approximately 12 millimoles of each reagent was normally taken, although only

5.66 millimoles of each component could be used in the reactions of 1-bromo-2-heptyne in "50% acetone," because of the low solubility of this halide. At measured intervals 10.0-ml. aliquots were pipetted from the reaction flasks into 20 ml. of 0.5 *N* aqueous nitric acid, treated with a slight excess of standard 0.1 *N* silver nitrate, 2 ml. of nitrobenzene was added, and the excess of Ag^+ was back-titrated with thiocyanate. Preliminary experiments proved that no detectable change in titer was found in aliquots titrated after 0.5 hour as compared with aliquots titrated immediately.[10]

The results of the titrations were converted to rate constants by plotting $X/A - X$ *vs.* t, where X was the amount of halide ion produced in t minutes, and A was the initial amount of alkyl halide and amine in moles/l. The slopes of the resulting straight lines were equal to Ak. The reactions were followed to 50–70% of completion. Five points were taken for each of the duplicate runs with the bromoheptyne in "50% acetone," and 8–11 points for each of the other runs. All constants reported were determined at least in duplicate.

The results of typical runs with the two acetylenic halides are given in Tables II and III.

of hydroxyl ion with allyl and propargyl chlorides in aqueous ethanol,[4] although the variation of the rate constant for the allyl chloride with concentration of base in Vernon's work makes precise comparison impossible. It was separately shown in preliminary experiments that the sum of the halide ion produced by solvolysis and by the Sn2 reaction with hydroxyl ion was too small to account for the results reported here.[13]

The increase in rate of quaternization in going from propargyl bromide to 1-bromo-2-heptyne (Table IV, lines 3 and 4) is in the same direction as the results reported (Table I, lines 3 and 5) for propargyl chloride *vs.* 1-chloro-2-butyne with iodide. The opposite order, however, would be anticipated from the propargyl bromide results (Table I, lines 4, 6 and 7). The increase in rate

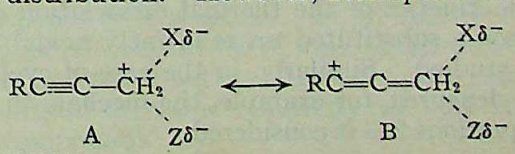
$C_4H_9C{\equiv}CCH_2Br$	"50% acetone"[9]	3.50 ± .02	2	2.86
$C_4H_9C{\equiv}CCH_2Br$	"75% acetone"[12]	1.59 ± .02	2	

The rate of quaternization is seen to be 2.5 times as fast for allyl bromide as for propargyl bromide. Comparison of this result with those summarized in Table I shows that our results are in opposite order to those found with the halide interchange reactions of either iodide or of radiochloride. However, the same order of reactivity appears to occur in the initial rate constants for the Sn2 reactions constant obtained for the iodide reaction on going from the 3-*n*-butyl- to the 3-*t*-butyl-substituted propargyl bromide (Table I, lines 6 and 7) shows an activating influence of additional alkyl groups, as would be expected from our results and from those based on the chlorides with iodide in acetone.

The high Sn2 reactivity of propargyl halides is not readily understood. It is commonly explained in terms of a contribution toward lowered energy of the transition state by a resonance form (illustrated for attack by nucleophile Z^-), by analogy with similar explanations for allylic systems (*cf.* ref. 4). Contribution of a resonance form resembling B to the structure of the propargyl halides has been used to explain the C–halogen distances determined by electron diffraction for those compounds.[14] An increased stabilization of B by electron feed-in when R = alkyl as compared to B when R = H might lead to the increase in rate found going from the propargyl bromide to the heptynyl bromide quaternization.

The structure B seems to have an unlikely electronic distribution. However, attempts were made



(10) Two adsorption indicators were tried unsuccessfully in an attempt to use direct titration with silver nitrate solution. Phenosafranin gave a poor end-point, as it frequently does with bromides, and eosin could not be used because the halide production was not "frozen" adequately by acetic acid solutions. Conductimetric measurement [*cf.* R. W. D. Preston and H. O. Jones, *J. Chem. Soc.*, **101**, 1930 (1912); R. P. Larsen and C. A. Kraus, *Proc. Nat. Acad. Sci.*, **40**, 70 (1954)] gave rate constants higher than were obtained titrimetrically, which increased with time. It is presumed that this was due to an increase in the relative contribution of the unimolecular solvolysis with lowered concentration of amine and halide. A disproportionately large effect of the hydrogen ion produced by the solvolysis on the conductivity of the solution would be expected.

(11) One of these, run in the presence of an equivalent of potassium nitrate to test for interference due to salt effect of the quaternary salt formed by the reaction under study, gave $k = 0.891 \times 10^{-2}$, in excellent agreement with the others.

(12) Three volumes of acetone to one of water; therefore, 70.3% by wt. of acetone.

(13) Neither propargyl bromide, 1-bromo-2-heptyne nor methyl iodide gave appreciable amounts of halide after 200 minutes in "50% acetone" containing an equimolar amount of disodium phosphate [pK_a for the conjugate acid, $H_2PO_4^-$ = 7.12; pK_a for the conjugate acid of 1-carbethoxy-4-methylpiperazine = 7.31—*cf.* M. Harfenist, This Journal, **76**, 4991 (1954)]. Only 7% of the amount of bromide produced by the Sn2 reaction in that time (70% completion) was produced in 200 minutes under those conditions by allyl bromide.

(14) L. Pauling, W. Gordy and J. H. Saylor, This Journal, **64**, 1753 (1942). However, see L. F. Hatch and D. J. Mangold, *ibid.*, **77**, 176 (1955), and reference 2.

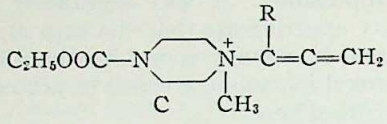
to detect any allene C which might have been produced by attack of the nucleophilic amine at the positive carbon of resonance form "B." The quaternary salt from propargyl bromide gave the



theoretical titer of acetylenic hydrogen by silver ion titration, and so appears free of detectable allene C, R = H. The hept-2-ynyl quaternary salt which might contain C, R = C_4H_9, showed no infrared absorption in the 5 μ region characteristic of allenic absorption (0.1 mm. thickness, 5% in $CHCl_3$). Surprisingly, for a compound with a "buried" acetylenic group,[15] this latter quaternary salt showed moderately intense acetylenic absorption at 4.41 μ.

It is, of course, possible to reconcile non-detection of allenes with existence of the allenic resonance form B. It would seem wiser, however, to tentatively explain the high SN2 reactivity of propargylic halides as due to the great polarizability of the triple bond,[16] and the increase in rate when R = alkyl by an increase in electron availability leading to a further increase in polarizability. This of course does not explain the electron-withdrawing properties of the propargyl group which are shown, for example, by the low basicity of propargylamines,[17] and the high acidity of α,β-acetylenic acids.[18]

The rate of quaternization with methyl iodide as compared with allyl bromide reported here seems reasonable. The most nearly comparable experiments[18] are the quaternizations of dimethylaniline by allyl *iodide* (k = 1.08) and methyl iodide (k = 0.143) in ethanol solution. If it is assumed that the rate of reaction of allyl bromide is slower than that of the iodide by a factor of about 6–7,[19] these constants would be in reasonable agreement with the ratio of rates reported here. Although the ratio of the results of Preston and Jones for triisoamylamine and the same halides differs from what would be expected from the work reported here, their methyl iodide results with this amine are also out of line with the rest of their own data.[20]

Acknowledgment.—The author acknowledges helpful discussions with Dr. R. Baltzly. The infrared absorption curve was run by Mr. J. E. Murphy of The Analytical Research Laboratory, Burroughs Wellcome & Co.

On the Thermal Dissociation of Organic Compounds. XIII. The Effect of Ring Size on the Rate of the Thermal Dissociation of Cyclopolymethyleneureas

BY SHOICHIRO OZAKI, TERUAKI MUKAIYAMA[1] AND KEIKICHI UNO

RECEIVED DECEMBER 7, 1956

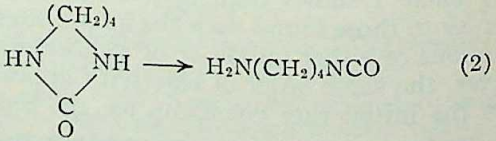
On heating, cyclic ureas dissociate into ω-aminoalkyl isocyanates with opening of the ring. The rate constants of the thermal dissociation of eight cyclic ureas in fatty acid were determined. The rates increase in the order 5-, 6- < 15- < 17- < 13- < 11- < 7- < 8-membered ring ureas. The relation between ring size and reactivity in this dissociation is discussed.

Introduction

It already has been shown that, on heating, ureas dissociate into isocyanates and amines.

$$RHN{-}CO{-}NHR \rightleftharpoons R{-}NCO + H_2N{-}R \quad (1)$$

The kinetics of the thermal dissociation of urea and some substituted ureas in fatty acids[2-6] have been studied. Similarly, in the case of cyclotetramethyleneurea, for example, the mechanism shown by equations 2–4 is considered.



$$H_2N(CH_2)_4NCO + 2ClCH_2COOH \longrightarrow ClCH_2CONH(CH_2)_4NHCOOCOCH_2Cl \quad (3)$$

$$ClCH_2CONH(CH_2)_4NHCOOCOCH_2Cl \longrightarrow ClCH_2CONH(CH_2)_4NHCOCH_2Cl + CO_2 \quad (4)$$

The reaction in chloroacetic acid can be followed by measuring the rate of evolution of carbon dioxide[5] (eq. 4), as reaction 2 is rate-determining.

In the present work, the kinetics of the thermal dissociation of eight cyclopolymethyleneureas in chloroacetic acid were studied, and the relation between ring size and the reactivity of the cyclic ureas was obtained.

Ring ureas were synthesized from polymethylene diisocyanate and water *via* equations 6 and 7.

$$OCN(CH_2)_{n-3}NCO + H_2O \longrightarrow H_2N(CH_2)_{n-3}NCO + CO_2 \quad (6)$$

$$H_2N(CH_2)_{n-3}NCO \longrightarrow \text{cyclic urea} \quad (7)$$

Experimental

Procedure.—The procedures for measuring the rates of dissociation of ureas in fatty acid[2,3,5] have been described previously. On plotting the logarithm of volume of carbon dioxide, ΔY, evolved at regular intervals of time, a straight line was obtained. This indicates a first-order reaction rate. The rate constant is given by the gradient of such a plot.[7]

Preparation of Materials.—Cylic ureas were synthesized[8] from the corresponding diisocyanates and water by methods a and b.

(a) **Without Using a High Dilution Technique. Cyclotetramethyleneurea (I).**—To a solution of 120 ml. of acetone and 120 ml. of water was added dropwise the mixture of 5.4 g. of tetramethylene diisocyanate and 40 ml. of acetone in a period of 3 hr. under refluxing. After another 30 minutes the reaction mixture was cooled and polytetramethyleneurea precipitated was filtered off. The filtrate was evaporated to about 20 ml., then the precipitate which deposited was separated. Recrystallization from acetone yielded 2.8 g. (64%) of I, as colorless crystals, melting at 172–173°.

(b) **Using a High Dilution Technique. Cycloöctamethyleneurea (II).**—To a solution of 900 ml. of acetone and 900 ml. of water was added, in the rate of a drop in 10 seconds, the mixture of 3.2 g. of octamethylene diisocyanate and 70 ml. of acetone in a period of 17 hr. using a Hunsdiecker apparatus.[9] After another 30 minutes, the solution was evaporated to about 900 ml., the poly-octamethyleneurea precipitated was filtered off and again evaporated to about 10 ml. and the precipitate was collected. Recrystallization from acetone yielded 0.5 g. (18.1%) of II as colorless crystals melting at 159–160°. The melting point, synthetic method, yield of cyclic ureas and boiling point for the corresponding diisocyanate are listed in Table I.

TABLE I

Methylene-ureas	Ring number	M.p., °C.	Synthetic method	Yield, (%)	B.p. °C. (corresponding diisocyanate)	Mm.
Cyclo-di-	5	129	a	35	85–86	76
Cyclo-tri-	6	258	b	60	98	26
Cyclo-tetra-	7	172–173	a	64	93	7
Cyclo-penta-	8	238	b	22	128–130	19

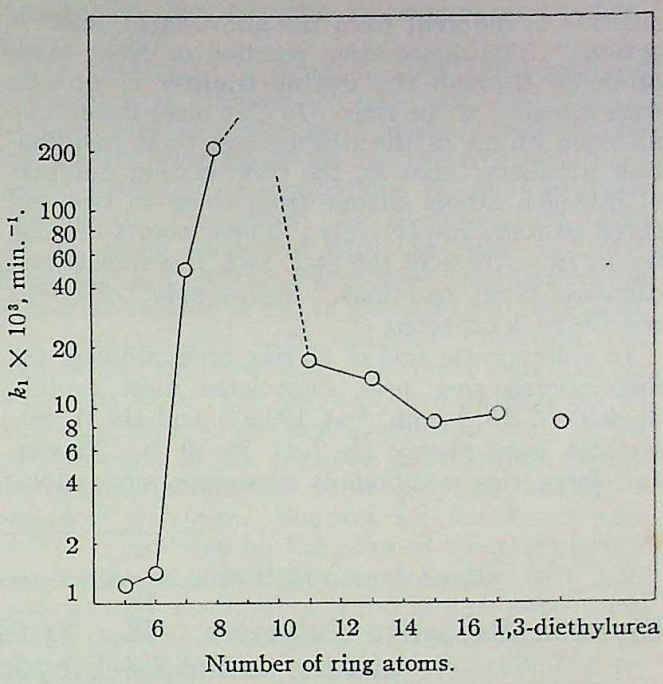

Fig. 1.—Relation between ring size and reactivity on the thermal dissociation of cyclopolymethyleneurea in chloroacetic acid: the plot of k_1 (at 139.5°) against ring number.

TABLE II

SUMMARY OF THE RATE DATA FOR THE THERMAL DISSOCIATION OF CYCLOPOLYMETHYLENEUREA IN CHLOROACETIC ACID AT 139.5°

Ring number	Rate constant $k_1 \times 10^3$, min.$^{-1}$	Relative rate
5	1.21	1
6	1.47	1.2
7	50.3	41.5
8	210	174
11	17	14
13	14.1	12
15	8.36	6.9
17	9.55	7.9
1,3-Diethylurea	8.51	7.0

Result and Discussion

It is commonly known that the reactivity of cyclic compounds depends on their ring sizes. On this matter, many[10] available kinetic results have been reported for common ring and several[11–14] for medium and large ring compounds. The SN1, SN2 and free radical type reactions proceed rapidly in 5- and 7-membered ring compounds and slowly in 6-membered compounds. 5- and 7-membered ring compounds react slower than 6- in the carbonyl-type reaction. In all reaction types mentioned above, the large ring compounds have medium reactivity between these two extremes and have almost the same reactivity as that of open chain compounds.

In the dissociation of ureas, the reaction mech-

Digitized by Arya Samaj Foundation Chennai and eGangotri

anism[5,6] is different from the above-mentioned reactions. The dissociation reaction of cyclic ureas proceeds through the double transfer of protons with opening of the ring. In this mechanism, two nitrogen atoms in the ring change their coördination numbers; that is, the coördination numbers of nitrogen atoms change from three to two and three to four, respectively. These points are different from those of the SN1, SN2, free radical and carbonyl-type reactions. Accordingly, different reactivity is expected.

In chloroacetic acid of all ring ureas studied, the 8-membered ring urea dissociates most rapidly (k_1 210 × 10^{-3} min.$^{-1}$ at 139.5°) and the 5- dissociates most slowly (k_1 1.21 × 10^{-3}). Eleven- and large ring compounds dissociate moderately. Comparing the results with those of other ring compounds reported, they generally resemble the reactivity of SN1, SN2 and radical-type reactions.[14] Accordingly, the reactivity of ring ureas is in inverse relation with that of carbonyl-type reactions.[11] A characteristic result obtained in the present experiment is that 5- and 6- ring ureas have similar reactivity, which has not been observed in other reaction types.

Acknowledgments.—The authors wish to express their hearty thanks to Prof. T. Hoshino for his helpful advice and encouragement throughout the course of this work and to Dr. H. C. Brown for his helpful discussion and to Mr. K. Teranishi for his help in the synthesis of ring ureas.

Electron Exchange Polymers. IX. Synthesis of Polymers of 2,5-Dihydroxyphenylalanine and of 3,4-Dihydroxyphenylalanine (DOPA)[1]

BY H. JAMES HARWOOD[2] AND HAROLD G. CASSIDY

RECEIVED JANUARY 23, 1957

Methods are given for the preparation by the N-carboxyl anhydride technique of high molecular weight polypeptides of 2,5-dihydroxyphenylalanine and 3,4-dihydroxyphenylalanine and of copolymers of each with L-glutamic acid. The methods include those for the preparation of the appropriate monomers in which the phenolic hydroxyls of the dihydroxyphenylalanines are protected by acetyl groups. These syntheses now make available new electron exchange polymers that are also polypeptides.

In the first paper of this series,[3] the possible usefulness of electron exchange polymers of suitable composition and structure as models for certain biological systems was suggested. It seemed desirable to investigate this possibility. The postulate on which this work was based is that a reactive group when incorporated in a polymeric structure will show one or more properties different in kind or different in quantity from those of the "same" group in the molecularly dispersed monomeric state. A number of investigations have been carried out effectively from this point of view. For example, the investigations of Haskell and Hammett[4] and the further investigations of Hammett and co-workers[5] fall in this category. These investigators compared the catalytic behavior of hydrochloric acid and the acid forms of cation exchangers toward the hydrolysis of esters. They found differences in rate and specificity effects. As another example from a growing literature, Morawetz and Zimmering[6] found that solvolysis of the ester group in acrylic acid–*p*-nitrophenyl methacrylate copolymers seemed to proceed by a mechanism different from that of the solvolysis of the ester group in the monomeric model *p*-nitrophenyl trimethylacetate. As a third example, Lautsch and his co-workers[7] have carried out extensive investigations of the changes in spectra, in catalytic properties and in oxidation–reduction potential that occur when a porphyrin group is incorporated into a large molecule. We have set out to examine the properties of hydroquinone and catechol groups when present as side-chains to a polypeptide structure, thus supplementing our earlier work.[8]

This paper reports the first steps in this investigation: the synthesis of polymers of 2,5-dihydroxyphenylalanine and 3,4-dihydroxyphenylalanine and copolymers of these two amino acids with L-glutamic acid by the N-carboxyl anhydride technique. Our synthesis is patterned after the polytyrosine synthesis reported by Schlögl, Wessely and Wawersich[9] and the polyserine synthesis reported by Frankel, Cordova and Breuer.[10]

2,5-Dihydroxyphenylalanine, (I), was treated

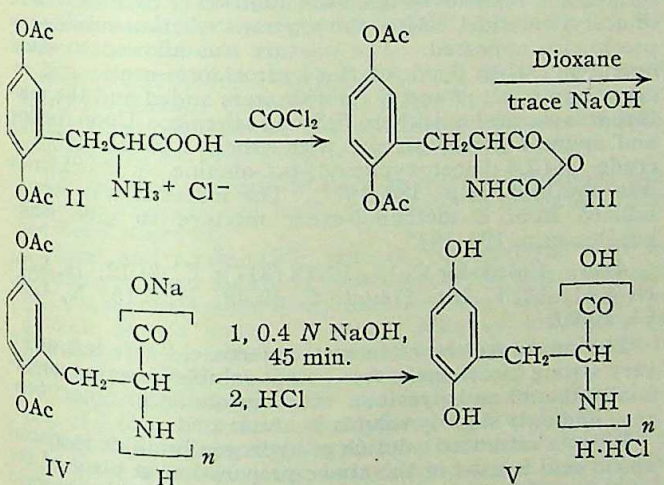
with acetyl chloride in the presence of glacial acetic acid saturated with hydrogen chloride, according to the procedure described by Bretschneider and Biemann[11] for the synthesis of O-acetyltyrosine hydrochloride, to form 2,5-diacetoxyphenylalanine hydrochloride (II). II was suspended in dioxane and treated with phosgene to form the desired monomer, 4-(2,5-diacetoxybenzyl)-2,5-oxazolidine dione (III). Polymerizations to IV were carried out in dioxane solution by initiation with 0.005 mole of sodium hydroxide in methanol per mole of monomer. Acetyl groups were cleaved by alkaline treatment in an inert atmosphere to give V. This method appears to be superior to that employing Overell and Petrow's hydrobromic–acetic acid reagent[12]; see Experimental.

Poly-DOPA was prepared through a synthetic sequence similar to I to V, except that it was more convenient to isolate the 3,4-diacetoxyphenylalanine as the hydrobromide than as the hydrochloride. The latter was characterized, but the former was used in the synthesis.

Copolymers were prepared by copolymerizing the above-described monomers with the N-carboxyl anhydride of γ-benzyl glutamate. Protecting groups were removed stepwise from the copolymers by first cleaving the benzyl esters with a saturated solution of hydrobromic acid in acetic acid, then completing the removal of acetyl groups in a separate step by alkaline treatment.



Katchalski and Sela[13] reported a polytyrosine synthesis which has advantages in the step where protective groups are removed. We found that the tricarbobenzoxy derivatives, intermediates in this synthesis, were inconvenient to work with. The tricarbobenzoxy derivative of 2,5-dihydroxyphenylalanine (N-benzyloxycarbonyl-β-(2,5-dibenzyloxycarbonyloxyphenyl)-D,L-alanine) was prepared and purified. A tricarbobenzoxy derivative of 3,4-dihydroxyphenylalanine could not be prepared, though a tricarbomethoxy derivative, m.p. 127°, was prepared in a small-scale run and characterized on the basis of its infrared spectrum. Attempts to repeat this synthesis failed to yield crystalline material. Apparently similar difficulty of this kind was encountered by O'Neill, Veitch and Wagner-Jauregg[14] in their attempts to prepare simple peptides of DOPA.

The molecular weights of the unhydrolyzed polymers were checked by end-group titrations.[15] Number average molecular weights between 5,000 and 10,000 were observed by this method. Intrinsic viscosity determinations of unhydrolyzed copolymers, determined in dichloroacetic acid (DCA), when compared with the data of Doty, Bradbury and Holtzer,[16] indicated weight average molecular weights in the range of 34,000 to 45,000. The unexpectedly large difference between the number and weight average molecular weights suggests that either the polymer preparations are of wide molecular weight distributions or that partial saponification of the phenolic ester groups during the polymerization led to a polymer having a branched structure. Support for the latter possibility is provided by the color of the polymerization mixtures (see Experimental), the fact that more amino[17] than carboxyl end groups were found in the polymer, the difficulty of titrating the dihydroxyphenylalanine monomers with alkaline reagents[15] and the known ready hydrolysis of acetylated phenolic groups in similar types of compounds.[18]

The intrinsic viscosity values observed for the simple polymers appear to be in better agreement with the number average molecular weights estimated from end-group titration results, although an exact assignment of weight average molecular weight values to these polymers cannot be made at present.

The difference in polydispersity between the simple polymers and the copolymers might suggest that the latter are polyblends; mixtures of relatively low molecular weight (5–6,000) polydiacetoxyphenylalanine and high molecular weight poly-γ-L-benzyl glutamate (*ca.* 50,000). Against this supposition is the observation that the hydrolyzed copolymers are completely soluble at *p*H 7.3, while poly-3,4-dihydroxyphenylalanine is insoluble at this *p*H. The differences in phenolic ionization behavior observed for the simple polymers and the copolymers is of interest in this connection, and we hope to report on this subsequently.

Methods for preparing these substances are presented because of the increasing interest in the catalytic and reagent properties of quinones. They provide reagents which are readily removable from a reaction mixture by precipitation or dialysis and which, like other oxidation–reduction polymers based on quinones,[3] contribute to or remove from the reaction only electrons and protons. Investi-

gation of the reagent and catalytic properties of these substances is being continued.

Experimental

N-Benzyloxycarbonyl-β-(2,5-dibenzyloxycarbonyloxyphenyl)-D,L-alanine.—An ice-cold solution of 4.01 g. of 2,5-dihydroxyphenylalanine[19] in 38 ml. of 0.74 *N* sodium hydroxide was treated slowly under nitrogen, with rapid stirring, with 12.2 g. of 93.5% benzyl chloroformate and 15.0 ml. of cold 4 *N* sodium hydroxide added simultaneously. The mixture became turbid and a heavy oily substance deposited upon the sides of the flask. Ether, 10 ml., was then added to help disperse the mixture. Stirring was continued for 2.5 hr., and the reaction mixture was diluted with ether. Three fractions were obtained: aqueous and ether phases, and the insoluble sodium salt of the tricarbobenzoxy derivative. The aqueous and sodium salt layers were acidified with 4 *N* HCl to congo red. The ether layer was extracted further with 5% sodium bicarbonate solution. The aqueous and sodium salt layers were again separated from the ether and acidified with 4 *N* hydrochloric acid. The aqueous and sodium salt layers could be made miscible if the mixture was diluted with distilled water. After several days in the refrigerator, the oily product solidified as a light brown mass. The material was filtered and washed with distilled water. The yield was 9.6 g. (78%).

The material is very difficult to purify. Repeated recrystallization from a dilute solution in 30% acetic acid led to 2.0 g. of small, white needles, m.p. 126.7–127.8°.

Anal. Calcd. for $C_{33}H_{23}O_{10}N$ (600): C, 66.09; H, 4.86; N, 2.34; neut. equiv., 600. Found: C, 65.95; H, 4.98; N, 2.30; neut. equiv., 600.6, 596.1.

Crystalline material may be obtained if the gummy mass which is often obtained from either the reaction mixture or the purification process is partially dissolved in ether. Some crystalline material is usually left undissolved. The ether solution on standing usually begins to deposit crystalline material after several days. The crystals thus obtained are cubic, and the substance melts at 169–170°. The cubic crystals are not appreciably soluble in chloroform whereas those in the needle form, melting at 127–8°, are readily soluble. Both types of crystals show almost identical infrared spectra in Nujol mulls. The soluble form, in chloroform solution, showed ester absorption at 5.68 μ and carboxyl absorption at 5.82 μ.

Regeneration of 2,5-Dihydroxyphenylalanine.—Purified tricarbobenzoxy derivative, 72.9 mg., was dissolved in 2 ml. of glacial acetic acid, and 3.7 ml. of a 50% solution (by weight) of hydrogen bromide in glacial acetic acid was added. After an hour, the solution was swamped with ether and the crystalline 2,5-dihydroxyphenylalanine hydrobromide was isolated. The yield was 30.7 mg. (91%), m.p. 272–273° dec. The infrared spectrum in Nujol was identical with that of an authentic sample of 2,5-dihydroxyphenylalanine hydrobromide prepared directly from the pure amino acid and the hydrobromic–acetic acid reagent, m.p. 274.5–275° dec.

β-(2,5-Diacetoxyphenyl)-D,L-alanine Hydrochloride.—Five grams of β-(2,5-dihydroxyphenyl)-D,L-alanine was added to 30 ml. of glacial acetic acid, previously saturated with dry hydrogen chloride. The amino acid dissolved and after a short time its salt settled out. Acetyl chloride, 25 ml., was added either to the solution or the suspension, and the mixture was allowed to stand overnight at room temperature, whereupon 30 ml. of the hydrochloric–acetic acid reagent and 30 ml. of acetyl chloride were added and the reaction mixture heated quickly to 75° with stirring. The mixture was allowed to cool and was then swamped with anhydrous ether. The crude β-(2,5-diacetoxyphenyl)-D,L-alanine hydrochloride after several hours quickly solidified, and was collected, washed with ether and allowed to dry in air. The yield was 5.3 g. (66%), m.p. 158–159°.

For analysis the sample was recrystallized from a methanol–ether mixture, giving colorless needles, m.p. 154–155° (after drying in the Abderhalden apparatus, m.p. 160–161°).

Anal. Calcd. for $C_{12}H_{16}O_6NCl$ (317.7): C, 49.12; H, 5.09; N, 4.41; Cl, 11.16. Found: C, 48.68; H, 5.74; N, 4.75; Cl, 10.81.

(19) H. B. Gillespie, *Biochem. Prep.*, **3**, 79 (1953).

The compound in a Nujol mull showed ester absorption in the infrared region at 5.65 μ and carboxyl absorption at 5.72 μ.

The compound is soluble in water, pyridine, methanol and is insoluble in chloroform, benzene and ether. It gives negative tests with ferric chloride, Millon reagent and iodine in potassium iodide.

4-(2,5-Diacetoxybenzyl)-2,5-oxazolidine Dione.—Phosgene was slowly bubbled into a rapidly stirred suspension of 4.8 g. of β-(2,5-diacetoxyphenyl)-D,L-alanine hydrochloride in 50 ml. of dry purified dioxane, maintained between 40 and 60°. After about 2 or 3 hr. all of the salt had dissolved and the flask was flushed with dry nitrogen for 0.5 hr. to remove unreacted phosgene. The dioxane was then removed by distillation *in vacuo* leaving a colorless sirup, which was dissolved in 50 ml. of ethyl acetate, and the ethyl acetate was removed by distillation *in vacuo*. This process was repeated and the sirupy residue was taken up in a small amount of ethyl acetate. The crude anhydride was precipitated from solution by the addition of a large excess of ligroin. The oily residue which deposited usually solidified upon standing for several hours; yield was 3.4 g. (73.5%).

Several recrystallizations from ethyl acetate–petroleum ether mixtures yielded 2.8 g. of nearly colorless needles, m.p. 132.3–134.0°. The material showed a negative ferric chloride test. It is soluble in chloroform, ethyl acetate, dioxane and methanol and is insoluble in petroleum ether. The compound showed ester absorption in the infrared region: at 5.65 μ and anhydride absorption at 5.35 and 5.57 μ.

Anal. Calcd. for $C_{14}H_{13}O_7N$ (307): C, 54.73; H, 4.26; N, 4.55; acetyl, 28.01. Found: C, 54.94; H, 4.49; N, 4.53; acetyl, 28.23, 28.62.

β-(3,4-Diacetoxyphenyl)-D,L-alanine Hydrochloride.—One gram of 3,4-dihydroxyphenylalanine (Eastman No. 4915) was dissolved in 6 ml. of glacial acetic acid saturated with hydrogen chloride; 5 ml of acetyl chloride was then added carefully with swirling. A gummy precipitate formed and redissolved upon the addition of each increment of acetyl chloride. After the vigorous reaction subsided, a precipitate appeared. The mixture was allowed to stand overnight, when 6 ml. of the hydrochloric–acetic acid reagent and 5 ml. of acetyl chloride were added and the mixture was warmed quickly to 70° with stirring. Upon cooling and swamping the mixture with ether, 1.06 g. (66%) of crude β-(3,4-diacetoxyphenyl)-D,L-alanine hydrochloride was obtained, m.p. 186–187°. The material was recrystallized from a methanol–ether mixture to give white needles, m.p. 193–194°.

Anal. Calcd. for $C_{13}H_{16}O_6NCl$ (317): C, 49.12; H, 5.09; N, 4.41; Cl, 11.16. Found: C, 49.48; H, 5.15; N, 4.36; Cl, 10.90.

The substance shows a negative ferric chloride test and a very strong bicarbonate test. It is soluble in water, methanol, ethanol and pyridine. It is insoluble in ether, benzene and only slightly soluble in acetic acid.

When a saturated solution of hydrogen bromide in glacial acetic acid is used in the above preparation in place of the hydrogen chloride–acetic acid reagent, a quantitative yield of the corresponding hydrobromide is obtained. The hydrobromide was used in further synthetic work but was not characterized since it was probably contaminated with the corresponding hydrochloride.

Both materials showed similar infrared spectra in Nujol mulls. Peaks occurring at 5.65 μ (phenolic ester) and 5.76 μ (carboxyl) were observed.

4-(3,4-Diacetoxybenzyl)-oxazolidine-2,5-dione.—Finely ground β-(3,4-diacetoxyphenyl)-D,L-alanine hydrobromide, 4.5 g., was mixed with 100 ml. of purified dioxane, and phosgene was bubbled slowly into the rapidly stirred suspension kept at 50–70° until all of the amino acid salt went into solution. This required 3 to 4 hr. The red solution was heated for 0.5 hr. longer and was then flushed with dry nitrogen for 1 hr. to displace unreacted phosgene. The solution was then concentrated to a viscous sirup under nitrogen *in vacuo* (40–60°). The sirup was taken up in ethyl acetate and precipitated by adding petroleum ether slowly. Scratching and allowing the mixture to stand for several hours usually led to the solidification of the crude anhydride. In some cases it was necessary to repeat the above process before solid material was obtained.

Several recrystallizations from ethyl acetate–petroleum ether mixtures at room temperature led to 2.90 g. (75%) of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

pure 4-(3,4-diacetoxybenzyl)-oxazolidine-2,5-dione as granular colorless crystals, m.p. 116–117° (swelling in sealed tube).

Anal. Calcd. for $C_{14}H_{13}NO_7$ (307.3): C, 55.06; H, 4.45; N, 4.52; acetyl, 28.01. Found: C, 54.73; H, 4.26; N, 4.55; acetyl, 28.13.

When 50.1 mg. of the material was heated slowly to 135° at 0.1 mm., it lost 7.3 mg. of CO_2. The calculated value for the weight loss during thermal polymerization was 7.2 mg. The material is soluble in ethyl acetate, hot benzene, ether, chloroform and dioxane. It is insoluble in petroleum ether and water. The compound shows infrared absorption in the carbonyl region at 5.31 and 5.55 mμ. Apparently ester and anhydride bands overlap at 5.55 μ for this compound.

When β-(3,4-diacetoxyphenyl)-D,L-alanine hydrochloride is used as the starting material in this preparation, identical material is obtained in 72% yield.

Poly-β-(2,5-diacetoxyphenyl)-D,L-alanine.—A solution of 2.75 g. of 4-(2,5-diacetoxybenzyl)-oxazolidine-2,5-dione in 35 ml. of purified dioxane was mixed with a solution of 0.45 ml. of 0.14 *N* sodium hydroxide in absolute methanol dissolved in 35 ml. of purified dioxane.

The mixture, on standing for one week, became light yellow in color. It was concentrated to one third its volume under reduced pressure at 40–50°. The polymer was then precipitated from solution by the addition of petroleum ether. The yellow sticky polymer was then taken up in ethyl acetate and reprecipitated by the addition of petroleum ether. The polymer was now cream in color and was no longer sticky. It was dissolved in a mixture of 125 ml. of redistilled benzene and 40 ml. of dioxane. The solution was filtered and freeze dried, yielding 2.23 g. (91%) of poly-2,5-diacetoxyphenylalanine.

The polymer thus obtained was fluffy and very friable but became very hard and dense during storage. Material which was convenient to work with was obtained by dissolving the polymer in glacial acetic acid and freeze-drying this solution. The light yellow powder thus obtained was dried *in vacuo* over sodium hydroxide to remove the last traces of acetic acid.

Anal. Calcd. for $(C_{13}H_{13}O_5N)_n$: C, 59.31; H, 4.98; N, 5.32. Found: C, 58.97; H, 5.18; N, 5.07; amino end-group titrations showed the polymer to have a number average mol. wt. of 11,000; [η] in DCA at 25°, 0.08.

The polymer appears to be somewhat hygroscopic, particularly when the last traces of dioxane or acetic acid have not been removed.

Biuret and picric acid[20] tests on this material were inconclusive due to the ready hydrolysis of the acetoxy groups and the accompanying discoloration of the liberated hydroquinone groups under the strong alkaline conditions required for these tests. The ninhydrin test, in contrast to most polypeptides, appeared to be negative.

The polymer showed ester absorption in the infrared region at 5.68 μ, and amide absorption at 6.00 and 6.46 μ.

Poly-β-(3,4-diacetoxyphenyl)-D,L-alanine.—A solution of 3.80 g. of 4-(3,4-diacetoxybenzyl)-oxazolidine-2,5-dione in 75 ml. of purified dioxane was mixed with a solution of 0.35 ml. of 0.186 *N* sodium hydroxide in anhydrous methanol dissolved in 50 ml. of dioxane. The mixture became light yellow overnight and was allowed to stand four days.

The polymerization solution was then filtered and concentrated to one-third its volume under nitrogen *in vacuo* (40–60°). The crude caramel-colored sticky polymer was obtained by precipitating it from solution by the addition of petroleum ether. A small amount of starting material (10–20 mg.) was isolated from the supernatant which was decanted from this precipitated polymer. This indicates that a somewhat longer polymerization time would perhaps have been advisable.

The crude polymer dissolved in ethyl acetate was treated with Norite and filtered. The polymer was then reprecipitated by adding petroleum ether. The light, cream-colored powder that separated from solution was then partially dissolved in fresh ethyl acetate, and enough petroleum ether was added to make the resulting solution contain 15% petroleum ether. The polymer was now dissolved in purified glacial acetic acid and freeze dried. The yield of poly-β-(3,4-diacetoxyphenyl)-D,L-alanine was 2.30 g. (67.4%). The polymer was obtained as a faintly yellow powder which did not appear to be hygroscopic, in contrast to the behavior of its 2,5-isomer.

The material showed a negative picric acid test. Heating the polymer with a ninhydrin solution caused the polymer to become blue in color, leaving a colorless solution. The biuret test was inconclusive, the catechol groups liberated in the alkaline solution apparently reduced the cupric reagent. The polymer showed ester absorption in the infrared region at 3.65 μ and monosubstituted amide absorption at 5.99 and 6.48 μ.

Anal. Calcd. for $(C_{13}H_{13}O_5N)_n$: C, 59.31; H, 4.98; N, 5.32. Found: C, 59.22; H, 5.17; N, 5.44; end amino titration showed the polymer to have a mol. wt. of 7000; [η] in DCA, 0.10

Poly-[90% γ-benzyl L-glutamate; 10%-β-(2,5-diacetoxyphenyl)-D,L-alanine].—A solution of 3.29 g. of benzyl L-4-β-(2,5-diketoöxazolidinyl)-propionate[21] (γ-benzyl N-carboxyl-L-glutamate anhydride) and 0.429 g. of 4-(2,5-diacetoxybenzyl)-oxazolidine 2,5-dione in 50 ml. of purified dioxane was diluted with 75 ml. of dioxane to which 0.69 ml. of 0.1 *N* sodium hydroxide in methanol had been added.

The polymerization mixture was allowed to stand for two weeks. Most of the dioxane was then removed by distillation under reduced pressure (40–60°) and the sirupy residue was treated with petroleum ether to precipitate the sticky, faintly green polymer. The material was then dissolved in ethyl acetate and partially reprecipitated by the addition of petroleum ether. The powdery precipitate was then dissolved in redistilled benzene to form a very viscous solution. This solution was treated with Norite, filtered and freeze-dried yielding 2.50 g. of the white spongy copolymer.

Anal. Calcd. for $[(C_{12}H_{13}O_3N)_9(C_{13}H_{13}O_5N)]_n$: C, 64.7; H, 5.80; N, 6.23. Found: C, 63.95; H, 5.86; N, 5.08; end carboxyl and amino group determinations gave number average mol. wts. of 7,500 and 5–6,000, respectively; [η] in DCA at 25°, 0.28 corresponding to a weight average mol. wt. of 34,000; $[\alpha]^{25}D$ +15.0 (*c* 5.62 mg./ml. in dioxane).

The material gave a negative picric test, appeared to give a negative ninhydrin test and showed a strongly positive biuret test only after being precipitated from dichloroacetic acid solution with water.

Poly-[90% γ-benzyl L-glutamate; 10% β-(3,4-diacetoxyphenyl)-D,L-alanine].—A solution of 4.50 g. of benzyl L-4-β-(2,5-diketoöxazolidinyl)-propionate[21] and 0.595 g. of 4-(3,4-diacetoxybenzyl)-oxazolidine 2,5-dione in 75 ml. of purified dioxane was mixed with a solution of 0.95 ml. of 0.1 *N* sodium hydroxide in anhydrous methanol dissolved in 100 ml. of purified dioxane. The solution became light pink immediately and became faintly blue in a few minutes. After several hours it developed a greenish cast. After three weeks the polymerization mixture was concentrated to one-half its volume under reduced pressure (50–60°). The crude polymer was precipitated as a very pale yellow sticky solid by the addition of petroleum ether.

The mixture was allowed to stand overnight and the supernatant liquid was decanted. The polymer was then taken up in ethyl acetate, treated with Norite and filtered. The polymer was then partially reprecipitated by the addition of petroleum ether. It was obtained as a colorless powder which when filtered was difficult to separate cleanly from filter paper. The polymer was then taken up in redistilled benzene and the resulting very viscous solution was filtered and freeze-dried.

The material was obtained as a white spongy mass which became easily charged when rubbed with glass. The yield was 2.8 g. (66%).

Anal. Calcd. for $[(C_{12}H_{13}O_3N)_9(C_{13}H_{13}O_5N)]_n$: C, 64.7; H, 5.79; N, 6.23. Found: C, 63.85; H, 5.76; N, 5.35; end carboxyl and amino group titrations showed the polymer to have number average mol. wts. of 8,900 and 5,500, respectively; [η] in DCA at 25°, 0.33 corresponding to a weight average mol. wt. of 45,000; $[\alpha]^{25}D$ +13.2 (*c* 7.04 mg./ml. in dioxane); $[\alpha]^{20}D$ +18.1 (*c* 32.0 mg./ml. in ethyl acetate).

The material showed a negative picric acid test. After being precipitated from dichloroacetic acid with water, the polymer gives a strongly positive biuret test. When the

polymer is boiled with ninhydrin, the polymer becomes blue in color but the solution remains colorless. The polymer showed ester absorption in the infrared region at 5.78 μ and monosubstituted amide absorption at 6.06 and 6.47 μ.

Poly-β-(2,5-dihydroxyphenyl)-D,L-alanine.—Poly-β-(2,5-diacetoxyphenyl)-D,L-alanine, 285 mg., was mixed with 25 ml. of 0.4 *N* sodium hydroxide in a nitrogen atmosphere. After 0.5 hr. the polymer had completely dissolved. The solution was allowed to stand 45 minutes longer and was then acidified with 1 ml. of concd. hydrochloric acid. The resulting light yellow solution was deionized by passage through a 20-g. Amberlite 1R-100 column. The polymer was isolated by freeze-drying. To ensure complete removal of inorganic material, the freeze-dried product was dissolved in distilled water and the resulting solution was passed through a fresh Amberlite 1R-100 column. The polymer was again isolated by freeze-drying. The polymer was dried 12 hr. at 80° (0.1 mm.) over sodium hydroxide for analysis.[22] The polymer is very hygroscopic and must be stored in a desiccator.

Anal. Calcd. for $(C_9H_9O_3N)_n$: C, 60.33; H, 5.06; N, 7.82. Found: C, 53.87; H, 4.01; N, 5.27; acetyl, 11.13.[23]

Poly-β-(3,4-dihydroxyphenyl)-D,L-alanine (Poly-DOPA).—Five hundred mg. of poly-β-(3,4-diacetoxyphenyl)-D,L-alanine was covered with 35 ml. of 0.4 *N* sodium hydroxide. During this time the flask was flushed out with a stream of nitrogen to prevent oxygen from reacting with the liberated hydroquinone groups. The polymer was difficult to wet but went into solution in a period of 0.5 hr. The light brown solution was allowed to stand 45 minutes longer and was then filtered and acidified with concentrated hydrochloric acid. The precipitated polymer was centrifuged and washed five times with distilled water. The polymer was almost white in color at this stage. A small amount of sticky material was taken up in absolute ethanol and reprecipitated by the addition of water. The material thus obtained was fine and powdery. The polymer was then dried over sodium hydroxide at 0.1 mm. and 80° for 12 hr. The yield was 142 mg. (48%).

Anal.[22] Calcd. for $(C_9H_9O_3N)_{20}$: C, 60.33; H, 5.06; N, 7.82; NH_2, 0.45. Found: C, 59.22; H, 5.30; N, 5.80; NH_2, 0.56; acetyl, 1.65.

The material is not appreciably soluble in water in contrast to its 2,5-isomer and does not appear to be hygroscopic. The material showed a negative picric acid test and an inconclusive biuret test similar to its parent acetylated derivative. One of the reviewers kindly pointed out that comparison of the ratio of found N (5.80) to found NH_2 (0.56) with that calculated for the assumed degree of polymerization suggests that some degradation had occurred during deacetylation.

Poly-[90% L-glutamic acid; 10% β-(2,5-dihydroxyphenyl)-D,L-alanine].—Poly-[90% L-γ-benzyl glutamate; 10%-β-(2,5-diacetoxyphenyl)-D,L-alanine], 336 mg., was mixed with 10 ml. of a freshly saturated (50% by weight) solution of anhydrous hydrogen bromide in purified glacial acetic acid. The polymer swelled and went almost completely into solution during the first hour the mixture was allowed to stand. One hour later solid material had begun to separate from solution again. The mixture was allowed to stand overnight in a calcium chloride-dried atmosphere. The next day the mixture was swamped with ether and centrifuged. The precipitate was washed with ether and the mixture was centrifuged. This process was repeated six or more times until the ether washings showed a negative test for acid.

The swollen gelatinous polymer was then dried to a white amorphous powder and dried in the Abderhalden apparatus at 80° and 0.1 mm. over sodium hydroxide to remove the last traces of acetic acid, ether and hydrogen bromide. It is important that hydrogen bromide be completely removed before the polymer is exposed to the atmosphere, otherwise colored material will be produced. The yield was 189 mg. (94.6%).

Anal.[22] Calcd. for $[(C_5H_7O_3N)_9(C_9H_9O_3N)]_n$: C, 48.3; H, 5.4; N, 10.4. Found: C, 48.00; H, 5.33; N, 9.43; acetyl, 2.50.

The material gave a positive biuret test. Hydrolysis could be completed by allowing the polymer to stand for 1 hr. in 0.2 *N* sodium hydroxide, whereupon its acetyl content fell to 0.92%.

Poly-[90%-L-glutamic acid; 10%-β-(3,4-dihydroxyphenyl)-D,L-alanine].—One gram of poly-[90% γ-benzyl-L-glutamate; 10% β-(3,4-diacetoxyphenyl)-D,L-alanine] was suspended in 5 ml. of purified glacial acetic acid, and the suspension was warmed to 45°; 25 ml. of a freshly prepared, saturated (50% by weight) solution of anhydrous hydrogen bromide in purified glacial acetic acid was then added and the mixture was allowed to stand in a calcium chloride dried atmosphere. After the first hour nearly all had gone into solution and approximately 1 hr. later white material began to separate from solution. After 18 hr. the mixture was swamped with ether and centrifuged. The supernatant liquid was decanted, the polymer was washed with fresh ether and the mixture was again centrifuged. This process was repeated five or six times until the ether washings showed a negative test for acid.

The swollen gelatinous polymer was then dried in the Abderhalden apparatus over sodium hydroxide at 80° and 0.1 mm. to ensure removal of the last traces of acetic acid, hydrogen bromide and ether. The yield of white powdery material was 540 mg. (90%). The material is slightly hygroscopic and was stored in a desiccator.

Anal. Calcd. for $[(C_5H_7O_3N)_9(C_9H_9O_3N)]_n$: C, 48.3; H, 5.4; N, 10.4. Found: C, 47.99; H, 5.26; N, 8.88; acetyl 1.09; $[\alpha]^{25}D$ −68.5° (*c* 5.522 mg./ml. in *p*H 7.3 phosphate buffer); $[\alpha]^{29}D$ −60.4° (*c* 4.70 mg./ml. in *p*H 7.3 phosphate buffer).

The material showed a negative picric acid test, an apparent negative ninhydrin test and a very strong biuret test. The infrared spectrum of this polymer in a Nujol mull was difficult to interpret because the bands were very broad and diffuse. Carboxylic acid (5 80 μ) and monosubstituted amide (6.05) and 6.53 μ) bands were observed, however.

A sample of the product of the hydrobromic–acetic hydrolysis, 176 mg., was mixed under nitrogen with 10 ml. of 0.35 *N* sodium hydroxide, and the solution was allowed to stand 1 hr. at room temperature. The solution was then acidified with 4 *N* hydrochloric acid, and the precipitate that formed was centrifuged and washed with distilled water until the washings were neutral. The gelatinous precipitate was dried at 80° and 0.1 mm. over sodium hydroxide pellets for 16 hr.; yield 138 mg. The polymer treated in this way analyzed for 4.46% "acetyl."[22,23] Resuspended in distilled water and washed six to eight times with fresh portions of distilled water, and dried as above, the polymer analyzed for 0.0% acetyl.

It was difficult to remove acetyl completely from the acetylated polymers. The hydrobromic acid–acetic acid

TABLE I

SUMMARY OF ACETYL ANALYSES[23]

Hydrolysis conditions	Acetyl, % 2,5-Series	Acetyl, % 3,4-Series
Pure polymers		
a, 50% HBr–HOAc overnight at RT[a]	...	1.55
b, 0.2 *N* NaOH, 1 hr. under N_2 at RT	...	13.9
c, 0.4 *N* NaOH, 1 hr. under N_2 at RT	11.3	1.65
d, 0.2 *N* NaOH, 1 hr. under N_2 at RT followed by 0.4 *N* NaOH, 1 hr. under N_2	0.0	...
Copolymers (γ-benzyl glutamate)		
a, 50% HBr–HOAc overnight at RT	2.50	1.09
b, 50% HBr–HOAc overnight at RT followed by 0.2 *N* NaOH, 1 hr. under N_2 at RT	0.92	...
c, 50% HBr–HOAc overnight at RT followed by 0.4 *N* NaOH, 1 hr. under N_2 at RT	...	4.46
d, Above product rewashed with distilled water	...	0.0

[a] RT is room temperature.

(22) The hydrolyzed polymers, in general, were difficult to purify and gave poor analytical results, it being difficult to remove inorganic material and to dry them.

(23) Experimental "acetyl" values tend to be high due to some hydrochloric acid (bound by end amino groups) in the distillate.

reagent of Overell and Petrow[12] was fairly effective. There was some indication that more vigorous conditions were required for the 2,5-series than the 3,4-series. The polymers prepared by this method of deacetylation analyzed poorly for carbon, hydrogen and nitrogen. A summary of results is given in Table I.

Acknowledgments.—We are indebted to Drs. Alfred M. Holtzer and E. Peter Geiduschek for furnishing the apparatus and solvents used in the viscosity studies and for helpful suggestions.

2-Substituted Derivatives of 3,4-Dihydroxyphenylalanine

BY CARL KAISER[1] AND ALFRED BURGER

RECEIVED MARCH 6, 1957

Because 2-methyl- and 2-chloro-3,4-dihydroxyphenylalanine inhibited the multiplication of influenza virus in the allantoic fluid of the chick embryo, the following additional 2-substituted derivatives of DOPA and their dimethyl ethers have been synthesized for biological screening: 2-bromo-, 2-fluoro-, 2-ethyl- and 2-nitro-DOPA. In addition, the synthesis of β-(2-methyl-3,4-dihydroxyphenyl)-N-methyl-α-alanine and β-(2-chloro-3,4-dihydroxyphenyl)-β-alanine has been performed.

3,4-Dihydroxyphenylalanine (DOPA) is the substrate of several enzyme systems such as dopa oxidase and dopa decarboxylase which convert it to melanins[2] and to 3,4-dihydroxyphenethylamine and norepinephrine.[3,4] These reactions play an important role in animal and plant metabolism and have been studied extensively *in vitro* and *in vivo*. Interference with these reactions should prevent the accumulation of the respective reaction products in certain pathogenic conditions and for this purpose inhibitors for dopa decarboxylase have been sought repeatedly.[5-10] When 2-methyl-3,4-dihydroxyphenylalanine[11,12] became available, it was included in a series of some two hundred compounds in tests for dopa decarboxylase inhibition *in vitro*, and the same substance and its 2-chloro analog[11] were screened for anti-phenylalanine behavior in various biological systems. Since several analogs of amino acids had been found to possess antiviral activity,[13,14] it seemed desirable to test the effect of both compounds against influenza virus. In the course of these experiments it was observed that both compounds inhibited the multiplication of the PR-8 strain of influenza virus in the allantoic fluid of the chick embryo.[15] Although in rats infected with the virus these two compounds were inactive, additional 2-substituted derivatives of 3,4-dihydroxyphenylalanine were prepared with the hope of overcoming this obstacle.

For the synthesis of 2-bromo-3,4-dihydroxyphenylalanine, 3-bromoveratrole (I)[16] was chloromethylated to 2-bromoveratryl chloride (II); this was condensed with diethyl acetamidomalonate to give III which was hydrolyzed to β-(2-bromo-3,4-dimethoxyphenyl)-α-alanine (IV) with hydrochloric acid. β-(2-Bromo-3,4-dihydroxyphenyl)-α-alanine (V) was obtained by ether cleavage with 47% hydriodic acid. By an analogous sequence (VI → VII → VIII → X) 3-fluoroveratrole (VI)[17] was transformed into β-(2-fluoro-3,4-dihydroxy-

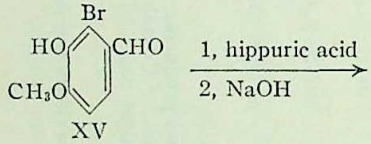
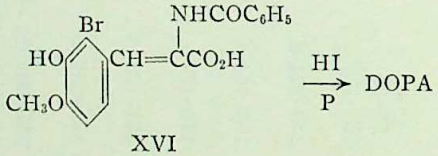
phenyl)-α-alanine (X); here, isolation of the intermediate dimethoxy derivative IX was possible but not necessary. This held also for the similar series of steps from 2-nitroveratryl chloride (XI)[18] to β-(2-nitro-3,4-dihydroxyphenyl)-α-alanine (XIV).

The position of the chloromethyl group in II was proved by oxidation to 2-bromoveratric acid.[16] In an analogous manner, 2-fluoroveratryl chloride (VII) was oxidized to 2-fluoroveratric acid. The identity of this acid was established by a Schiemann synthesis from methyl 2-aminoveratrate.[19]

An attempt was made to synthesize β-(2-bromo-3,4-dihydroxyphenyl)-α-alanine (IV) by a shorter route starting from the readily accessible 2-bromoisovanillin (XV).[20] The acetoxy-azlactone from this aldehyde was hydrolyzed to α-benzamido-2-bromo-3-hydroxy-4-methoxycinnamic acid (XVI) but this compound was debrominated to DOPA on heating with hydriodic acid and phosphorus.

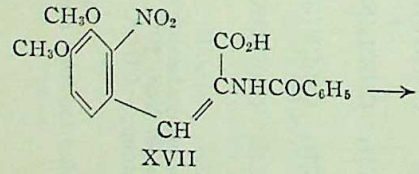


XV

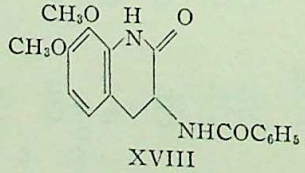


XVI

α-Benzamido-2-nitro-3,4-dimethoxycinnamic acid (XVII) was prepared from 2-nitroveratraldehyde[21] in a similar way and was hydrogenated in the presence of Adams catalyst in the hope of securing the corresponding saturated 2-amino derivative. While this compound was undoubtedly formed, it lactamized spontaneously to 3-benzamido-7,8-dimethoxy-3,4-dihydro-2-quinolone (XVIII).



XVII

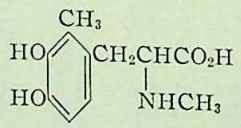


XVIII

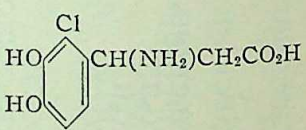
The yields in the preparation of the ethyl substituted malonate ester XXI from 3-ethylveratrole (XIX) were so low that a different route to β-(ethyldihydroxyphenyl)-α-alanine (XXIII) was chosen. 3-Ethylveratrole,[22] obtained by the Huang-Minlon modification of the Wolff–Kishner method[23] from 2,3-dimethoxyacetophenone, was subjected to a Gattermann aldehyde synthesis with hydrogen cyanide; the position of the formyl group in the resulting ethyldimethoxybenzaldehyde could not be proved conclusively since oxidation with potassium permanganate or chromic acid only led to an ethyldimethoxybenzoic acid which decomposed on continued oxidation. The same acid was obtained from the oxidation of the chloromethylation product of 3-ethylveratrole. Since the chloromethylation of 3-methyl-, 3-chloro-, 3-bromo- and 3-fluoroveratrole introduced the chloromethyl group *ortho* to the 3-substituent, a similar orientation could be expected for the chloromethylation of 3-ethylveratrole. In support of this assumption the infrared spectra of pertinent dimethoxybenzoic acids are listed in Table I. It may be significant that 2-methylveratric acid and our ethyldimethoxybenzoic acid differ from 5-methylveratric acid in their absorption characteristics at 11.0–12.3 μ. The aldehyde and chloromethyl derivatives obtained from 3-ethylveratrole are tentatively assigned the structures 2-ethylveratraldehyde and 2-ethylveratryl chloride (XX), respectively.

2-Ethylveratraldehyde gave β-(2-ethyl-3,4-dimethoxyphenyl)-α-alanine (XXII) by an azlactone synthesis followed by hydrolysis, saturation of the side chain and removal of the benzoyl group. The ether groups of XXII were cleaved with hydriodic acid (XXIII).

In order to study the effect of various structural alterations in the amino group of antiviral 2-substituted derivatives of 3,4-dihydroxyphenylalanine, β-(2-methyl-3,4-dihydroxyphenyl)-N-methyl-α-alanine (XXIV) and β-(2-chloro-3,4-dihydroxyphenyl)-β-alanine (XXV) have been synthesized. Diethyl acetamido-(2-methyl-3,4-dimethoxybenzyl)-malonate[11] was hydrolyzed and decarboxylated, the amino acid XXVI was tosylated and the N-



XXIV



XXV

tosyl derivative treated with dimethyl sulfate. Scission of the methoxyl groups and the N-tosyl linkage furnished XXIV. The chloro derivative XXV was prepared by subjecting 2-chloroveratraldehyde[11] to a Perkin reaction, treating the resulting 2-chloro-3,4-dimethoxycinnamic acid with hydroxylamine and cleaving the methoxyl groups.

β-(2-Fluoro-3,4-dihydroxyphenyl)-α-alanine had activity against influenza virus similar to β-(2-methyl-3,4-dihydroxyphenyl)-α-alanine. 2-Bromo-, 2-fluoro-, 2-ethyl- and 2-nitro-DOPA and their dimethyl ethers were screened for bacteriostatic, antifungal and antiviral activity. In chick embryo protection tests, using the PR-8 strain of the influenza virus, XXII and XXVI possessed slight activity. β-(2-Chloro-3,4-dihydroxyphenyl)-β-alanine (XXV), in concentrations of 1:500, inhibited the growth of *Histoplasma capsulatum* and *Micrococcus pyogenes*, as well as *Diplococcus pneumoniae*, and provided slight protection in mice infected with this organism.[15]

Experimental[24]

General Directions. (a) Chloromethylation of Veratrole Derivatives (II, VII, XX).—A solution of 0.25 mole of the 3-substituted veratrole derivative and 0.50 mole of monochloromethyl ether in 175 ml. of glacial acetic acid was stirred and warmed. Reaction times and temperatures were as follows: for 3-bromoveratrole,[16] 24 hr., 50–55°; for 3-ethylveratrole,[22] 8 hr., 30°; and for 3-fluoroveratrole,[17] 24 hr., 60°. The mixture was poured into 750 ml. of ice-water and the colorless solid recrystallized.

(b) (1) Structural Proof of Chloromethylveratrole Derivatives.—A solution of 1.5 g. of the chloromethyl derivative and 3.0 g. of potassium permanganate in 50 ml. of water and 1.0 ml. of 25% sodium hydroxide solution was refluxed for 1 hr., filtered from manganese dioxide and acidified. The precipitated benzoic acid derivatives were recrystallized. 2-Bromo-[16] and 2 fluoroveratric acid were identified by mixture melting points with samples prepared by unequivocal routes.

(2) 2-Fluoroveratric Acid.—An ice-cold stirred suspension of 23.7 g. of methyl 2-aminoveratrate[19] and fluoboric acid, prepared by saturating 60 ml. of 48% hydrofluoric acid with boric acid at 10°, was diazotized with 30 ml. of a 33% aqueous solution of sodium nitrite. The yellow diazonium fluoborate was filtered and recrystallized. For data, see Table II. Thirteen grams of the salt was decomposed by heating at 170° for 2 hr., the black tarry residue was distilled under reduced pressure and recrystallized.

A mixture melting point of the resulting methyl 2-fluoroveratrate with a sample obtained by diazomethane methylation of 2-fluoroveratric acid from the oxidation of 2-fluoroveratryl chloride showed no depression.

Saponification of 0.1 g. of methyl 2-fluoroveratrate with 0.5 ml. of a hot 10% sodium hydroxide solution yielded, upon acidification, 70 mg. (74.5%) of 2-fluoroveratric acid, m.p. 188–190°. A mixture melting point of this substance and of the acid procured by oxidation of 2-fluoroveratryl chloride remained undepressed.

(c) Diethyl Arylacetamidomalonates (III, VIII, XII, XXI).—To 250 ml. of an absolute ethanolic solution of 0.13 mole of sodium ethoxide were added 0.13 mole of diethyl acetamidomalonate and 0.13 mole of the 2-substituted chloromethylveratrole, and the mixture was stirred and refluxed for 8 hr. The precipitated sodium chloride was filtered, the filtrate concentrated under reduced pressure and the residue recrystallized.

(d) β-(2-Substituted-dimethoxyphenyl)-α-alanine Derivatives (IV, IX, XIII, XXII, XXVI).—To a solution of 2.0 g. of the respective diethyl arylacetamidomalonate in 5 ml. of glacial acetic acid was added 8 ml. of 37% hydrochloric acid, and the mixture was heated at 95° for 6 hr. The solvents were distilled under reduced pressure, the crystalline hydrochloride was triturated with dry acetone and recrystallized.

The free phenylalanine derivatives were prepared by buffering the aqueous solutions of the hydrochlorides with potassium carbonate to *p*H 5–6 and purifying by reprecipitation from dilute hydrochloric acid solution with the same reagent.

(e) Nuclear 2-Substituted Derivatives of DOPA.—(1) A solution of 8.5 g. of the diethyl malonate derivatives (VIII, XII) in 40 ml. of redistilled 47% hydrobromic acid was refluxed for 7 hr. while hydrogen was bubbled through, concentrated under reduced pressure at 90° and the residual hydrobromide was recrystallized. The amino acid was liberated by adjusting the concentrated aqueous solution of the pure salt to *p*H 5–6 with sodium acetate with the help of a trace of sodium hydrosulfite. The material crystallized on cooling.

(2) Solutions of 6.4 g. of the dimethoxyphenylalanine derivatives (IV, XXII) in 60 ml. of 47% hydriodic acid were refluxed for 7 hr., concentrated as above, and the amorphous residue was adjusted to *p*H 5–6 with a saturated solution of sodium acetate. The amino acids crystallized on prolonged standing.

(f) Azlactones.—Starting with 2-bromoisovanillin,[20] 2-nitroveratraldehyde[21] and 2-ethylveratraldehyde, respectively, a mixture of 0.08 mole of the aldehyde, 0.09 mole of hippuric acid and 0.09 mole of anhydrous sodium acetate and 35 ml. of acetic anhydride was heated at 95° for 3 hr. The mixture solidified; it was diluted with 100 ml. of absolute ethanol, cooled to 0° and the crystalline deposit was filtered and washed with water.

(g) Hydrolysis of Azlactones.—The azlactones were refluxed with 30 volumes of a 1% sodium hydroxide solution in 50% aqueous ethanol for 10 minutes, the mixture was filtered and the filtrate acidified with 10% hydrochloric acid. The precipitated oils crystallized on standing.

Reductive Cleavage of α-Benzamido-2-bromo-3-hydroxy-4-methoxycinnamic Acid.—To an ice-cold mixture of 35 ml. of acetic anhydride and 35 ml. of 57% hydriodic acid was added 3.5 g. of red phosphorus and 6.5 g. of the acid XVI, and the mixture was refluxed for 3 hr. After filtering from phosphorus and extraction with ether, the solution was evaporated to dryness under reduced pressure, the residue was taken up in 10 ml. of water and buffered to *p*H 5–6 with sodium acetate. After standing for several days, 2.5 g. (77%) of crystals deposited which were recrystallized from water, m.p. 280° dec. The compound contained no halogen and did not depress the melting point of β-(3,4-dihydroxyphenyl)-α-alanine.

2-Ethylveratraldehyde.—3-Ethylveratrole[22] (30 g.) was dropped with stirring into a suspension of 29.8 g. of powdered aluminum chloride in 21 ml. of benzene at 0°, and then an anhydrous solution of 18.6 g. of hydrogen cyanide in 25 ml. of benzene was added. A slow stream of anhydrous hydrogen chloride was passed through at 28–30° for 8 hr., and the dark red mixture was poured onto a mixture of 106 ml. of 37% hydrochloric acid and 250 g. of crushed ice. Excess hydrogen cyanide was boiled out, the cooled mixture was extracted with ether, the ether extract was dried and distilled. The aldehyde was a straw-colored oil, b.p. 145–148° (5 mm.), yield 24.8 g. (70.5%). It was converted to the **oxime** and **semicarbazone** (Table II).

Oxidation of the aldehyde with alkaline potassium permanganate or chromic acid yielded the same ethyldimethoxybenzoic acid, m.p. 152–154°, which also resulted from the oxidation of ethyldimethoxybenzyl chloride (XX).

α-Benzamido-2-ethyl-3,4-dimethoxyphenylpropionic Acid.—A solution of 1.0 g. of α-benzamido-2-ethyl-3,4-dimethoxycinnamic acid in 50 ml. of absolute ethanol containing 0.1 g. of Adams catalyst was hydrogenated under 3 atm. of pressure at 25° for 48 hr. and worked up as usual. The oily residue of the evaporated solution crystallized on standing. The yield was quantitative.

The benzamido group was hydrolyzed with a 5:8 mixture of glacial acetic acid and 37% hydrochloric acid as described under the general directions (d) above.

3-Benzamido-7,8-dimethoxy-3,4-dihydro-2-quinolone (XVIII).—A solution of 13.0 g. of α-benzamido-2-nitro-3,4-dimethoxycinnamic acid in 100 ml. of absolute ethanol was hydrogenated in the presence of 0.25 g. of platinum oxide at a pressure of 3 atmospheres for 24 hr. and worked up. The filtered solution deposited 4.5 g. (39%) of a colorless product on cooling, m.p. 223.5–226° after recrystallization from ethanol. The substance was insoluble in dilute acid and base.

Anal. Calcd. for $C_{18}H_{18}N_2O_4$: C, 66.24; H, 5.56. Found: C, 66.42; H, 6.23.

2-Chloro-3,4-dimethoxycinnamic Acid.—A mixture of 20.6 g. of 2-chloroveratraldehyde,[11] 10 g. of anhydrous sodium acetate and 20 ml. of acetic anhydride was heated at 170–180° for 8 hr., allowed to cool and diluted with 100 ml. of water. The solid precipitate was filtered and recrystallized.

β-(2-Chloro-3,4-dimethoxyphenyl)-β-alanine.—To a hot solution of 6.8 g. of sodium ethoxide in 80 ml. of ethanol was added a hot solution of 6.95 g. of hydroxylamine hydrochloride in 5 ml. of water. The mixture was cooled rapidly and the precipitated sodium chloride was filtered. To the filtrate was added 12.1 g. of 2-chloro-3,4-dimethoxycinnamic acid and the mixture heated on a steam-bath for 24 hr. After cooling, the crystalline product was filtered.

β-(2-Chloro-3,4-dihydroxyphenyl)-β-alanine (XXV).—A mixture of 1 g. of β-(2-chloro-3,4-dimethoxyphenyl)-β-alanine and 10 ml. of 57% hydriodic acid was refluxed for 5 hr., evaporated to dryness under reduced pressure and the residue was taken up in 5 ml. of water. Colorless crystals formed when the *p*H was adjusted to 6 with sodium acetate. They were filtered, washed with water, acetone and ether.

β-(2-Methyl-3,4-dimethoxyphenyl)-N-*p*-tosyl-α-alanine.—A mixture of 17 g. of β-(2-methyl-3,4-dimethoxyphenyl)-

(24) All melting points are corrected. Microanalyses by Miss Barbara J. Williamson.

α-alanine (XXVI), 17 g. of *p*-toluenesulfonyl chloride and 170 ml. of 4% sodium hydroxide solution was shaken for 24 hr. The reddish-black solution was filtered and acidified with 10% hydrochloric acid. The gummy precipitate solidified when the mixture was heated on a steam-bath for 30 minutes and was filtered.

β-(2-Methyl-3,4-dimethoxyphenyl)-N-methyl-N-*p*-tosyl-α-alanine.—To a stirred solution of 19.6 g. of β-(2-methyl-3,4-dimethoxyphenyl)-N-*p*-tosyl-α-alanine in 100 ml. of 10% sodium hydroxide solution was added 20 ml. of dimethyl sulfate, at room temperature. After 10 minutes, the mixture was made alkaline by adding 10% sodium hydroxide solution, diluted with 2 l. of water and heated on a steam-bath until solution was complete. After treatment with Darco the solution was acidified with dilute hydrochloric acid. The gummy solid became crystalline after standing for several hours.

β-(2-Methyl-3,4-dihydroxyphenyl)-N-methyl-α-alanine (XXIV).—A mixture of 2 g. of β-(2-methyl-3,4-dimethoxyphenyl)-N-methyl-N-*p*-tosyl-α-alanine and 17 ml. of 57% hydriodic acid was heated under reflux for 4 hr. The dark brown reaction mixture was concentrated under reduced pressure, the residue suspended in 20 ml. of water and extracted continuously with ether for 5 days. The clear aqueous layer was separated and concentrated to dryness under reduced pressure. When the residue was dissolved in 4 ml. of water and adjusted to *p*H 5–6, colorless crystals appeared.

5-Methylveratric Acid.—5-Methylvanillin[25] was methylated with dimethyl sulfate and 10% sodium hydroxide solution, as described for an analogous case,[26] and the crude oily 5-methylveratraldehyde was oxidized with alkaline potassium permanganate solution under the conditions used in the oxidation of 2-methylveratryl chloride.[11] Recrystallization from 50% aqueous ethanol gave colorless needles, m.p. 146–148°.

Anal. Calcd. for $C_{10}H_{12}O_4$: C, 61.21; H, 6.17. Found: C, 60.87; H, 5.91.

The $BF_3 \cdot N_2O_3$ Complex. Its Use in Diazotization and Nitration[1]

BY G. BRYANT BACHMAN AND TAKEO HOKAMA

RECEIVED JANUARY 2, 1957

Boron trifluoride reacts with nitrogen trioxide to form a stable, white, solid complex, $BF_3 \cdot N_2O_3$. Physical and chemical properties suggest that the structure is best represented as $(F_3B \leftarrow NO_2)^-(NO)^+$. The complex is a weak nitrating agent but a powerful diazotizing agent in the aromatic series.

It was reported recently that boron trifluoride forms a 1:1 addition complex with dinitrogen tetroxide[2] which is an excellent nitrating agent. It has now been found that boron trifluoride also forms a similar complex with dinitrogen trioxide. The combining ratio was determined gravimetrically to be 1:1. The complex is a white, stable solid, insoluble in all solvents with which it does not react, including alkanes, nitroalkanes and polychlorinated alkanes. It sublimes at room temperatures and does not melt in a sealed tube below 300°. Above this temperature, the very dark color of the dissociation products (especially NO_2) prevents observation of the remaining solid. These properties suggest that the complex is ionic in character and is formed as illustrated in equation 1 or 2

$$F_3B + ON\dot{:}NO_2 \longrightarrow \underset{A}{(F_3B \leftarrow NO_2)^-(NO)^+} \quad (1)$$

$$F_3B + O_2N\dot{:}NO \longrightarrow \underset{B}{(F_3B \leftarrow NO)^-(NO_2)^+} \quad (2)$$

That the preferred one of the above two formulations is A is probable on the basis of the chemical properties described below.

The $BF_3 \cdot N_2O_3$ complex reacts rapidly with substances with which BF_3 and N_2O_3 react separately, including water, alcohols, ethers, ketones, carboxylic acids, amines and pyridine. However, under rather vigorous conditions it will introduce an NO_2 group into aromatic nuclei. If benzene is refluxed over the complex in a glass fiber thimble in a Soxhlet extractor for 42 hr., a 5–6% yield of nitrobenzene is obtained. Under the same conditions, toluene yields a red-black tar, but in the solvent nitroethane at 60–65° for 3 days, toluene gives a 56% yield of *o*-nitrotoluene. Other nitration results are shown in Table I. It will be noted that the complex produces a different ratio of isomers than is reported for nitric acid nitrations of toluene, 1-nitronaphthalene and chlorobenzene. This apparently is the result of its mild nitrating action since the isomer distribution obtained represents increased amounts of the principal isomer produced in nitric acid nitrations. Powerful reagents favor a more nearly statistical distribution of isomers in aromatic substitution.

The nitrating action of the complex suggests structure B but does not preclude structure A since it has been shown by Ingold[3] that primary attack by a nitrosonium ion is probably a factor in the nitration of *p*-nitrophenol and *p*-chloroanisole. Furthermore it has been shown that nitrogen trioxide produces nitrosonium cations in the presence of another strong acid, namely, sulfuric acid.[4,5] In addition there remains the possibility that oxidation by air occurs during the nitration and converts the nitroso product to a nitro product or converts the complex $BF_3 \cdot N_2O_3$ to $BF_3 \cdot N_2O_4$ a known nitrating agent.[2] To test this, naphthalene was nitrated at 25° in three different ways: under air, under nitrogen, and with oxygen bubbling through the mixture. The second of these produced a low yield (14%) of 1-nitronaphthalene and

	4-Nitrochlorobenzene	50			
Cyclohexane	No reaction	..	4	*ca.* 80	Nitroethane

[a] An *ortho–para* ratio of 60:40 in the mononitration of toluene with mixed acids has been reported by A. F. Holleman, J. Vermeulen and W. J. deMooy, *Rec. trav. chim.*, **33**, 1 (1914). [b] In the nitration of *o*-nitrotoluene with mixed acids, a 91% yield of dinitrotoluene with a 66:34 ratio of 2,4- to 2,6-dinitrotoluene was obtained by W. H. Gibson, R. Deuckham and R. Fairbairns, *J. Chem. Soc.*, 121, 270 (1922). [c] A 1:2 ratio of 1,5- and 1,8-dinitronaphthalene was obtained in the nitration of 1-nitronaphthalene with mixed acids by H. H. Hodgson and J. S. Whitehurst, *J. Chem. Soc.*, 202 (1945). [d] An *ortho–para* ratio of 30:70 in the nearly quantitative mononitration of chlorobenzene by mixed acids was obtained by A. F. Holleman and B. R. deBruyn, *Rec. trav. chim.*, 19, 189 (1900). [e] No attempt was made to determine isomer distributions by highly refined techniques, such as infrared analyses. The results are believed, however, to be accurate enough to indicate marked differences between the nitrating actions of the complex and nitric acid.

much tar. The first and third produced good yields of 1-nitronaphthalene (>60%). The oxygen experiment also gave a considerable amount (13%) of mixed dinitronaphthalenes. We conclude that the nitrating action of the complex is negligible in the absence of oxidizing agents such as air or pure oxygen, and that the structure B for the complex is therefore unlikely.

The $BF_3 \cdot N_2O_3$ complex is a powerful diazotizing agent in inert (non-aqueous) solvents and will convert weak aromatic amines such as 2,4-dinitroaniline into diazonium salts in a few minutes at room temperatures or below. The diazonium salts formed are generally insoluble in the reaction medium and may be isolated readily in a pure, stable form by filtration. If heated, these salts decompose to form fluoro derivatives of the starting aromatic nucleus (Schiemann reaction). Thus, fluorobenzene is prepared readily in 56% yield by diazotizing aniline with the complex in nitrobenzene and then raising the temperature gradually to about 85° when nitrogen is smoothly evolved and fluorobenzene distills.

Another reaction which can be accomplished satisfactorily in non-aqueous solvents is the Gomberg–Bachmann reaction.[6] Thus, if the diazotization is carried out in benzene solution and then sodium acetate is added, nitrogen is evolved and the corresponding biphenyl derivative is formed. The yields of 2,4-dinitrobiphenyl and 4-chlorobiphenyl by this method were better than those reported by Hey.[7]

Alternatively, the isolated diazonium salt may be coupled with phenols or otherwise treated in aqueous solution in the customary manner. Table II shows some of the results obtained with a series of aromatic amines, most of which were selected because of their weak basicity and corresponding troublesomeness in ordinary diazotization procedures. It will be noted that the results were uniformly excellent except for the tetrazotizations of the *p*-phenylenediamines. Apparently the complex is not effective in preventing coupling between the diazotized intermediates and the unreacted diamine.

A study of the nitrosating action of the complex was made with diethyl malonate at −40° in nitroethane. A 39% yield of diethyl oximinomalonate and a 28% yield of diethyl mesoxalate were obtained, results which are comparable to those resulting by the action of N_2O_3 alone on diethyl malonate.[8] Ethyl propionate did not react with the complex in 12 hr. at its reflux temperature.

An addition reaction was attempted with the complex and cyclohexene in chloroform of 0°. A thick dark oil was obtained which decomposed on attempted vacuum distillation. Steam distillation produced very little volatile material and a non-volatile tar. The isolation procedures[9] used successfully in working up the reaction products of cyclohexene and N_2O_4 failed to yield identifiable products in this case.

Conclusions.—The complex $BF_3 \cdot N_2O_3$ is prepared readily and serves as a useful reagent in mild nitrations of aromatic compounds. It produces the usual isomers in different ratios than are normally obtained with nitric acid and absorbs oxygen (from the air) in the process. The complex is a powerful nitrosating agent and is especially useful and convenient in diazotizing weakly basic aromatic amines in non-aqueous solvents and in preparing pure, dry, stabilized diazonium salts. Decomposition of these diazonium salts by heat leads to the corresponding fluoro compounds

(Schiemann reaction). Isolation by filtration and reaction in aqueous media leads to the usual replacement reactions.

Experimental

Preparation of $BF_3 \cdot N_2O_3$.—Dry nitroethane (300 ml.) was placed in a 3-necked flask fitted with a stirrer, a reflux condenser having a calcium chloride drying tube at the top and a gas inlet tube extending below the surface of the liquid. The flask and contents were cooled to −20° with a Dry Ice–trichloroethylene bath and previously collected, dry, liquid nitrogen tetroxide,[2] 23 g. (0.5 mole), was added. Then dry nitric oxide gas was bubbled slowly into the solution while the bath temperature was lowered quickly to −70°. A low temperature is used to minimize the dissociation of N_2O_3 and to avoid the formation of $BF_3 \cdot 2NO_2$. Abel and Proisl[10] report that N_2O_3 is 90% dissociated at 25°, while Berl and Winnacker[11] report that it is not over 6% dissociated at −50°. Good cooling is essential since the complex formation is exothermic. When brown fumes began to be emitted from the condenser as a result of unabsorbed nitric oxide being oxidized to nitrogen dioxide by the air, the nitric oxide flow was stopped and a dry, gaseous, flow of boron trifluoride was started. This was continued until the blue color of the dinitrogen trioxide disappeared and white fumes of boron trifluoride appeared at the end of the condenser. The flask now contained a suspension of the white, solid complex in nitroethane. It could be used as such or the complex could be filtered off under anhydrous conditions, washed with an inert solvent and stored in stoppered bottles or suspended in another inert liquid medium.

In a series of five experiments, the combining mole ratios by weight of the reactants were determined in the absence of solvents. The results are shown in Table III. In order

TABLE III

COMPOSITION OF THE COMPLEX BY COMBINING WEIGHTS

Expt.	Dinitrogen trioxide Gram	Dinitrogen trioxide Mmoles	Boron trifluoride Gram	Boron trifluoride Mmoles	Mole ratio N_2O_3/BF_3
1	0.3785	4.98	0.3302	4.87	1.02
2	.2567	3.37	.2306	3.40	0.99
3	.1837	2.42	.1650	2.43	0.99
4	.2014	2.68	.1803	2.66	0.99
5	.3432	4.51	.3016	4.51	1.00
Av.	.2727	3.59	.2415	3.57	1.00

to be sure that the complex was not a mixture of the two complexes, $BF_3 \cdot 2NO$ and $BF_3 \cdot 2NO_2$, an attempt was made to form a complex between boron trifluoride and nitric oxide alone but without success. Furthermore no gas, including nitric oxide, was evolved during the addition of the boron trifluoride. Any evolution of nitric oxide would have led to the formation of $BF_3 \cdot 2NO_2$. Hence it may be concluded that the reactants combine in a 1:1 ratio and that the correct formula for the complex is $BF_3 \cdot N_2O_3$.

Nitration Procedure.—The complex was prepared in one of the lower nitroalkanes, and the material to be nitrated was added in about an equimolar amount. The temperature of mixing was adjusted to the expected reactivity of the aromatic compound, being about 0° for a substance such as naphthalene and room temperature for a substance such as *o*-nitrotoluene. The reaction mixture was allowed to stand or, if reaction was slow, it was heated until the insoluble complex disappeared. Boron trifluoride and oxides of nitrogen were evolved during the reaction. Eventually, the mixture was cooled, poured into water, the organic layer separated, dried and distilled or steam distilled. In some cases (*e.g.*, dinitronaphthalene), the product separated as a solid during the reaction. In such cases the solid was filtered off, washed with water and recrystallized.

The isomeric ratio of dinitronaphthalenes (1,5- and 1,8-) formed was determined by the method of Hodgson and Walker.[12] The ratio for the nitrochlorobenzenes and the nitrotoluenes (*o*- and *p*-) was determined by separating the isomers in part by distillation and in part by recrystallization from alcohol.

Diazotization Procedure.—The aromatic amine was added with stirring to a suspension of a 10% molar excess of the complex in dry chloroform at 0–5°. After 30 minutes, 20 ml. of ether was added to destroy the excess complex. The precipitated diazonium salt was filtered off and used as such.

Thermal Decomposition of Diazonium Salts.—The diazonium salt of aniline was prepared as described above except that the solvent was nitrobenzene instead of chloroform. After diazotization was complete the temperature was raised until nitrogen evolution began and fluorobenzene distilled; yield 56%, b.p. 84–85°.

The diazonium salt of *p*-nitroaniline was prepared in chloroform, isolated by filtration and decomposed by heating in the absence of solvent. The yield of *p*-nitrofluorobenzene was 43%, m.p. 26–27°, b.p. 203–205°.

p-Nitroaniline was diazotized in dibutyl phthalate, and the diazonium salt was decomposed by heating. The *p*-nitrofluorobenzene distilled from the reaction mixture amounted to a 5% yield.

Coupling Procedure.—The isolated diazonium salt was added with stirring to a solution of 2-naphthol in 10% sodium hydroxide. The precipitated azo dye was filtered off, washed with water and dried and recrystallized.

Replacement Reactions. (a) **In Aqueous Solvent.**—The isolated diazonium salt was added to a solution of potassium iodide in 50% phosphoric acid and allowed to stand overnight to obtain the corresponding iodide. (b) **In Non-aqueous Solvents (Gomberg–Bachmann Reaction).**—The diazonium salt was prepared in benzene, and 10% molar excess of sodium acetate and 2 ml. of acetic anhydride were added. The reaction mixture was heated with stirring until the evolution of nitrogen ceased and the benzene solution

was filtered. The solid obtained by removal of the benzene was purified according to the methods utilized in the literature references (*cf.* Table II).

Nitrosation Procedure.—Diethyl malonate, 55.0 g. (0.32 mole), was added dropwise at −40° to a suspension of 72.0 g. (0.45 mole) of complex in 300 ml. of nitroethane in a 500-ml. flask equipped with a dropping funnel, stirrer and reflux condenser. After 45 minutes the blue-colored mixture was allowed to warm to room temperature whereupon an exothermic reaction occurred which required cooling to maintain the temperature below 35°. When the reaction subsided, the mixture was washed with 5% sodium carbonate solution and water, dried and distilled. There were obtained: (a) diethyl mesoxalate, 11 g. (28%), b.p. 95–115° (18 mm.), hydrate m.p. 56°; (b) diethyl oximinomalonate, 25 g. (39%), b.p. 170–180° (18 mm.).

A 90% yield of diethyl mesoxalate was obtained by Curtiss[13] using gaseous N_2O_3 on diethyl malonate in the absence of solvent while Cerchez[6] reported a 50–90% yield of diethyl oximinomalonate using N_2O_3 and sodium ethoxide.

Dimethylaniline, 1.2 g., dissolved in 30 ml. of nitroethane, was added to a suspension of complex in nitroethane at 0–2°. The nitroethane was boiled off after washing with 5% sodium carbonate solution giving 1.5 g. of *p*-nitrosodimethylaniline, m.p. 84°.

Triphenylsilyl Phenyl Ketone

BY A. G. BROOK

RECEIVED APRIL 1, 1957

Triphenylsilyl phenyl ketone, the first reported α-silyl ketone, has been prepared. Although not susceptible to thermal rearrangement, it is readily decomposed by base to triphenylsilanol and benzaldehyde. It reacts abnormally with phenylmagnesium bromide and phenyllithium.

The abnormal behavior of substituents (especially halogen) attached to carbon alpha to a silicon atom has been referred to as the "α-silicon effect."[1,2] It is also apparent that functional groups located alpha to a silicon atom display unusual reactivity: the susceptibility of α-silanecarboxylic acids and their esters both to thermal rearrangement and to base-catalyzed decomposition have been reported recently from this Laboratory.[2] It seemed of interest to see whether this enhanced reactivity was present in other α-silylcarbonyl compounds, to which end the ketone, triphenylsilyl phenyl ketone, has been prepared. No α-silyl ketones have previously been reported in the literature, although indirect evidence for the formation of an α-silylaldehyde has been reported.[3]

Triphenylsilyl phenyl ketone was best prepared from triphenylbenzylsilane. Neither permanganate oxidation nor chromic acid oxidation yielded the desired compound, probably because of its instability, and only triphenylsilanol was isolated. Treatment with two equivalents of N-bromsuccinimide led to triphenylsilyl-α,α-dibromobenzylsilane. This compound was converted readily with silver acetate in an acetone–ethanol–water medium to the yellow ketone, m.p. 102–104°, in good yield. A phenylhydrazone derivative was prepared; attempts to prepare the oxime led to the formation of triphenylsilanol and benzaldehyde.

The ketone was also prepared, but in poor yield, by treatment of benzoyl chloride with an ethereal suspension of triphenylsilylpotassium: attempts to prepare it from triphenylsilane and benzoyl chloride using pyridine, aluminum chloride or boron fluoride as catalysts failed, and only tars or starting materials were isolated.

(3) L. H. Sommer, D. L. Bailey, G. M. Goldberg, C. E. Buck, T. S. Bye, F. J. Evans and F. C. Whitmore, *ibid.*, **76**, 1613 (1954).

That the ketone is colored is of interest since organosilicon compounds are generally colorless, a fact generally attributed to the failure of silicon to participate significantly in resonance hybridization.[4] In the present case the color is even more unusual since the carbon analog, β-benzopinacolone, is colorless. The infrared spectrum of the ketone shows apparently normal absorption for the benzoyl group at about 1575 and 1610 cm.$^{-1}$.

The ketone does not rearrange thermally. When heated to 250°, it was recovered almost quantitatively, and when heated to 365°, although some decomposition occurred, no carbon monoxide was eliminated, and 70% of the material was recovered unchanged. However, the compound is extremely labile in basic medium. If a dilute ethanol solution is treated at room temperature with a few drops of aqueous alkali, the yellow color disappears in a few minutes and triphenylsilanol and benzaldehyde are formed. The same reaction occurs when the compound is chromatographed on activated alumina, although it may be recovered by elution from acid-washed alumina. This decomposition is evidently analogous to the base-catalyzed decomposition of triphenylsilanecarboxylic acid and its esters.

$$Ph_3SiCOPh \xrightarrow{OH^-} Ph_3Si(OH)—CO—Ph \xrightarrow{HOH} Ph_3SiOH + PhCHO + OH^-$$

When triphenylsilyl phenyl ketone was treated with phenylmagnesium bromide, the expected product of addition to the carbonyl group, triphenylsilyldiphenylcarbinol, was not isolated. Instead, the only product isolated was tetraphenylsilane (5%), other than some recovered ketone and triphenylsilanol, presumably formed by decomposition of the ketone when the reaction mixture

Digitized by Arya Samaj Foundation Chennai and eGangotri

was hydrolyzed. The same product was isolated in 10% yield when phenyllithium was used. This product was probably formed by nucleophilic attack on silicon by the organometallic reagent analogously to the reaction described above, although, as will be shown in a forthcoming publication, the addition product triphenylsilyldiphenylcarbinol is itself decomposed by phenyllithium forming tetraphenylsilane in high yield.

$$Ph_3SiCOPh + PhLi \longrightarrow Ph_3-\overset{\curvearrowright}{Si}-COPh \longrightarrow \begin{matrix} \\ \vdots \\ Ph^- \ Li^+ \end{matrix}$$

$$Ph_4Si + \text{fragments}$$

From this and related work it seems probable that all α-silylcarbonyl compounds will be susceptible to base-catalyzed hydrolysis in which the silicon–carbonyl bond is broken.

Experimental[5]

Triphenyl-α,α-dibromobenzylsilane.—To 4.85 g. (0.0138 mole) of triphenylbenzylsilane[6] in 50 ml. of carbon tetrachloride was added 5.3 g. (0.030 mole) of N-bromosuccinimide. The mixture was refluxed for 18 hr., cooled and 3.05 g. (110%) of crude succinimide, m.p. 117–122°, was filtered off. The filtrate was evaporated to dryness under reduced pressure and the gummy solid recrystallized from ethyl acetate to yield 4.85 g. (70%) of crude white triphenyl-α,α-dibromobenzylsilane, m.p. 112–116°. One additional crystallization raised the melting point to 119–120°.

Anal. Calcd. for $C_{25}H_{20}SiBr_2$: Si, 5.51; Br, 31.5. Found: Si, 5.53; Br (as AgBr), 31.7.

Triphenylsilyl Phenyl Ketone. A. From Triphenyl-α,α-dibromobenzylsilane.—A mixture of 3.0 g. (0.059 mole) of triphenyl-α,α-dibromobenzylsilane and 2.0 g. (0.12 mole) of silver acetate in 40 ml. of ethanol, 15 ml. of water and 30 ml. of acetone was stirred at room temperature for 15 hr. The purplish-gray precipitate was filtered off and washed with acetone to yield 2.31 g. (103%) of silver bromide. The combined filtrates were evaporated to dryness under reduced pressure at room temperature to yield 1.99 g. of yellow powder, m.p. 90–99°. This was twice recrystallized from absolute ethanol to yield 1.67 g. (78%) of yellow needles, m.p. 102–103°.

Anal. Calcd. for $C_{25}H_{20}OSi$: C, 82.4; H, 5.53; Si, 7.70. Found: C, 82.7; H, 5.50; Si, 7.63.

When silver nitrate was used to remove the bromine, the same compound was obtained, but considerable decomposition occurred as indicated by the formation of triphenylsilanol and benzaldehyde (see below).

B. **From Triphenylsilylpotassium and Benzoyl Chloride.**[7]—To a solution of 2.81 g. (0.02 mole) of benzoyl chloride in 50 ml. of dry ether at 0° was added over an hour a suspension of 0.02 mole of amalgamated triphenylsilylpotassium in 100 ml. of ether. The green suspension was stirred for 14 hr. and then was hydrolyzed with water. Insoluble hexaphenyldisilane, m.p. 353–355°, weighing 1.66 g. (33%) was filtered off and identified by mixed melting point with an authentic specimen.

The ether layer, dried over sodium sulfate, was concentrated and then distilled under reduced pressure (1 mm.). There was isolated 0.13 g. (6%) of benzoyl chloride and 0.90 g. of a yellow solid boiling at 130–170°. Several recrystallizations from carbon tetrachloride and petroleum ether (b.p. 60–70°) yielded 0.28 g. (4%) of triphenylsilyl phenyl ketone, m.p. 102–104°, whose identity was confirmed by a mixed melting point with the material described above.

A phenylhydrazone derivative was prepared by refluxing a mixture of 0.5 g. (0.00137 mole) of the ketone in 8 ml. of ethanol with 0.18 g. of phenylhydrazine and 5 drops of glacial acetic acid for 5 minutes. During this time the yellow color of the original solution faded. On cooling white crystals were deposited which on recrystallization from 1:1 benzene–ethanol yielded 0.35 g. (56%) of almost colorless crystals, m.p. 150–151.5°.

Anal. Calcd. for $C_{31}H_{26}N_2Si$: C, 82.0; H, 5.78; N, 6.17. Found: C, 82.1; H, 5.77; N, 6.33.

Attempts to prepare the oxime by treatment of the ketone with hydroxylamine hydrochloride and pyridine in ethanol–water caused rapid fading of the yellow color. The odor of benzaldehyde was noticeable and a small amount of triphenylsilanol, m.p. 150–151°, was the only product isolated.

Attempted Thermal Rearrangement of Triphenylsilyl Phenyl Ketone.—A 0.5-g. sample of the ketone was heated in a small test-tube to 250° and held at this temperature for 5 minutes. No carbon monoxide[8] was evolved, but a faint odor of benzaldehyde was detected. After cooling the yellow solid melted at 100–102°, and one recrystallization from absolute ethanol gave 0.42 g. (84%) of ketone which melted at 102–103°.

When a 0.1-g. sample was heated at 365° for 10 minutes, no carbon monoxide was evolved, but a strong odor of benzaldehyde was observed and the color of the liquid darkened. The crude material melted at 88–93°, but one recrystallization from ethanol yielded 0.07 g. (70%) of ketone, m.p. 101–102°, identified by mixed melting point with an authentic specimen.

Reaction of Triphenylsilyl Phenyl Ketone with Alkali.—When 0.5 g. (0.00137 mole) of the ketone, dissolved in acetone (or ethanol), was treated with a few drops of 10% aqueous sodium hydroxide at room temperature, the yellow color rapidly faded (2–5 minutes). The odor of benzaldehyde was noticeable. When the solution was drowned in water, a white precipitate formed. After recrystallization from petroleum ether (b.p. 90–100°), this 0.34 g. (89%) of triphenylsilanol melted at 150–152°, and a mixed melting point with an authentic sample was not depressed.

To isolate the benzaldehyde, a hydrolyzed ethanol solution of the ketone was drowned in water and extracted 3 times with ether. The ether solution was treated with 1 ml. of phenylhydrazine, several drops of glacial acetic acid and 10 ml. of ethanol. The solution was boiled to remove the ether and then cooled. Fractional crystallization of the reaction mixture yielded a total of 0.23 g. (85%) of crude benzaldehyde phenylhydrazone, which after recrystallization from ethanol yielded 0.19 g. (70%) of pale yellow needles, m.p. 154–156°, which were identified by mixed melting point with an authentic specimen, m.p. 156–157°. In addition, 0.03 g. (8%) of triphenylsilanol, m.p. 150–152°, was isolated.

Reaction of Triphenylsilyl Phenyl Ketone with Phenylmagnesium Bromide and Phenyllithium.—When 2.0 g. (0.0055 mole) of triphenylsilyl phenyl ketone in 45 ml. of ether was treated with 2.5 ml. of 2.16 *N* phenylmagnesium bromide (0.0055 mole) no apparent change occurred until after 1 hr. when a white precipitate formed. The mixture was stirred for 18 hr. but still gave a positive Color Test I.[9] It was then hydrolyzed with water and acid. The yellow ether layer was worked up yielding a yellow oil which eventually partially crystallized. Recrystallization from benzene gave 0.1 g. (5%) of tetraphenylsilane, m.p. 233–235°, identified by mixed melting point. The residual oil was chromatographed on acid-washed alumina, eluting with petroleum ether (b.p. 60–70°), and although some decomposition occurred as evidenced by the loss of color, 0.18 g. (9%) of the ketone, m.p. 102–104°, was eventually isolated. Finally 0.23 g. (15%) of triphenylsilanol, m.p. 150–152°, was isolated and identified by mixed melting point.

When 2.0 g. (0.0055 mole) of the ketone in 30 ml. of dry ether was treated with 15 ml. of 0.5 *N* phenyllithium (0.0075 mole), the first few drops added caused a color change to orange and then to orange-red. A white solid then precipitated. The mixture was refluxed for 8 hr. at which time a positive Color Test I was obtained. The reaction mixture was poured into cold dilute acid. The only products isolated were 0.64 g. (42%) of crude triphenylsilanol, m.p. 135–145°, which was recrystallized from petroleum ether (b.p. 90–100°) to yield 0.32 g. (21%) of triphenylsilanol,

m.p. 149–151°, and 0.28 g. (15%) of crude tetraphenylsilane, m.p. 193–208°, which after recrystallization from benzene gave 0.18 g. (10%) of pure tetraphenylsilane, m.p. 230–232°, all products identified by mixed melting point.

10-(3-Dimethylaminopropyl)-2-(Trifluoromethyl)-phenothiazine Hydrochloride (VESPRIN[1]) and Related Compounds. I

BY HARRY L. YALE, FRANCIS SOWINSKI AND JACK BERNSTEIN

RECEIVED MARCH 18, 1957

The thionation of 3-(trifluoromethyl)-diphenylamine has yielded 2- and 4-(trifluoromethyl)-phenothiazine. These two nuclei have been allowed to react with various dialkylaminoalkyl chlorides in the presence of sodamide to give 10-dialkylaminoalkyl-2- and 4-(trifluoromethyl)-phenothiazine. Hydrogen peroxide has converted these compounds to various oxygenated derivatives. An improved procedure is described for the preparation of 3-(trifluoromethyl)-phenothiazine. Since this nucleus did not react with dimethylaminopropyl chloride in the presence of sodamide, an indirect procedure was used to prepare the 10-(3-dimethylaminopropyl) derivative.

We have for several years been interested in variously substituted phenothiazine derivatives[2] and wish now to report on a series of 10-dialkylaminoalkyl-2-, -3- and -4-(trifluoromethyl)-phenothiazines and their oxygenated derivatives. Several of these compounds have shown good specificity and high potency as ataractic agents in laboratory animals[3] and are now undergoing clinical evaluation.

The thionation of 3-(trifluoromethyl)-diphenylamine should lead to the formation of both 2-(trifluoromethyl)-phenothiazine and 4-(trifluoromethyl)-phenothiazine. From such a reaction, however, Smith[4] isolated only one (trifluoromethyl)-phenothiazine. This compound showed a deep band in the infrared at 12.17 μ, an absorption band not seen in the spectrum of phenothiazine itself. Since the infrared spectra of asymmetrical trisubstituted benzenes show a characteristic deep band in the region 12.0–12.5 μ while vicinal trisubstituted benzenes show a characteristic deep band in the region 12.5–13.15 μ, Smith concluded that his product was 2-(trifluoromethyl)-phenothiazine. This method of differentiating isomers in monosubstituted phenothiazines received additional support in the observation of Roe and Little[5] that 3-(trifluoromethyl)-phenothiazine, prepared by an unambiguous synthesis, showed a deep band in the infrared at 12.2 μ.

The work of Charpentier[6] has demonstrated that the thionation of 3-substituted diphenylamines, *e.g.*, 3-methyldiphenylamine, leads to 2- and 4-substituted phenothiazines; the less soluble, higher melting isomer (m.p. 187–188°) when heated with copper bronze gave 2-methylcarbazole, while the more soluble, lower melting isomer (m.p. 114–115°) gave 4-methylcarbazole.

We have re-examined the thionation of 3-(trifluoromethyl)-diphenylamine, and have isolated both 2-(trifluoromethyl)-phenothiazine, m.p. 188–189°, in 45% yield, and the hitherto unreported 4-(trifluoromethyl)-phenothiazine, m.p. 72–73° in 32% yield. It is of interest that the latter isomer showed a strong band at 12.7 μ, as anticipated, since it corresponds to a *vicinal* substituted benzene.

3-(Trifluoromethyl)-phenothiazine was prepared in one step in 52% yield by Roe and Little[5] *via* the Smiles rearrangement of 2-formamido-2′-nitro-4′-(trifluoromethyl)-diphenyl sulfide. Based on our own experience, we prefer the two step modification of the Smiles rearrangement, which employed the *2-acetamido derivative* and which gave a 91% yield over-all.

The reactions of 2- and 4-(trifluoromethyl)-phenothiazine with various dialkylaminoethyl chlorides and dialkylaminopropyl chlorides in toluene or xylene, in the presence of sodamide, gave the desired 10-substituted derivatives in good yields. The reaction of 3-(trifluoromethyl)-phenothiazine with dimethylaminopropyl chloride under the same conditions was unsuccessful. Instead of the usual dark brown colored reaction mixtures, deep violet colored solutions were obtained, which, even after prolonged reflux periods, when cooled and hydrolyzed with water became colorless and when worked up in the usual manner yielded only unreacted 3-(trifluoromethyl)-phenothiazine. It became necessary to use the indirect procedure outlined below which gave the desired product.

2-(Trifluoromethyl)-10-phenothiazinepropionitrile[7] and lithium aluminum hydride gave 10-(3-aminopropyl)-2-(trifluoromethyl)-phenothiazine.

The preparation of 10-(4-dimethylaminobutyl)-2-(trifluoromethyl)-phenothiazine followed the sequence of reactions shown below, employing 4-

chlorobutyl-2-tetrahydropyranyl ether as the side chain precursor; several of the intermediates were high boiling viscous oils which were difficult to obtain analytically pure, although the final product, as the hydrochloride, was easily purified.[8] It was observed that during the reaction of thionyl chloride with 10-(4-hydroxybutyl)-2-(trifluoromethyl)-phenothiazine some cleavage to 2-(trifluoromethyl)-phenothiazine occurred. This is not surprising since Charpentier[9] found that 10-(2-dimethylaminopropyl)-phenothiazine and boiling 48% hydrobromic acid readily gave phenothiazine and 2-dimethylaminopropyl bromide, hydrobromide.

These 10-dialkylaminoalkyl-2- and 4-(trifluoromethyl)-phenothiazines were obtained as viscous

[a] Titratable N with $HClO_4$ in glacial acetic acid. [b] Base was not distilled but converted directly to hydrochloride. [c] The 2-dimethylaminopropyl side chain is tentatively assigned to this compound by analogy with similar compounds prepared by P. Charpentier, *et al.*, *Compt. rend.*, **225**, 306 (1947); **232**, 415 (1951), by the reaction of phenothiazine with 1-dimethylamino-2-chloropropane. As shown by Charpentier and also by N. D. Edge and W. R. Wragg, *J. Pharm. Pharmacol.*, **5**, 279 (1953), this reaction leads to two isomers. The isomer formed in the larger quantity has the 2-dimethylaminopropyl side chain and can be separated from the isomeric product with the 2-dimethylamino-1-methylethyl side chain by fractional crystallization of their hydrochlorides. The less soluble hydrochloride has the 2-dimethylaminopropyl side chain. [d] Recrystallized successively from dry chlorobenzene and from absolute isopropyl alcohol. [e] Recrystallized from dry chlorobenzene. [f] Recrystallized from acetonitrile. [g] Recrystallized from absolute ethanol–ether. [h] Recrystallized from dry toluene. [i] Recrystallized from dry benzene. [j] Recrystallized from water. [k] Recrystallized from dry xylene.

(8) This procedure is very briefly outlined in U. S. Patent 2,645,640 (July 14, 1953) as the method used to prepare 2-chloro-10-(4-dimethylaminobutyl) phenothiazine.

(9) P. Charpentier, P. Gailliot and J. Gaudechon, *Compt. rend.*, **232**, 2232 (1951).

liquids which could be distilled *in vacuo* without decomposition; they formed crystalline hydrochlorides and acid oxalates. Their properties along with analytical data are summarized in Tables I, II and III.

It was of interest that 10-dimethylaminopropyl-2-(trifluoromethyl)-phenothiazine hydrochloride showed a deep band at 12.2 μ, 10-dimethylaminopropyl-3-(trifluoromethyl)-phenothiazine hydrochloride a deep band at 12.3 μ and 10-dimethylaminopropyl-4-(trifluoromethyl)-phenothiazine a deep band at 12.6 μ.

The 10-dialkylaminoalkyl-2- and 4-(trifluoromethyl)-phenothiazines were converted to the **5-oxide derivatives** by refluxing the oxalate in ethanol with one molar equivalent of 30% hydrogen peroxide. The N,5-dioxides were obtained by refluxing the base in ethanol with two molar equivalents of 30% hydrogen peroxide. To prepare the 5,5-dioxides, the 2- and 4-(trifluoromethyl)-phenothiazines were first converted to the **10-acetyl derivatives** and the latter in glacial acetic acid were oxidized with an excess of 30% hydrogen peroxide; during the latter step, as was observed previously,[2] deacetylation also occurred and the product obtained was 2- or 4-(trifluoromethyl)-phenothiazine-5,5-dioxide. These 5,5-dioxides, either because of their insolubility or lack of reactivity under the usual condensation conditions, gave low yields of the 10-3-dimethylaminopropyl derivatives.

In the ultraviolet, 10-dimethylaminopropyl-2-(trifluoromethyl)-phenothiazine hydrochloride showed two maxima at 255 and 305 mμ ($E^{1\%}_{1cm}$ 700, 90); four maxima, however, were shown by the corresponding 5-oxide, 235, 278, 302 and 348 mμ ($E^{1\%}_{1cm}$ 608, 256, 177, 116) and the corresponding N,5-dioxide 233, 274, 303 and 348 mμ ($E^{1\%}_{1cm}$ 548, 257, 173, 119); in the infrared, the latter two compounds showed deep bands at 9.8 μ, which is attributed to the S → O group.

The pertinent data on the oxygenated 10-dialkylaminoalkyl-(trifluoromethyl)-phenothiazines are summarized in Table IV.

Acknowledgment.—The microanalyses were carried out by Mr. Joseph F. Alicino and his associates. The infrared and ultraviolet spectra were determined by Dr. Nettie Coy and her associates.

Experimental Part

All melting and boiling point temperatures are uncorrected.

2- and 4-(Trifluoromethyl)-phenothiazines.—A mixture of 506 g. (2.14 moles) of 3-(trifluoromethyl)-diphenylamine, 134 g. (4.18 moles) of sulfur and 12.9 g. of iodine were fused at 150–160° for 3.5 hr. and the hot melt poured into 3.5 l. of warm toluene. The toluene solution was heated to boiling, treated with Hyflo and filtered hot. The filtrate was cooled to −5° and filtered to give 216 g. of 2-(trifluoromethyl)-phenothiazine, m.p. 183–185; concentration of the mother liquors by one-half and cooling gave an additional 45 g. of product. The over-all yield was 261 g. (45%). The filtrate from the second crop was freed of toluene and the residue distilled. The viscous distillate, b.p. 172–175° (0.5 mm.), solidified on cooling. It was recrystallized from ligroin to give 185 g. (32% yield) of 4-(trifluoromethyl)-phenothiazine, m.p. 72–73°.

Anal. Calcd. for $C_{13}H_8F_3NS$: C, 58.41; H, 3.01. Found: C, 58.84; H, 3.08.

10-(3-Dimethylaminopropyl)-2-(trifluoromethyl)-phenothiazine Hydrochloride.—The following description represents a typical preparation. A mixture of 26.7 g. (0.1 mole) of 2-(trifluoromethyl)-phenothiazine, 4.7 g. (0.12 mole) of sodamide, 14.6 g. (0.12 mole) of 3-dimethylaminopropyl chloride and 500 ml. of dry xylene was stirred and refluxed 17 hr. and the hot solution filtered. The filtrate

was concentrated *in vacuo*, the residue was taken up in 400 ml. of ether and the ether solution was extracted with 200, 100 and 100 ml. of 5% hydrochloric acid. The hydrochloric acid extracts were washed with ether, made strongly alkaline with 40% aqueous sodium hydroxide and the base extracted with ether; the ether extracts were dried, concentrated and distilled to give 30 g. (85% yield) of product, b.p. 176° (0.7 mm.), $n^{23}D$ 1.5780.

The above distilled base in 300 ml. of dry ether was cooled and treated with a slight excess of ethereal HCl. The precipitated **hydrochloride** was filtered and dried; it weighed 34.0 g., m.p. 165–168° dec. A recrystallization from xylene gave 26.5 g. (69% yield) of product, m.p. 172–174° dec.

10-(3-Dimethylaminopropyl)-3-(trifluoromethyl)-phenothiazine Hydrochloride. 2-[2-Nitro-4-(trifluoromethyl)-phenylthio]-acetanilide.—A mixture of 23.7 g. (0.075 mole) of 2-[2-nitro-4-(trifluoromethyl)-phenylthio]-aniline, 35 ml. of acetic anhydride and 2.5 ml. of pyridine was heated on the steam-bath for 1.5 hr. and then concentrated *in vacuo* to a small volume. The product which crystallized on cooling was filtered, washed consecutively with water, 5% aqueous sodium bicarbonate and water and dried to give 24.9 g. (93% yield) of the **acetanilide**, m.p. 148–149°. An analytical sample, from isopropyl alcohol, melted at 148–149°.

Anal. Calcd. for $C_{15}H_{11}F_3N_2O_3S$: C, 50.55; H, 3.08. Found: C, 50.88; H, 3.11.

To a nitrogen diffused solution of 22 g. (0.33 mole) of 85% potassium hydroxide in 375 ml. of 95% ethanol was added 3.0 l. of acetone, the mixture was stirred and again diffused with nitrogen, 119.5 g. (0.33 mole of the **acetanilide** was added and the mixture distilled rapidly from the steam-bath. The residual material was treated with 1.8 l. of ether and 275 ml. of water, the ether layer was separated, washed with saturated sodium chloride solution, dried and concentrated. The **10-acetyl-3-(trifluoromethyl)-phenothiazine** was isolated as a viscous *gum*. This gum was dissolved in a mixture of 250 ml. of 95% ethanol and 50 ml. of concentrated hydrochloric acid and the solution refluxed for 2 hr. The cooled mixture was filtered to give 80 g. of **3-(trifluoromethyl)-phenothiazine**, m.p. 213–215° (lit.[5] m.p. 217–218°). The filtrate when concentrated to dryness gave 6 g. of additional material, m.p. 214–216°. The combined yield was 86 g. (96%). A mixture of 46.8 g. (0.175 mole) of 3-(trifluoromethyl)-phenothiazine, 125 ml. of acrylonitrile and 2 ml. of 40% Triton B was warmed to initiate reaction and then refluxed for 1 hr. The solution was concentrated to a small volume, cooled and the solid filtered. The crude product was recrystallized from acetone to give 34.7 g. (62% yield) of 3-(trifluoromethyl)-10-phenothiazinepropionitrile, m.p. 110–111°.[10]

Anal. Calcd. for $C_{16}H_{11}F_3N_2S$: N, 8.74. Found: N, 9.10.

To an ice-cooled slurry of 6.4 g. (0.17 mole) of lithium aluminum hydride in 500 ml. of anhydrous ether, with stirring, was added, in portions, 27.3 g. (0.085 mole) of 3-(trifluoromethyl)-10-phenothiazinepropionitrile. Subsequently, the mixture was refluxed and stirred for 1 hr., cooled and decomposed by the addition of 25 ml. of water and 10 ml. of 20% aqueous sodium hydroxide. The ether solution was separated, dried, concentrated and distilled to give 9.3 g. (33% yield) of **10-(3-aminopropyl)-3-(trifluoromethyl)-phenothiazine**. To the **3-aminopropyl derivative**, 9.2 g. (0.028 mole) in 14.7 g. (0.28 mole) of formic acid, was added 7 g. (0.086 mole) of 37% formalin and the mixture heated in an oil-bath at 90–100° for 8 hr. The mixture was cooled, filtered and the filtrate treated with 30.4 ml. of 0.955 *N* aqueous hydrochloric acid. The mixture was concentrated to dryness *in vacuo*, the residue was dissolved in 100 ml. of water and then made alkaline with an excess of 20% aqueous sodium hydroxide. **The base** was isolated, distilled and converted to the hydrochloride in the manner described above.

10-(4-Dimethylaminobutyl)-2-(trifluoromethyl)-phenothiazine Hydrochloride. 10-[4′-(2″-Tetrahydropyranoloxy)-1′-butyl]-2-(trifluoromethyl)-phenothiazine.—A mixture of 66.8 g. (0.25 mole) of 2-(trifluoromethyl)-phenothiazine, 11.7 g. (0.30 mole) of sodamide and 750 ml. of dry xylene were refluxed for 2 hr. The reaction mixture was cooled, and a solution of 58.6 g. (0.30 mole) of 2-tetrahydropyranyl-4-chlorobutyl ether[8] in 250 ml. of dry xylene was added dropwise. The mixture was then refluxed for 3.5 hr., filtered hot and the xylene removed *in vacuo*. The residue was extracted with 500 ml. of ether, the filtered ether extracts were concentrated and the residue distilled to give 97.8 g. (96% yield) of crude product, b.p. 200–202° (0.2 mm.). *Anal.* Calcd. for $C_{22}H_{24}F_3NOS$: C, 64.84; H, 5.93. Found: C, 62.44; H, 5.67. **10-(4-Hydroxybutyl)-2-(trifluoromethyl)-phenothiazine.**—A solution of 97.8 g. (0.24 mole) of the **pyranyl derivative**, 25 ml. of concentrated hydrochloric acid and 1 l. of 75% ethanol was refluxed for 1 hr. The alcohol was then distilled from the steam-bath and the residue extracted with ether. The dried ether extracts were concentrated and distilled to give 64.8 g. (79% yield) of product, b.p. 178–181° (0.3 mm.). *Anal.* Calcd. for $C_{17}H_{16}F_3NOS$: C, 60.10; H, 4.75. Found: C, 60.93; H, 4.93. **10-(4-Chlorobutyl)-2-(trifluoromethyl)-phenothiazine.** To a refluxing solution of 9.8 g. (0.03 mole) of 10-(4-hydroxybutyl)-2-(trifluoromethyl)-phenothiazine in 65 ml. of dry benzene was added dropwise 3.6 g. (0.03 mole) of thionyl chloride. The mixture was then refluxed for 1 hr. and poured into 50 ml. of ice-water. The mixture was treated with an excess of solid sodium bicarbonate, the organic layer was separated and the aqueous layer extracted with ether. The combined dried extracts were then concentrated and the residue distilled to give 6.6 g. of crude product, b.p. 182–185° (0.7 mm.), which was contaminated with some (2-trifluoromethyl)-phenothiazine. This crude distillate was dissolved in 25 ml. of boiling hexane and the solution cooled; the (2-trifluoromethyl)-phenothiazine was filtered off. Concentration of the filtrate gave 5.2 g. (48% yield) of crude product suitable for the next step.

Anal. Calcd. for $C_{17}H_{15}ClF_3NS$: Cl, 9.90. Found: Cl, 7.69.

10-(4-Dimethylaminobutyl)-2-(trifluoromethyl)-phenothiazine Hydrochloride.—A solution of 5.0 g. of crude 10-(4-chlorobutyl)-2-(trifluoromethyl)-phenothiazine in 10 ml. of anhydrous dimethylamine was kept in a sealed tube for seven days at room temperature. The tube was opened, the excess dimethylamine allowed to evaporate and the pasty residue dissolved in 50 ml. of 10% hydrochloric acid. This

(10) This cyanoethylation procedure has been used by Smith, ref. 7, in the reaction between 2-(trifluoromethyl)-phenothiazine and acrylonitrile.

acid solution was extracted with three 50-ml. portions of ether, treated with an excess of 20% potassium hydroxide and the liberated base extracted with ether. Concentration of the ether extracts gave 4.2 g. (82% yield) of **base** as a viscous oil. The oil, in ether, was converted to the hydrochloride in the usual manner.

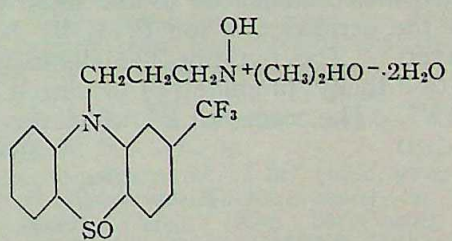
10-(3-Diethylaminopropyl)-2-(trifluoromethyl)-phenothiazine 5-Oxide. 10-(3-Diethylaminopropyl)-2-(trifluoromethyl)-phenothiazine Oxalate.—To 11.4 g. (0.03 mole) of 10-(3-diethylaminopropyl)-2-(trifluoromethyl)-phenothiazine in 100 ml. of 95% ethanol was added a solution of 2.7 g. (0.03 mole) of anhydrous oxalic acid in 10 ml. of 95% ethanol; the oxalate separated directly and was filtered to give 14.1 g. (100% yield) of product, m.p. 192–194° dec., unchanged by recrystallization from water. This product, in a mixture of 250 ml. of 95% ethanol and 100 ml. of water, was treated with 3.4 ml. of 30% hydrogen peroxide and the solution refluxed for 17 hr. The mixture was concentrated *in vacuo* to give a quantitative yield of the **oxalate of the 5-oxide**, m.p. 229–230° dec. The m.p. was unaffected by a recrystallization from *n*-butyl alcohol. This latter product was decomposed with warm 10% aqueous sodium hydroxide and the **base** extracted with chloroform. The chloroform extracts were concentrated to dryness and the crystalline residue recrystallized from Skellysolve E to give **10-(3-diethylaminopropyl)-2-(trifluoromethyl)-phenothiazine 5-oxide.**

10-(3-Diethylaminopropyl)-2-(trifluoromethyl)-phenothiazine N,5-Dioxide Hydrochloride.—A solution of 11.4 g. (0.03 mole) of 10-(3-diethylaminopropyl)-2-(trifluoromethyl)-phenothiazine, 100 ml. of 95% ethanol and 6.8 ml. of 30% hydrogen peroxide was refluxed for 17 hr. and then concentrated to dryness. The residual oil crystallized. The crude **base** could be recrystallized from ethyl acetate or methyl ethyl ketone–hexane and formed colorless crystals, m.p. 136–138° dec. On standing, however, the crystals changed to a deep yellow color; satisfactory analytical data could not be obtained. The crude base was dissolved in 200 ml. of boiling methyl ethyl ketone, the solution was cooled and treated with an excess of ethereal HCl; the salt which separated was filtered and recrystallized from a mixture of glacial acetic acid–dry ether to give the product.

10-(3-Dimethylaminopropyl)-4-(trifluoromethyl)-phenothiazine 5,5-Dioxide Hydrochloride.—A mixture of 40 g. (0.15 mole) of 4-(trifluoromethyl)-phenothiazine 75 ml. of acetic anhydride and 4 ml. of pyridine was refluxed for 4 hr. and then concentrated to dryness. The residual solid was washed with hexane to give 45.9 g. (quantitative yield) of crude 10-acetyl-4-(trifluoromethyl)-phenothiazine, m.p. 135–137°. An analytical sample was recrystallized from isopropyl alcohol and melted at 140–141°. *Anal.* Calcd. for $C_{15}H_{10}F_3NOS$: C, 58.24; H, 3.23. Found: C, 57.81; H, 3.27. **The acetyl derivative**, 30.3 g. (0.098 mole), 33.3 g. of 30% hydrogen peroxide, 225 ml. of glacial acetic acid and 25 ml. of acetic anhydride were refluxed for 4 hr. and the mixture cooled. The solid which separated was filtered; it weighed 19.7 g., m.p. 273–274°. A recrystallization from aqueous Cellosolve raised the m.p. to 275–276°. As noted previously, deacetylation had occurred during the oxidation so that the product obtained was **4-(trifluoromethyl)-phenothiazine 5,5-dioxide.** The yield was 68%. *Anal.* Calcd. for $C_{13}H_8F_3NO_2S$: C, 52.17; H, 2.69. Found: C, 52.06; H, 2.86. The condensation between 14.1 g. (0.047 mole) of 4-(trifluoromethyl)-phenothiazine 5,5-dioxide, 0.1 mole of 3-dimethylaminopropyl chloride and 2.7 g. (0.07 mole) of sodamide in 250 ml. of xylene was carried out under the usual conditions. The reaction mixture was filtered hot and the filtrate concentrated to dryness. The residue, 1.7 g., m.p. 159–160°, was recrystallized from toluene to give 1.4 g. (8% yield) of **10-(3-dimethylaminopropyl)-4-(trifluoromethyl)-phenothiazine 5,5-dioxide**, m.p. 164–165°. To 1.3 g. of the **5,5-dioxide** in 25 ml. of warm toluene was added slowly with stirring a slight excess of ethereal hydrogen chloride. The solid which separated, m.p. 233–235°, was recrystallized from acetonitrile–ether to give 1 g. (70% yield) of **10-(3-dimethylaminopropyl)-4-(trifluoromethyl)-phenothiazine 5,5-dioxide hydrochloride**, m.p. 240–241°.

10-(3-Dimethylaminopropyl)-2-(trifluoromethyl)-phenothiazine 5-Oxide, Hydrochloride.—To a solution of 9.7 g. (0.036 mole) of 10-(3-dimethylaminopropyl)-2-(trifluoromethyl)-phenothiazine in 25 ml. of acetonitrile was added 3.28 g. (0.036 mole) of oxalic acid in 10 ml. of acetonitrile. **The oxalate** separated directly and was filtered; the crude product, m.p. 193–195° dec., was recrystallized from acetonitrile to give 6 g. (49% yield) of pure product, m.p. 196–197° dec. A solution of 6 g. of the **oxalate**, 150 ml. of absolute ethanol and 1.6 g. of 30% hydrogen peroxide when refluxed for only 1 hr. began to deposit a crystalline product; after 5 hr. of refluxing, heating was interrupted and the mixture was cooled and filtered to give 5.5 g. (88% yield) of the **oxalate of the 5-oxide derivative**, m.p. 213–215° dec.; a recrystallization from 95% ethanol did not affect the m.p. The oxalate was decomposed with warm 5% aqueous sodium hydroxide, the liberated base extracted with ether, the ether solution was dried and treated with an excess of ethereal hydrogen chloride. The hydrochloride which separated was filtered and recrystallized from chlorobenzene to give 2.5 g. (55% yield) of 10-(3-dimethylaminopropyl)-2-(trifluoromethyl)-phenothiazine 5-oxide hydrochloride, m.p. 203–205°.

10-(3-Dimethylaminopropyl)-2-(trifluoromethyl)-phenothiazine N,5-Dioxide Trihydrate.—A mixture of 15.4 g. (0.044 mole) of 10-(3-dimethylaminopropyl)-2-(trifluoromethyl)-phenothiazine, 150 ml. of 95% ethanol and 10 ml. of 30% hydrogen peroxide was refluxed for 24 hr. and concentrated on the steam-bath. The residual oil crystallized partially when kept in the cold. A wash with 50 ml. of dry ether removed the oily by-product and left behind a nicely crystalline material. After recrystallization from methyl ethyl ketone, the product sintered at 80° and melted with decomposition at 135–137°. An analytical sample when pistol-dried at 58° lost considerable weight; the dried sample thus obtained was very hygroscopic in air, forming a trihydrate. Since the product is 2% soluble in water at room temperature, it is suggested that the hydrated compound probably has the structure



2-(Trifluoromethyl)-phenothiazine 5,5-Dioxide.—A mixture of 13.4 g. (0.05 mole) of 2-(trifluoromethyl)-phenothiazine, 25 ml. of acetyl chloride and 50 ml. of acetic anhydride was refluxed for 4 hr. and then concentrated *in vacuo* on the steam-bath. To the viscous residue was added 50 ml. of glacial acetic acid and 17 ml. of 30% hydrogen peroxide. The mixture was gradually heated to the boiling point at which temperature a vigorous exothermic reaction occurred. The source of heat was removed until the reaction subsided after which the mixture was refluxed for 4 hr. During this time a crystalline solid began to separate. The mixture was cooled and filtered to give 13.5 g. (90% yield) of product, m.p. 265–267°. On recrystallization from 95% ethanol, the product melted at 268–270°. Again, deacetylation has occurred during the oxidation.

Anal. Calcd. for $C_{13}H_8F_3NO_2S$: C, 52.19; H, 2.70. Found: C, 52.22; H, 2.87.

Synthesis of Thieno[b]quinolizinium Salts

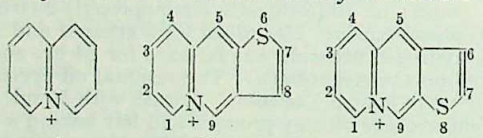
BY M. NEEMAN,[1] E. KRAKAUER AND Y. SHORR

RECEIVED JANUARY 28, 1957

3-Thenyl bromide and pyridine-2-aldehyde reacted to form a quaternary salt, which was cyclodehydrated in boiling hydrobromic acid. The structure of the product, thieno[2,3-b]quinolizinium bromide, was established by desulfurization–reduction with Raney nickel to 3-ethylquinolizidine hydrobromide, which was converted into its known picrate. An analogous synthesis starting from 2-thenyl chloride and pyridine-2-aldehyde yielded a small amount of product to which the structure of thieno[3,2-b]quinolizinium bromide is assigned. The linear thieno- and benzoquinolizinium ions show ultraviolet spectra of considerable similarity.

The synthesis of the quinolizinium ion I is of recent date.[2,3] A number of benzologs of the quinolizinium ion have been reported.[4–6]

The present study was undertaken to prepare heterocyclic ions of a new type, in which the quinolizinium ion is condensed with a thieno ring (thienologs of quinolizinium). The synthesis of the two linear thieno[b]quinolizinium ions (II) and (III) was attempted first, as it was expected that the two linear isomers would be accessible by cyclodehydration of more readily available inter-



I II III

mediates than would be required for the synthesis of any of the six possible angular isomers, or of the third linear isomer, thieno[3,4-b]quinolizinium ion.

The synthesis of the thieno[2,3-b]quinolizinium ion was effected in good over-all yield (72%) by a reaction sequence analogous to the reported synthesis of the acridizinium ion (VII) by Bradsher and Beavers.[5] The pyridine-2-aldehyde (IV) reacted with 3-thenyl bromide (V) to form a quaternary salt VI. The crude salt VI, which was not isolated, was cyclized in boiling aqueous hydrobromic acid to thieno[2,3-b]quinolizinium bromide (II·Br⁻). The product had an ultraviolet absorption spectrum (Table I) which was closely related to that of the acridizinium ion (VII).[5] The new heterocyclic ion II showed a spectrum which indicated a high degree of conjugation.

379.5	4.01				
				387	4.11
399	3.93				

The structure of II was established by desulfurization–reduction of its bromide with Raney nickel to a sulfur-free hydrobromide (VIII·HBr), which was converted into a picrate. The latter was proved to be 3-ethylquinolizidine picrate (VIII·picrate)[7] by comparison of infrared spectra and melting points with an authentic sample kindly supplied by Dr. Boekelheide. Apparently the same racemate was obtained by both routes. The ultraviolet and infrared spectra of VIII·HBr support this structure. Hence, the formally possible isomeric structure of thieno[3,4-b]quinolizinium ion is excluded for the product of the cyclodehydration. This result is in accord with the known higher electron density at the α-position relative to that at the β-position of thiophene.[8] Accordingly, the electrophilic cyclizing attack at the α-position of thiophene in VI was favored.

The reaction of 2-thenyl chloride with pyridine-2-aldehyde was considerably slower than the corresponding quaternization with 3-thenyl bromide. The glassy reaction product gave an intractable black residue after attempted cyclization with boiling 48% hydrobromic acid. A crystalline reaction product could be isolated in 4% yield by alumina chromatography. It afforded analytical values in accord with the formulation of a thienoquinolizinium bromide. The product showed spectral characteristics of pronounced similarity to those of the acridizinium ion and of the isomeric II·Br⁻ (Table I). Salts of the two ions also showed comparable, though distinct, properties. The structure of thieno[3,2-b]quinolizinium bromide (III·Br⁻) is assigned tentatively to the second cyclodehydration product pending its conversion into a compound of established structure.

Biological Activity.—Thieno[2,3-b]quinolizinium bromide was tested for curariform activity. It showed no effect by itself, but it was observed to

potentiate the effect of succinylcholine when tested on the sciatic nerve in male cats.

Acknowledgment.—Thanks are due to Dr. F. Bergmann for biological tests.

Experimental

3-Thenyl bromide (V) was prepared by the method of Campaigne and LeSuer.[9]

Thieno[2,3-b]quinolizinium Bromide (II·Br⁻).—The method of Bradsher and Beavers[5] was used. Pyridine-2-aldehyde (7.35 g.) and 3-thenyl bromide (12.1 g.) were mixed and kept at 25–30° for 12 days. The reaction mixture formed a dark reddish-brown glass-like mass. On the ninth day about 1 ml. of a light yellow liquid was decanted. The mass was washed with ether and taken up in 48% aqueous hydrobromic acid (110 ml.) with gentle heating. The resulting solution was left overnight. A small amount of a dark impurity was filtered off. The dark red-brown solution was refluxed for 20 hr. The hydrobromic acid was distilled off at 20 mm. pressure. The black solid residue was taken up in hot water (130 ml.), boiled with charcoal (0.15 g.) and filtered. Dark-colored crystals were deposited from the solution on standing overnight in the refrigerator, which were filtered off and washed with ice-water. The yield was 12.1 g., m.p. 226–228°. The mother liquor was concentrated to a small volume at 20 mm. giving 1 g. of the product with the same m.p. The total yield was 72%. Recrystallization from ethanol (charcoal) yielded light brown needles, 10.5 g., m.p. 227–228°. The product was subjected to alumina chromatography (ethanol as solvent and eluent), yielding long glistening lemon-yellow needles, m.p. 227–228° (hot-stage).

Anal. Calcd. for $C_{11}H_8NSBr$: C, 49.64; H, 3.03; N, 5.26. Found: C, 49.39; H, 3.07; N, 4.96, 5.18.

The infrared spectrum of II·Br⁻ (solid, potassium bromide pellet) showed the following bands (cm.$^{-1}$): 3400-(strong); 3050(s); 2924; 2850; 2359(weak); 1616(s); 1500(w); 1475; 1460(s); 1430(w); 1385(s); 1312(s); 1293; 1247(w); 1174(w); 1167(w); 1152; 1130; 1033; 952(w); 910(w); 870(s); 830(w); 799(w); 765–760(s); 674–670; 664(w).

The picrate was precipitated from an ethanolic solution of the bromide and was crystallized twice from nitromethane. It was obtained as felted yellow needles, m.p. 213–214° (hot-stage).

Anal. Calcd. for $C_{17}H_{10}O_7N_4S$: C, 49.28; H, 2.43; N, 13.52; S, 7.74. Found: C, 49.64; H, 2.49; N, 13.63; S, 7.48.

3-Ethylquinolizidine Hydrobromide (VIII·HBr).—Thieno-(2,3-b)quinolizinium bromide (II·Br⁻) (1.06 g., 0.004 mole) and Raney nickel W-2[10] (12 g.) in ethanol (50 ml.) were refluxed for 2 hr. Fresh Raney nickel (4 g.) and ethanol (100 ml.) were added, and hydrogen was introduced (in a Parr apparatus) for 3 hr. at 2 atm. and 25°. The catalyst was filtered off, washed with ethanol and finally extracted with ethanol in a Soxhlet extractor. The combined ethanol extracts gave on evaporation a sticky brown product, which yielded 0.13 g. (13%) of a crystalline product, m.p. 184°, from butyl acetate. Recrystallization from this solvent gave a product of m.p. 190–191.5° (0.07 g.).

Anal. Calcd. for $C_{11}H_{22}NBr$: C, 53.22; H, 8.94; N, 5.64. Found: C, 52.97; H, 8.87; N, 5.44.

3-Ethylquinolizidine hydrobromide (VIII·HBr) showed very weak absorption in the ultraviolet above 215 mμ. The infrared spectrum (solid, potassium bromide pellet) showed no evidence of unsaturation. The following bands were observed (cm.$^{-1}$): 3425; 2941(strong); 2700–2674(s); 2577-(s); 2551(s); 2359(weak); 1650(w); 1460(s); 1342; 1174–1168; 1053-1048; 1032; 1010-1006(w); 995; 970-(w); 945(w); 920(w).

3-Ethylquinolizidine Picrate (VIII·Picrate).—The hydrobromide VIII·HBr was dissolved in ethanol and treated with ethanolic picric acid solution under reflux for 10 minutes. The picrate was deposited in clusters of lemon yellow needles, m.p. 156–157.5°.

The m.p. was undepressed by an authentic specimen of 3-ethylquinolizidine picrate of Boekelheide and Rothchild.[7] The infrared spectra of both specimens were superposable and showed the following bands (cm.$^{-1}$; solid, potassium bromide pellet): 3440(weak); 3070(w); 2950(strong); 2750(s); 2600; 1625–1610(s); 1565–1560(s); 1515(s); 1506(s); 1472(s); 1462(shoulder); 1430(s); 1362(s); 1340–1316(s); 1265(s); 1207(w); 1160; 1078; 1052; 996(w); 972-(w); 943(shoulder); 936; 917(w); 907; 787; 744; 723-(shoulder); 708(s); 678(w); 667(w).

Thieno(3,2-b)quinolizinium Bromide (III·Br⁻).—Pyridine-2-aldehyde (23.5 g.) and 2-thenyl chloride[11] (29.1 g.) were kept for eight weeks at 20–30° in a stoppered flask in the dark. Most of the reaction mixture turned into a dark brown-red glassy mass. A small amount of dark brown-red viscous supernatant liquid was decanted, and the glassy solid was left under the same conditions for a further period of four weeks. Hydrobromic acid (100 ml., 48%) was added. The glassy solid dissolved overnight, leaving a slight black residue, which was filtered off. The acid solution was refluxed for 19 hr. and filtered. The hydrobromic acid was removed at 20 mm., leaving a black residue. The latter was extracted with hot water, leaving a considerable part undissolved. The aqueous extract was evaporated to dryness at 20 mm., and the black residue was extracted with ethanol, leaving a considerable part undissolved. The ethanolic extract was passed through a column of alumina, which was subsequently eluted with ethanol, from which dark greenish needles were deposited on concentration, m.p. 216° (2.7 g.). After five crystallizations from ethanol, light yellow needles of m.p. 216–217° (hot-stage) were obtained.

Anal. Calcd. for $C_{11}H_8NSBr$: C, 49.64; H, 3.03; N, 5.26; Br, 30.03; S, 12.05. Found: C, 49.66; H, 3.16; N, 5.37; Br, 30.33; S, 11.94.

The infrared spectrum of III·Br⁻ (solid, potassium bromide pellet) showed the following bands (cm.$^{-1}$): 3472-(strong), 3068(s); 2941; 2874; 2370(weak); 1626(s); 1582(w); 1560(w); 1479(w); 1447(s); 1412(s); 1380(s); 1360, 1340; 1300(s); 1260(w); 1217(w); 1160(s); 1097-(w); 1029; 948(w); 893–890; 865(s); 830(w); 804; 788; 755(s); 680(s).

The picrate (III· picrate) was precipitated from an ethanolic solution of the bromide III·Br⁻ and crystallized from nitromethane as fine felted light yellow needles, m.p. 210.5–211°.

Anal. Calcd. for $C_{17}H_{10}O_7N_4S$: C, 49.28; H, 2.43; N, 13.52. Found: C, 49.97; H, 2.51; N, 13.00.

Derivatives of 1-Thia-4,5-diazacyclohepta-2,4,6-triene. III. Isomeric Dibenzo-1-thia-4,5-diazacyclohepta-2,4,6-triene-1,1-dioxides and Dibenzo-1-thia-4,5-diazacyclohepta-2,4,6-triene-1,1,4-trioxides

BY H. HARRY SZMANT AND YUAN-LANG CHOW[1]

RECEIVED JUNE 8, 1956

The isolation of three isomers of the previously described heterocyclic system containing either the azo or the azoxy function is described. Isomerization, oxidation and reduction experiments, as well as physical properties are utilized in the provisional assignment of conformations to the three isomers in each series. While two of each group of three isomers seem to be chair and boat conformations of the heterocyclic ring, the third isomer appears to be a novel seven-membered puckered ring in which a *trans* azo or azoxy group is part of the ring.

Repetition of the previously described[2] oxidation of di-(*o*-aminophenyl) sulfone by means of phenyliodoso acetate gave in addition to the already reported dibenzo-1-thia-4,5-diazacyclohepta-2,4,6-triene-1,1-dioxide (I) of melting point 170–171°,[3] another compound melting at 130°. This material was shown to be an isomer of I by analysis and by thermal conversion to the higher melting solid, and the two compounds are herewith designated IA and IB, respectively. As previously reported,[2] the oxidation of IA by peracetic acid gave dibenzo-1-thia-4,5-diazacyclohepta-2,4,6-triene-1,1,4-trioxide (II) of melting point 251–252°, and analogous oxidation of IB gave a mixture of the already known azoxy compound and an isomeric azoxy compound of melting point 239°. These two azoxy compounds are herewith designated IIA and IIB, respectively, and as in the case of IA and IB, the new isomer (IIB) could be isomerized thermally (and also photochemically) to IIA.

It was of interest to confirm the existence of the two isomeric compounds I by the reduction of the azoxy function of II to the azo function in I. To our surprise, the reduction of either IIA or IIB by means of lithium aluminum hydride or zinc in acetic acid gave neither IA or IB but rather a third isomer of I, a solid of melting point 193°, which is herewith designated as IC. The fact that IC is related structurally to IA was established by successful photochemical isomerization of IC to IA. The same isomerization could be accomplished by dissolving IC in cold sulfuric acid and precipitating IA upon dilution of the solution with ice. The oxidation of IC by means of peracetic acid gave IIA just as did the oxidation of IA.

The existence of three isomers of I implied the possible existence of three isomers of II, and the third isomer of II of melting point 250–251° (IIC) was indeed isolated when dibenzo-1-thia-4,5-diazacyclohepta-2,6-diene was subjected to oxidation with peracetic acid. While IIB and IIC have almost identical melting points they differ in several respects. Thus while IIA is a yellow solid which melts without decomposition, IIC is a white solid which undergoes complete decomposition upon melting. IIC is isomerized to IIA when heated in acetic acid solution and reduction of IIC by means of lithium aluminum hydride gives IC.

The above mentioned results prove the existence of three isomers in the azo series I and also in the azoxy series II. Assuming a non-planar structure of the heterocyclic ring in I and II, there can be visualized two isomers in which the heterocyclic ring assumes either a chair or a boat conformation. This hypothesis still does not account for the existence of the third pair of isomers. We wish to suggest at this time that the third pair of isomers represents a puckered, seven-membered ring in which the azo function exists in the *trans* form. Evidence in support of this suggestion is cited below. The three suggested conformations in the azo series I are represented schematically in Fig. 1.

Assuming the correctness of the proposed conformational differences between IA,B,C and IIA,B,C, our efforts were next directed toward the assignment of specific conformations to the individual isomers.

Examination of the ultraviolet spectra of IA,-B, C(Fig. 2) revealed a distinct feature differentiating IC from IA and IB. The 430 mμ band, the well recognized[4] R-band of azo compounds, was abnormally weak in IC (ε 14) while it was of normal intensity in IA and IB (ε 380–595). Since in negatively substituted azo compounds the intensity of the R band is generally higher in the *cis* isomer, the weak R band in IC favors the assignment of the *trans* azo structure to this isomer. Supporting this assignment is the above mentioned facile isomerization of IC to IA by ultraviolet light or by acid catalysis. In the course of both kinds of treatments the temporary breaking of the nitrogen–nitrogen double bond would permit the rearrangement to the *cis* azo structure which would be expected to be the more stable structure in a cyclic azo compound. Further support of the *trans* azo assignment to IC is the fact that the reduction of all three isomers of II gave exclusively this particular isomer. Badger[5] has shown that the reduction of both *cis*- and *trans*-azoxybenzene gives the *trans* azo system and explains these results in terms of the preferential *trans* elimination of water from the intermediate dihydroazoxy structure. The same explanation may account for the formation of IC from IIA,B,C on reduction with lithium aluminum hydride or zinc, even though IC is readily isomerized to IA.

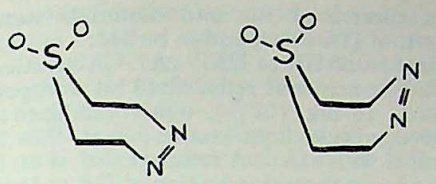

Fig. 1.—Conformations of I. Heavy lines indicate fusion of benzene rings.

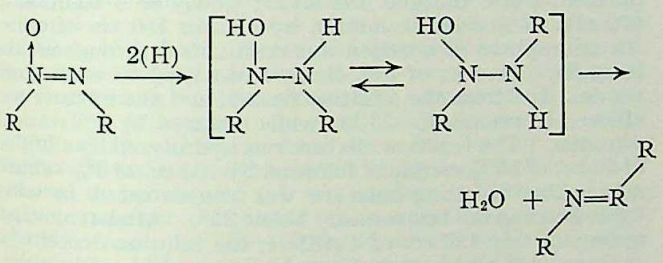
The assignment of the conformations to IA and IB is more difficult in the absence of additional physical data,[6] but provisionally the higher melting and more stable isomer IA is assigned the *cis* azo chair structure. In this connection it was found that IB was oxidized 13 times faster than IA by perbenzoic acid. Badger[5] has shown that the greater rate of oxidation of *cis*-azobenzene as compared to *trans*-azobenzene (50–80 fold difference) can be accounted for by considering the greater electron-availability in the *cis* azo linkage. In the case of IA and IB, both compounds are assumed to be *cis* azo structures and apparently the electron-withdrawing sulfone group is more effective in the chair structure.



The comparison of the behavior of the isomeric II compounds at their respective melting points reveals that IIA is the most stable compound since it is the only isomer which does not decompose. It is of interest that IIB decomposes violently with evolution of brown gas, while IIC decomposes to a tar without noticeable gas evolution. The relative stability of IIA suggests that it may have the *cis*-azoxy chair configuration. The oxidation of IA to IIA was reported in the preceding publication[2] and the formation of a mixture of IIA and IIB by peracetic acid oxidation of IB was mentioned above. These results indicate that IA and IIA are configurationally related, and the fact that IB isomerizes to IA upon heating explains why the oxidation of IB gives some IIA in addition to IIB. A mixture of IIA and IIB was also obtained when di-(*o*-aminophenyl) sulfone was oxidized by peracetic acid. The conclusion that IB and IIB are configurationally related also is supported by the selective oxidation of IB to IIB by perbenzoic acid. The success of the last mentioned experiment is in line with the experiences of Badger[5] who demonstrated that perbenzoic acid oxidizes *cis*-azobenzene without isomerization while peracetic acid also brings about isomerization.

In an attempt to bring about a controlled reduction of the azoxy to the azo linkage, IIB was treated with deactivated nickel (see Experimental) but in place of the expected IB the only product which could be isolated from this reaction was II-A. Since this experiment was performed without application of heat it demonstrates the relatively greater stability of IIA.

(6) The measurement of the dipole moments of the compounds under discussion is planned for the near future.

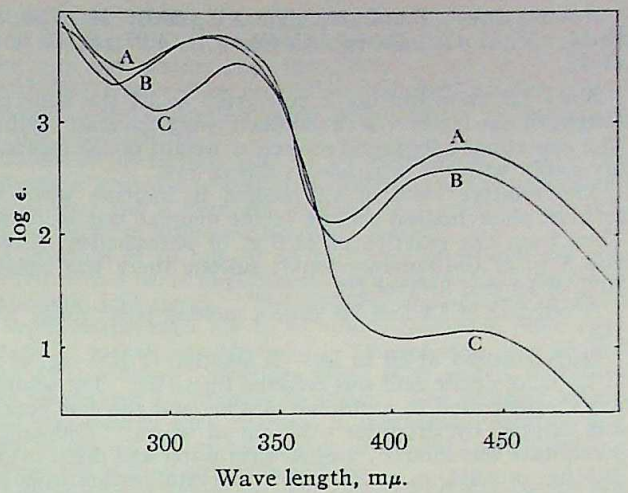


Fig. 2.—Ultraviolet spectra of IA (curve A), IB (curve B), and III (curve C).

The assignment of the chair and boat conformations to IIA and IIB, respectively, leaves the *trans*-azoxy conformation for the IIC isomer. It was hoped to confirm this assignment by the perbenzoic acid oxidation of IC to IIC but unfortunately the oxidation of IC gave exclusively IIA. When the kinetics of this reaction was examined it was found that IC is subject to a very rapid isomerization to IA with the loss of one equivalent of perbenzoic acid. The isomerized product could be isolated when the oxidation was stopped at that point, and when the oxidation was allowed to continue it proceeded at a rate essentially equal to that of IA. The mechanism of isomerization of IC to IA with loss of perbenzoic acid is not understood at this time and is subject to additional study.

The successful isomerization of IC to IA by concentrated sulfuric acid prompted the examination of possible isomerization of IIC under the same conditions. Neither IIC nor the other two azoxy compounds were found to be isomerized when dissolved in concentrated sulfuric acid in the cold and were recovered when the solutions were poured on ice. The failure of IIC to be isomerized can be ascribed to the protonation of the azoxy group at the oxygen atom without disturbing the nitrogen–nitrogen double bond.

Experimental[7]

Preparation and Isolation of IA and IB.—A mixture of 5 g. (0.02 mole) of di-(*o*-aminophenyl) sulfone, 5.8 g. (0.02 mole) of phenyliodoso acetate and 500 cc. of dry toluene was allowed to stand at room temperature for 5 days. A brown precipitate, 0.8 g., was filtered, washed with hot toluene and discarded since it did not melt at 350°. The filtrate and washings were concentrated *in vacuo* and the residue was crystallized from methanol to give 2.2 g. of dark red crystals, m.p. 164–169°; yield 42%. Three crystallizations from isopropyl alcohol gave orange crystals, m.p. 174°, which did not depress the m.p. of the previously reported[2] IA. Concentration of the filtrates yielded 2.1 g. (40%) of dark orange crystals, m.p. 125–130°, which were purified to constant m.p. 130.5–131.5° by crystallization from methanol. Chromatography of this material (IB) on alumina gave only one band.

(7) All melting points are uncorrected. Microanalyses by Drs. Strauss and Weiler, Oxford, England, and by Dr. Bernhardt, Mülheim, Germany.

Anal. Calcd. for $C_{12}H_8O_2N_2S$: C, 59.0; H, 3.30; S, 13.11; N, 11.47. Found: C, 59.4; H, 4.07; S, 13.3; N, 11.40.

Since IB upon heating is converted to IA the molecular weight of the latter was determined using the Rast method. The experimentally found molecular weight of 233 compares favorably with the calculated value of 244.

The relative yield of IA seemed to increase when the ratio of phenyliodoso acetate to the diamine was increased. Thus from the reaction of 15.0 g. of phenyliodoso acetate and 8 g. of di-(*o*-aminophenyl) sulfone there was isolated 70% of IA and 21% of IB.

A mixture of IA and IB gave a melting point range 129–148°.

Isomerization of IB to IA.—A solution of 300 mg. of IB in 12 cc. of acetic acid was refluxed for 13 hr. The solution was concentrated to a volume of 4 cc. and the cold residue was diluted by dropwise addition of water. The orange precipitate was filtered, washed with water and dried to give 210 mg. of solid, m.p. 169–173°. Crystallization from isopropyl alcohol gave orange crystals, m.p. 173–174°, which did not depress the m.p. of IA.

Attempts to effect isomerization of IB by irradiation with ultraviolet light were unsuccessful. Also attempted isomerizations of IA by either thermal or photochemical means failed.

IA and IB were recovered in nearly quantitative yields when solutions in cold concd. sulfuric acid were poured on ice.

Oxidation of IB.—Ten cc. of 40% peracetic acid was added over a period of 30 minutes to a solution of 1 g. of IB in 35 cc. of acetic acid. The mixture was stirred and cooled by means of an ice-bath during the addition, and then was allowed to stand at room temperature for 15 hr. Faintly yellow needles precipitated from the solution and they were filtered, washed with methanol and dried to give 850 mg. (80%) of solid, m.p. 212–218° dec. The filtrate was poured on ice and gave an additional 210 mg. of the same solid. The combined crystals were purified by dissolving in a minimum volume of hot dioxane, addition of approximately 100 cc. of water, and slow cooling. The resulting product gave a constant m.p. 243–245° dec. Admixture with IIA gave m.p. 244–251°, and admixture with IIB gave m.p. 242–244°. A portion of the product on heating in glacial acetic acid for 14 hr. was converted quantitatively to IIA, m.p. and mixture m.p. 250–251°.

Oxidation of IB with 30% hydrogen peroxide in refluxing acetone gave the same results, but oxidation of IB with peracetic acid in refluxing acid gave directly a quantitative yield of IIA, m.p. and mixture m.p. 251–252°.

Oxidation of IA to IIA.—A solution of 50 mg. of IA in 10 cc. of hot acetic acid was treated with 1 cc. of 40% peracetic acid. The solution was refluxed for 10 hr. and then poured on ice to give greenish-yellow needles, m.p. 247–249°. Crystallization from acetic acid gave pure IIA, m.p. and mixture m.p. 251–252°.

Preparation of IIA and IIB.—A solution of 2.5 g. of di-(*o*-aminophenyl)sulfone in 35 cc. of acetic acid and 10 cc. of benzene was cooled below 10° and stirred while a solution of 10 cc. of 40% peracetic acid in 50 cc. of acetic acid was added dropwise over 40 hr. The colorless solution turned brown. Mechanical stirring was extended for another 24 hr. at room temperature. The reaction mixture on cooling in an ice-bath deposited dark needles which were filtered, washed with methanol and water. The solid, 2.1 g., m.p. 235–241° dec., was fractionally crystallized from acetone. The first fraction, 1.8 g. (69%), consisted of white needles, m.p. 235° dec., while the second fraction, 0.3 g., consisted of yellow-green needles, m.p. 235–245°. The first fraction was crystallized repeatedly from acetone and gave white needles of constant m.p. 239° (violent decomposition with evolution of brown gas). This material is considered to be IIB.

Anal. Calcd. for $C_{12}H_8O_3N_2S$: S, 12.31; N, 10.8; mol. wt., 260. Found: S, 11.95; N, 10.8; mol. wt. (Rast), 247.

The mother liquor was poured into water and gave 0.5 g. of green-yellow needles, m.p. 238–245°. This material was combined with the second fraction from the above crystallization and the solids (30%) were treated with charcoal in acetic acid solution. The purified product, m.p. 251–252°, did not depress the m.p. of IIA and the ultraviolet spectra of the two materials were identical. The mol. wt. of IIA was found to be 244.

Isomerization of IIB to IIA. (A).—A solution of 15 mg. of IIB in acetic acid was refluxed 48 hr. and poured on ice. The product, 13 mg. (87%), was crystallized from acetic acid to give green-yellow needles, m.p. 250–251°, which were identical with IIA. A reflux period of 30 hr. was also sufficient to cause the isomerization of IIB to IIA. When in addition to acetic acid there was present also a small amount of hydrochloric acid (1 cc. of concd. hydrochloric acid in 20 cc. of acetic acid), the yield of IIA was only 60% and an unidentified brown gelatinous precipitate was produced.

(B).—A solution of 50 mg. of IIB in 50 cc. of acetic acid was irradiated for 3 days in a quartz vessel by means of an ultraviolet lamp. The solution turned brown and when poured on ice there was obtained 42 mg. (84%) of solid, m.p. 241–244°. A charcoal treatment in acetic acid and an additional crystallization from the same solvent gave pure IIA, m.p. and mixture m.p. 251–252°.

(C).—A solution of 130 mg. of IIB in 180 cc. of toluene was added to two scoops of deactivated Raney nickel[8] covered by toluene. The mixture changed from the original slight yellow color to a green-yellow color upon shaking, and after 5 hr. it was filtered and the solvent was evaporated *in vacuo*. The residual solid, 100 mg. (78%), m.p. 237–239°, was recrystallized from methanol to give pure IIA, m.p. and mixture m.p. 251–252°.

Reduction of IIA and IIB to IC. (A) Lithium Aluminum Hydride.—A suspension of 350 mg. of IIA in 80 cc. of purified, warm dioxane was added slowly to a solution of 470 mg. of lithium aluminum hydride in 180 cc. of ether. An atmosphere of nitrogen was maintained throughout the reaction. Ten cc. of hot dioxane was used to wash down residual IIA from the addition funnel, and the mixture was allowed to remain for 25 hr. while agitated by a stream of nitrogen. The reaction mixture was hydrolyzed by addition of 50 cc. of 50% methanol followed by 100 cc. of 3% sulfuric acid. The resulting mixture was concentrated *in vacuo* while keeping the temperature below 35°. After removal of approximately 120 cc. of distillate, the solution deposited a yellow solid which was filtered and washed with water. The product, 270 mg., m.p. 183–187°, was crystallized from isopropyl alcohol to give IC, yellow needles, m.p. 194–196°.

Anal. Calcd. for $C_{12}H_8O_2N_2S$: C, 59.00; H, 3.30; N, 11.47; S, 13.11; mol. wt., 244. Found: C, 58.82; H, 3.80; N, 11.35; S, 13.00; mol. wt. (Rast), 244.

Using the same procedure the reduction of IIB gave 83% of IC, m.p. and mixture m.p. 194–196°. In another experiment in which the amount of dilute sulfuric acid was in excess of the amount required to neutralize the reaction mixture and the temperature during the distillation was raised to 100°, IA was obtained instead of IC. IA was identified by m.p. and mixture m.p. with authentic IA.

(B) **Zinc Dust.**—A solution of 100 mg. of IIA in 15 cc. of acetic acid was warmed on a hot plate while 1 g. of zinc dust was added in small portions. The mixture was filtered after 20 minutes and the solid was washed with 3-cc. portions of boiling acetic acid. The combined filtrate and washings were poured into a large volume of water and a solid was collected. The crude product was charcoaled and crystallized from methanol to give 60 mg. (64%) of yellow needles, m.p. 185–190°. Additional crystallization gave m.p. and mixture m.p. 194–196°.

The same procedure was applied to 150 mg. of IIB and gave 100 mg. (79%) of IC.

Isomerization of IC to IA.—A solution of 30 mg. of IC in 30 cc. of ethanol was irradiated in a quartz vessel for one week by means of an ultraviolet lamp. The solution was poured on ice and the resulting solid, 28 mg. (94%), m.p. 169–172°, was recrystallized from ethanol to give pure IA, m.p. and mixture m.p. 173–174°.

The same reaction was followed spectrophotometrically using a 1.134×10^{-3} *M* solution of IC and determining the ϵ at 430 mμ. The initial value of ϵ agreed with that reported for IC and upon irradiation, the ϵ gradually approached the value of 550.

The isomerization of IC to IA also could be achieved by refluxing an ethanolic solution for 40 hr. However, the product was isolated in a yield of only 65–75%.

IC, 20 mg., was dissolved in cold concd. sulfuric acid and the resulting red solution was immediately poured on ice. There was isolated 17 mg. (85%) of crude IA, m.p. 157–167°, which upon crystallization from ethanol gave m.p. and mixture m.p. 173–174°.

Oxidation of IC to IIA.—A solution of 50 mg. of IC in 10 cc. of acetic acid was warmed with 2 cc. of 40% peracetic acid and the temperature was raised gradually to reflux. The color was observed to change from yellow to dark orange and finally to green-yellow. After a reflux period of 2 hr. the solution was diluted with an equal volume of water and gave 40 mg. (78%) of solid, m.p. 245–250°. One crystallization from acetic acid gave pure IIA, m.p. and mixture m.p. 250–252°.

A solution of 50 mg. of IC in 5 cc. of acetic acid was treated dropwise with 5% solution of potassium permanganate in acetone. The addition was continued until the pink color persisted and then an additional 2-cc. volume of oxidizing solution was added. The mixture was warmed for two hours and allowed to stand until a crystalline precipitate began to appear. The mixture was then diluted with an equal volume of water and was filtered. The solid was extracted with isopropyl alcohol and the filtrate yielded upon concentration 20 mg. of solid, m.p. 250–252°. The product did not depress the m.p. of authentic IIA. The filtrate was poured into a large volume of water and the orange precipitate was crystallized to give IA, m.p. and mixture m.p. 173.5–174°.[9]

Preparation of Dibenzo-1-thia-4,5-diazacyclohepta-2,6-diene.—Di-(*o*-nitrophenyl) sulfide, 15 g., in 700 cc. of hot isopropyl alcohol was diluted with an equal volume of water and 42 g. of sodium acetate was dissolved in the mixture. The vigorously stirred solution was treated with 30 g. of zinc dust while a nitrogen atmosphere was maintained in the flask. The temperature was gradually raised to reflux (30 minutes) and maintained at reflux for 10 minutes. The reaction mixture was filtered rapidly and the filtrate was collected in a preheated 2-l. suction flask. Without changing the container the filtrate was concentrated by application of vacuum and 350–400 cc. of solvent was removed in this fashion. During all these operations care was taken to prevent excessive contact of the solution with air since the latter caused discoloration and separation of solid. The concentrated solution was diluted with water to a volume of 2 l. and, after refrigeration, there was isolated 8.5 g. (75%) of white crystals, m.p. 121° (with evolution of gas). Attempted crystallizations from alcohol caused discoloration of the product and in view of the failure to obtain satisfactory analysis of the previously prepared[10] cyclic hydrazo compounds the material from this experiment was used immediately for the preparation of IIC.

Preparation of IIC.—The hydrazo compound from the preceding experiment, 8.5 g., was dissolved in 30 cc. of acetic acid and the resulting solution was stirred and treated dropwise with a solution of 10 cc. of 40% peracetic acid in 100 cc. of acetic acid. An additional 20 cc. of 40% peracetic acid was added after 5 hr. When a white solid began to precipitate the mixture was first heated for 30 minutes on a hot plate, cooled and then filtered. The white solid was washed with methanol to give 7.0 g. (72%) of product, m.p. 243–247° dec. Crystallization from acetic acid raised the m.p. to 250–251° dec.

Anal. Calcd. for $C_{12}H_8O_3N_2S$: C, 55.38; H, 3.09; S, 12.31; N, 10.88; mol. wt., 260. Found: C, 55.13; H, 3.03; S, 12.28; N, 10.91; mol. wt. (Rast), 257.

Isomerization of IIC to IIA.—A solution of 50 mg. of IIC in 100 cc. of acetic acid was refluxed for 100 hr., treated with charcoal, filtered and cooled to give 35 mg. (70%) of green-yellow needles, m.p. 251–252° (no decomposition!). This material did not express the m.p. of IIA.

Neither irradiation by ultraviolet light nor dissolution in concentrated sulfuric acid were effective in the isomerization of IIC.

Reduction of IIC to IC. (A) Lithium Aluminum Hydride.—The procedure described for the reduction of IIA and IIB gave 390 mg. (92.5%) of crude IC, m.p. 190–192°, from 450 mg. IIC. A single crystallization from ethanol gave m.p. and mixture m.p. 194–196°.

(B) Zinc Dust.—The procedure described for the reduction of IIA and IIB was applied to 600 mg. of IIC and gave 490 mg. (87%) of IC.

Oxidation of IA, IB and IC by Perbenzoic Acid.—The perbenzoic acid was prepared as described in the literature[11] except that the chloroform solution was washed with 1% sodium bisulfite before washing with water.

A solution of 70 mg. of IA in 20 cc. of chloroform was treated with 3 cc. of chloroform containing 0.1807 mmole of perbenzoic acid per cc. The solution was allowed to stand at room temperature for 48 hr. and a change in color from orange to yellow was observed. The solution was washed with 10% sodium hydroxide, twice with water, and then was evaporated to dryness *in vacuo*. The residual yellow solid was treated with charcoal in methanolic solution and gave 70 mg. of yellow solid, m.p. 246–249°, which did not depress the m.p. of authentic IIA.

Application of the same procedure to 76 mg. of IB and 5 cc. of perbenzoic acid solution of the same concentration gave 65 mg. (80%) of crude product, m.p. 225–235° dec. Crystallization from methanol gave white needles, m.p. 239° (violent dec.), which did not depress the m.p. of authentic IIB.

A solution of 66 mg. (0.2712 mmole) of IC in 20 cc. of chloroform was mixed with 4 cc. of chloroform containing a total of 0.386 mmole of perbenzoic acid. The color of the solution changed instantly from yellow to dark orange and immediate iodimetric titration of an aliquot showed the loss of 0.27 mmole of perbenzoic acid. The solution was shaken with 10% sodium hydroxide 15 minutes after mixing, and the washed chloroform layer was evaporated to give 66 mg. of product which was obtained as orange cubes from methanol, m.p. 173–174°. This material did not depress the m.p. of IA.

In another experiment in which IC was allowed to react at room temperature with 2.5 equivalents of perbenzoic acid there was isolated after 50 hr. a quantitative yield of IIA.

Kinetics of the Oxidation of IA, IB and IC by Perbenzoic Acid. General Procedure.[5]—An accurately weighed sample of I was dissolved in reagent grade chloroform and the solution was thermostated at 25.0 ± 0.1° in a 25-cc. volumetric flask coated with black enamel. A stock solution of freshly prepared perbenzoic acid in chloroform (approximately 0.20 mmole perbenzoic acid per cc.) was also thermostated. The time at which one-half of the perbenzoic acid solution was added to the solution of I was taken as zero time, and the mixture was rapidly diluted to the 25 cc. mark and shaken. Approximately 1.5 equivalents of perbenzoic acid were used in each oxidation of I. The first aliquot was titrated as promptly as possible upon mixing and subsequent aliquots were titrated at suitable intervals. The initial concentration of perbenzoic acid was determined by extrapolation. A sample of perbenzoic acid solution of equal concentration was kept side by side with the kinetic sample and the autodecomposition of perbenzoic acid was also followed by iodimetric titration in order to correct the observed loss of perbenzoic acid in the kinetic experiments. The reactions were followed for at least 50% oxidation of I and second-order rate constants were calculated.

Oxidation of IA.—The solution contained 0.4725 mmole of IA and 0.5862 mmole of perbenzoic acid. Aliquots of 2.0 cc. were titrated with 0.00493 *N* sodium thiosulfate.

Time, min.	Titer, cc. Oxid.	Control	$k \times 10^2$ ./mole min.

Av. $k \times 10^2 = 2.2 \pm 0.3$ l./mole min.

(9) The permanganate oxidation of IC is apparently accompanied by isomerization of IC to IA, and the latter is then oxidized to IIA. The isomerization of IC to IA by means of permanganate (without oxidation) was demonstrated in an independent experiment and is subject to additional study.

Oxidation of IB.—The solution contained 0.1600 mmole of IB and 0.1875 mmole of perbenzoic acid. The average rate constant was found to be 0.29 ± 0.03 l./mole-min.

Oxidation of IC.—The solution contained 0.4355 mmole of IC and 0.9035 mmole of perbenzoic acid. After an almost instantaneous loss of one equivalent of perbenzoic acid the rate of oxidation approached that of the rate of oxidation of IA, and during the interval of 400–800 minutes the rate of oxidation coincided with the rate reported above for IC.

Ultraviolet Spectra.—The ultraviolet spectra were determined in 95% ethanol by means of a Beckman DU spectrophotometer. The absorption curves are reproduced in Fig. 2.

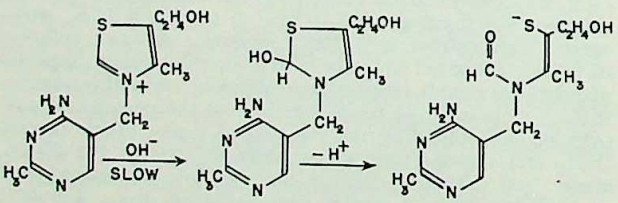
Structures of Thiamine in Basic Solution[1]

BY GEORGE D. MAIER AND DAVID E. METZLER

RECEIVED MARCH 29, 1957

Thiamine in basic solution is instantly converted to a yellow form which fades within a few minutes in water but which persists for several hours in methanol. The *p*H dependence of the zero-time concentration of this yellow form indicates that it arises by the simultaneous loss of two protons from the neutral form of thiamine with an apparent average pK value of 11.6 at 19°. In methanol the two dissociation steps are distinct and an intermediate can be detected. This intermediate non-ionic form of thiamine has been isolated as a white crystalline solid. It apparently arises through the intramolecular addition of the amino group of thiamine to the thiazolium ring with loss of one proton; opening of the thiazole ring and loss of a second proton produce the yellow form. The *p*H dependence indicates that fading of the yellow color results from formation of the pseudo-base and open-ring thiol forms. The possible biochemical significance of these unstable forms of thiamine is considered.

Thiamine (I) reacts slowly with hydroxyl ions to form a pseudo-base II and a thiol form III in which the thiazole ring has been opened.[2–4] In addition, it has been known for many years that thiamine in alkaline solutions develops a transient yellow color.[5,6] We have investigated this latter phenomenon in the belief that it might shed some light on the mechanism of the catalytic action of this vitamin.



I II III

Pseudo-Base and Colorless Thiol Forms.—Figure 1, curve A shows the ultraviolet absorption spectrum of the neutral form of thiamine (I) and (curve B) that of thiamine at *p*H 10.4, 90 minutes after its addition to this basic buffer. The latter represents the spectrum of the thiol, III, which forms slowly over a period of about an hour at this *p*H. An identical spectrum is observed for the crystalline sodium salt of III[6] dissolved in 0.02 *N* KOH. (Addition of base to simpler thiazolium salts such as 3,4-dimethyl-5-(2-hydroxyethyl)-thiazolium chloride causes very similar absorbancy increases at all wave lengths.)

The two reactions by which the neutral form of thiamine is converted to the thiol form III can be regarded as formally equivalent to the stepwise dissociation of a diprotic acid with characteristic acid dissociation constants which can be measured titrimetrically. Williams and Ruehle[2] have reported the apparent pK_{av} (average of the apparent pK's for the two steps) of 9.0, and Watanabe and Asahi,[4] of 9.33 at 25°. We have estimated pK_{av} spectrophotometrically as 9.3 for thiamine and 10.3 for the simpler 3,4-dimethyl-5-(2-hydroxyethyl)- and 3-benzyl-4-methyl-5-(2-hydroxyethyl)-thiazolium salts.

The Yellow Form of Thiamine.—The addition of thiamine to solutions of *p*H 11 and above leads to the instantaneous production of a yellow color, which fades rapidly in aqueous media,[5] but which is clearly visible, depending on the basicity, for an hour or more in methanol. Figure 1C shows the spectrum of thiamine in 0.1 *N* NaOH extrapolated to zero time (see Experimental) and Fig. 4A the spectrum in methanolic KOH. Since these spectra are not further changed at higher base concentrations, we believe that they represent a single substance. No other forms of thiamine absorb light above 325 mμ; hence we have used the absorbancy at 349 mμ to measure the concentration of this yellow form in mixtures. In water the yellow form decays within several minutes to a substance having a spectrum identical to that of the thiol form III (Fig. 1B). A similar but much slower decay occurs in methanol. The change leading to color formation appears to be completely and rapidly reversible as indicated by the quenching of the yellow color and the immediate appearance of the spectrum of thiamine hydrochloride upon addition of hydrochloric acid to a solution containing the yellow form. The yellow color can then be regenerated quantitatively (97% or more of the original amount) by addition of more base.[5]

Figure 2 shows the increase in zero time absorbancy at 349 mμ with increasing *p*H of an aqueous

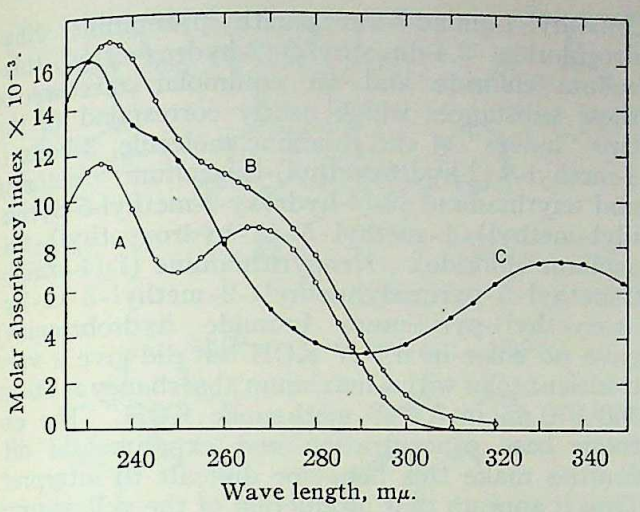

Fig. 1.—Spectra of thiamine in aqueous solutions: A, thiamine at *p*H 6.8, phosphate buffer; B, thiamine in *p*H 10.4 piperidine buffer after standing 90 minutes, or in 0.02 *N* KOH after standing 30 minutes, and white sodium salt of thiamine in 0.02 *N* KOH; C, thiamine in 0.1 *N* NaOH at time of mixing (from extrapolation).

solution of thiamine. The curve is an S-shaped "titration curve" similar to that ordinarily observed when a spectral change results from the dissociation of an acidic group. Curve A (Fig. 2) has been constructed to pass through the experimentally observed mid-point at *p*H 11.6 and to approach the limiting absorbancies at the high and low *p*H ends; it has the shape theoretically expected for the dissociation of a monoprotic acid or a diprotic acid in which $K_1 >> K_2$. However, the experimental points do not fit this curve, but do fit curve B which has a mid-point slope of twice that of curve A and which represents the theoretical shape expected for a diprotic acid in which the two protons dissociate simultaneously with no detectable amount of an intermediate singly dissociated form ($K_1 << K_2$) and $pK_{av} = {}^1/_2(pK_1 + pK_2) = 11.6$ (the apparent pK_{av} for an ionic strength of 0.2) at 19°. This unusual type of behavior is known for several compounds reported by Schwarzenbach[7] and for benzothiazole methiodide.[8] It is evident from the shapes of the published titration curves that the conversion of thiamine to the colorless thiol form III is also a reaction of this type. In thiamine solutions the pseudo-base form II is never present in amounts great enough to affect the shape of titration curves,[2,4] nor can II be detected through oxidation to the thiazolone.[9]

From the foregoing results we conclude that the yellow form arises from neutral thiamine by a reaction involving the removal of *two* protons. Zima and Williams in 1940 isolated a crystalline yellow sodium salt of thiamine by treatment of thiamine hydrochloride in ethanol with three moles of sodium ethoxide.[6] We have prepared this salt and find its spectrum and fading behavior in methanol and water to be identical to those of the yellow form described here.

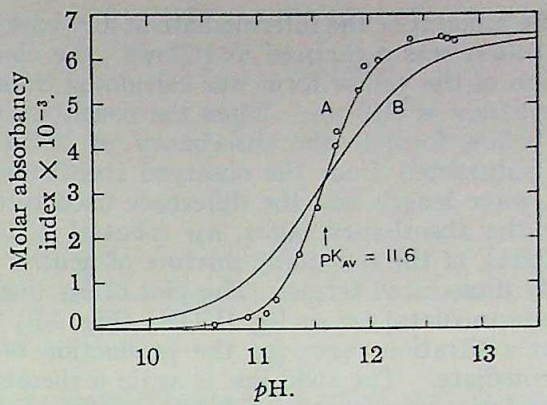

Fig. 2.—Absorbancy of thiamine at 349 mμ *versus* *p*H. Data are extrapolated back to the time of mixing. The lines are theoretical curves constructed for: A, a monoprotic acid; B, a diprotic acid with no detectable singly dissociated intermediate.

The Intermediate between the Neutral and Yellow Forms.—The development of the yellow color in methanol shows a fundamental difference from that in water. In Fig. 3A the absorbancy at 349 mμ is plotted against the logarithm of the excess, unreacted KOH concentration. The solid line is a curve of the theoretical shape for a monoprotic acid and in this case fits the experimental points well. This suggests that in methanol a more normal situation prevails in which $K_1 > K_2$ and that at intermediate basicities the thiamine should exist largely in the form of a singly dissociated intermediate. The spectra of the yellow and neutral forms exhibit points of equal absorbancy at 263 and 290 mμ. The absorbancies of thiamine in methanolic KOH of basicities intermediate to those in which either the neutral and yellow forms predominate were measured at these wave lengths. The presence of an intermediate was clearly indicated at 290 mμ by a marked increase in absorbancy (to an a_M of 5.55×10^3 at log [KOH] = −2.86) and subsequent decrease at higher base concentrations, and at 263 mμ by a lower absorbancy at intermediate base concentrations. (Similar measurements in *water* at 289 mμ indicate that no more than 5% of the intermediate is ever present, that amount being present at *p*H 11.6.)

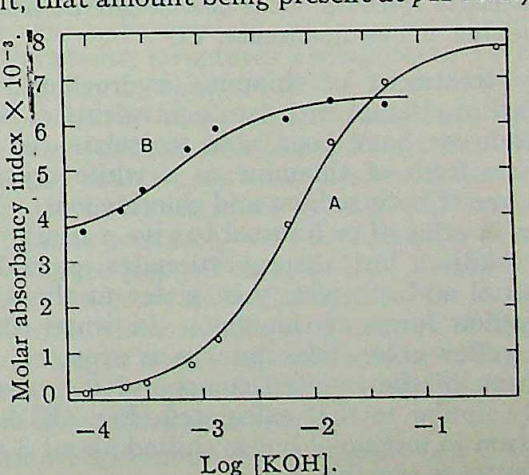

Fig. 3.—Ultraviolet absorbancy of thiamine *versus* concentration of methanolic KOH: A, molar absorbancy index at 349 mμ; B, molar absorbancy index of the intermediate plus free base forms at 290.3 mμ (see text). The lines are theoretical curves for dissociation of monoprotic acids.

The amount of the intermediate at any base concentration was computed as follows: the concentration of the yellow form was calculated from the absorbancy at 349 mμ. Then the contribution of the yellow form to the absorbancy at 290.3 mμ was subtracted from the observed absorbancy at that wave length and the difference used to compute the absorbancy index, a_M (neutral + intermediate), of the remaining mixture of neutral plus singly dissociated forms. The plot of a_M (neutral + intermediate) *versus* log [KOH] (Fig. 3B) is in effect a titration curve for the production of the intermediate. The solid line is again a theoretical curve for a monoprotic acid with a mid-point at log [KOH] = −3.2. From Fig. 3A, the mid-point of the second dissociation step is estimated as log [KOH] = −2.15 and it follows that K_1 is about 16 times K_2. These constants are sufficiently far apart that the lower points in Fig. 3A should deviate from the constructed curve by only a few per cent. From the spectrum of a solution of log [KOH] = −3.1 in which 58% of the thiamine exists as the intermediate, the spectrum of the intermediate was computed (by subtracting the absorbancy of the neutral and yellow forms at each wave length) Fig. 4B shows the spectrum of the intermediate form in methanol.

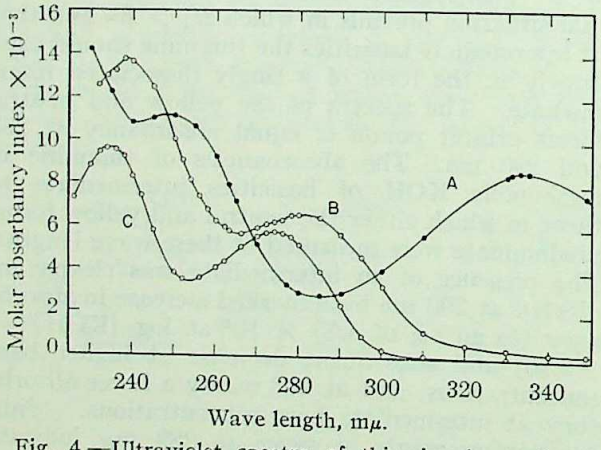

Fig. 4.—Ultraviolet spectra of thiamine in methanol: A, thiamine, 1 *N* KOH, 1–6 minutes after addition of KOH; B, calculated spectrum of the intermediate tricyclic form; C, spectrum of dihydrothiamine, VI.

By treatment of thiamine hydrochloride suspended in ethanol with two equivalents of sodium ethoxide we have been able to isolate the intermediate form of thiamine as a white crystalline solid free of both sodium and chloride ions. It dissolves in ethanol or butanol to give a nearly colorless solution but disproportionates partially in methanol and completely in water to the neutral and yellow forms of thiamine. In water the intense yellow color fades quickly as expected. The spectrum of the isolated compound in butanol is closely similar to that calculated (Fig. 4B) for the spectrum in methanol but is shifted about 3 mμ to shorter wave lengths.

The Structures of the Yellow and Intermediate Forms.—The following compounds which are structurally related to thiamine do not undergo spectral changes in 0.1 or 5.4 *N* methanolic KOH corresponding to those observed with thiamine: 2-methyl-4-amino-5-aminomethylpyrimidine dihydrochloride, 3,4-dimethyl-5-(2-hydroxyethyl)-thiazolium chloride and an equimolar mixture of these substances which nearly correspond to the two "halves" of the thiamine molecule, 3-benzyl-4-methyl-5-(2-hydroxyethyl)-thiazolium chloride and oxythiamine (3-(4-hydroxy-2-methyl-5-pyrimidyl-methyl)-4-methyl-5-(2-hydroxyethyl)-thiazolium chloride). Neopyrithiamine (1-(4-amino-2-methyl-5-pyrimidylmethyl)-2-methyl-3-(2-hydroxyethyl)-pyridinium bromide hydrobromide) gave no color in 0.1 *N* KOH but did give a very transient color with a maximum absorbancy at about 360–370 mμ in 5.4 *N* methanolic KOH. The extreme base concentration and experimental difficulties make this behavior difficult to interpret. Thus it appears that production of the yellow form requires the presence of the primary amino group on the pyrimidine ring and the presence of the thiazolium ring in the same molecule.

We propose that the amino group of thiamine adds, with simultaneous loss of a proton, to the thiazolium ring to yield the intermediate, tricyclic, dihydrothiachromine form IV in a manner analogous to the addition of a hydroxyl ion to form the pseudo-base II. The intramolecular nature of the reaction with the amino group helps to explain its rapidity as compared to the reaction of a hydroxyl group. The ionization of IV with an opening of the thiazole ring leads to the yellow thiol form V. This structure for the yellow form was proposed by Zima and Williams[6] for their isolated compound and is supported by their analyses.

Additional support for the tricyclic structure IV for the intermediate comes from a comparison with the spectra of other aminopyrimidines. The absorption band of the intermediate near 280 mμ is shifted about 10 mμ to a longer wave length than that of the corresponding pyrimidine absorption band of dihydrothiamine (VI, Fig. 4C). Similarly, Brown and Short[10] have shown that methylation of 4-aminopyrimidines leads to bathochromic shifts of 8–9 mμ. However, IV absorbs more strongly around 240 mμ than does dihydrothiamine. It is quite possible that in IV the carbon–sulfur bond which breaks to yield V is already weakened and that this polarization of the molecule results in a higher absorption around 240 mμ, similar to that observed with the thiol form III (Fig. 1B).

The tricyclic form, IV, is closely related to thiochrome (VII) and in alcoholic solutions is gradually oxidized by air to VII as evidenced by the development of an intense blue fluorescence.[11]

(10) D. J. Brown and L. N. Short, *J. Chem. Soc.*, 334 (1953).

(11) Thiamine is oxidized readily to thiochrome by alkaline ferricyanide [G. Barger, F. Bergel and A. R. Todd, *Ber.*, **68**, 2257 (1935)]. However, we find that if the thiamine stands in base long enough for the yellow form to disappear before addition of the ferricyanide, no thiochrome is formed, nor is thiochrome formed from the white sodium salt of the thiol III (except for a trace which arises from the small amount of yellow form V in equilibrium with III. See the succeeding section of this paper for a discussion of this equilibrium). The thiol III apparently is oxidized to thiamine disulfide instead of thiochrome. On the other hand, the yellow sodium salt of V and the tricyclic form IV are oxidized readily to thiochrome by alkaline ferricyanide in accord with Syke's and Todd's view (reference 9) that V is the precursor of thiochrome.

Structure IV has also been suggested as an intermediate in the de-

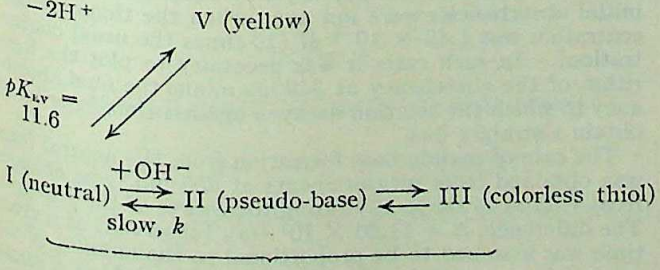
VI VII

The Kinetics of Decay of the Yellow Color.—The yellow color decays in aqueous solutions at all *p*H values, with a half-life of less than one minute at 19° in some cases. By plunging a portion of thiamine into an alkaline buffer in a spectrophotometer cell and measuring the absorbancy at 349 mμ as a function of time, we were able to determine the rates of decay with satisfactory accuracy. At all *p*H values this decay was accurately first order with respect to the yellow form. First-order rate constants were calculated, and their logarithms are plotted against *p*H in Fig. 5. The yellow form does not exist to an appreciable extent below a *p*H of about 10.6; hence, no points could be obtained at lower *p*H values. However, the rate of reaction of thiamine with hydroxyl ion to form the colorless thiol form III could be measured in the *p*H range 10 to 10.8 by following the increase in absorbancy at 255 mμ. Again the rate was first order, this time with respect to the neutral form of thiamine. Rate data for this second reaction are also plotted against *p*H in Fig. 5. The points fall on the *same* hyperbola-like curve that describes the *p*H dependence of the rate of fading of the yellow color suggesting that the fading is caused by the *slow* reaction of hydroxyl ion with the neutral form I which is in a *rapid* equilibrium with the yellow form V. The final product is the more stable colorless thiol form III. From the pK_{av} values of 11.6 for the conversion to the yellow form



V and of 9.3 for conversion to the thiol form III, it follows that at equilibrium, the ratio of the colorless thiol form to the yellow form should be 200

composition of thiamine disulfide (ref. 9) and as a product of the reduction of thiochrome by hydrosulfite [R. Kuhn and H. Vetter, *Ber.*, **68**, 2375 (1935)].

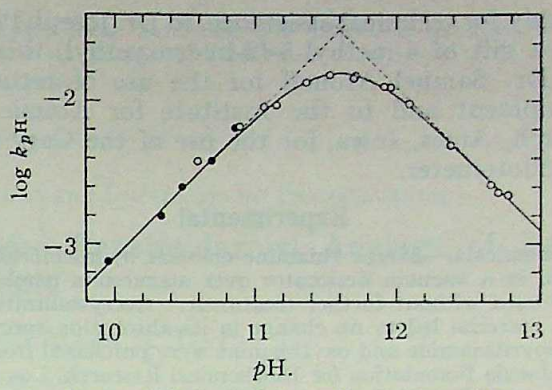


Fig. 5.—Rates of fading of the yellow color: ○, apparent first-order rate constants for the disappearance of the yellow form of thiamine in buffers of 0.2 ionic strength; ●, apparent first-order rate constants for conversion of neutral thiamine to the thiol form. The line represents the theoretical *p*H dependence (see text).

and the disappearance of the yellow color will be almost complete.

This scheme leads to the prediction that the apparent first-order rate constants k_{pH} for the fading of the yellow color and for reaction of the neutral form to give the thiol form should have the *p*H dependence

$$\log k_{pH} = \log kK_w - pH - \log (K_{av}^2 + [H^+]^2)$$

where k is the *second-order* rate constant for the reaction of the neutral form of thiamine with hydroxyl ion; K_w is the ion-product of water, and K_{av} is the average of K_1 and K_2 for the dissociation of thiamine to form the yellow compound V. The solid line in Fig. 5 is a theoretical curve constructed to fit the foregoing equation using values of log $kK_w = -13.1$ moles liter^{-1} sec.$^{-1}$ and $pK_{av} = 11.6$ at 19.2°. The excellent fit of the experimental points to this theoretical curve provides additional support for the assumption of a two-proton dissociation of thiamine to form the yellow substance.

Significance with Respect to Enzymic Catalysis.—The mechanism of the catalytic action of thiamine is still uncertain although Breslow[12] has recently presented a plausible new theory. Consideration should also be given to the possibility that at some stage in the reaction sequence by which thiamine functions, structures analogous to IV or V occur. It may be objected that a *p*Kav of 11.6 for the formation of these structures is too high to permit their function in a biological system. However, a prior reaction with a substrate such as pyruvate might decrease *p*Kav greatly. If an intermediate analogous to V were formed after reaction with pyruvate (*e.g.*, as visualized by Breslow[12]) its decarboxylation would be assisted by the conjugation with the electron-accepting centers of the pyrimidine ring in a manner quite similar to that suggested in the decarboxylation of α-amino acids by vitamin B_6-containing enzymes.[13,14]

Roddy for technical assistance, to Dr. Joseph Picken for a gift of 4-methyl-5-(2-hydroxyethyl)-thiazole, to Dr. Samuel Aronoff for the use of recording equipment and to the Institute for Atomic Research, Ames, Iowa, for the use of the Cary spectrophotometer.

Experimental

Chemicals.—Merck thiamine chloride hydrochloride was dried in a vacuum desiccator over magnesium perchlorate and used without further treatment. Recrystallization of this material led to no change in its absorption spectrum. Neopyrithiamine and oxythiamine were purchased from the California Foundation for Biochemical Research, Los Angeles, and 2-methyl-4-amino-5-(2-aminomethyl)-pyrimidine from Nutritional Biochemicals Corp., Cleveland. 3,4-Dimethyl-5-(2-hydroxyethyl)-thiazolium chloride was prepared from du Pont 4-methyl-5-(2-hydroxyethyl)-thiazole and methyl iodide.[15] Eight g. of the resulting methiodide was dissolved in water and shaken for 1 hour with an excess of freshly precipitated silver chloride. The precipitated silver iodide was filtered off and the solution was concentrated in vacuum to a thick sirup. This was dissolved in 20 ml. of absolute alcohol, 15 ml. of ether was added and the methochloride was allowed to crystallize, then recrystallized from alcohol and ether; m.p. 136–138°. *Anal.* Calcd. for $C_7H_{12}ONSCl$: C, 43.4; H, 6.25; Cl, 18.3. Found: C, 43.4; H, 6.2; Cl, 18.4. 3-Benzyl-4-methyl-5-(2-hydroxyethyl)-thiazolium chloride was prepared by the procedure of Livermore and Sealock[16]; m.p. 145–147°.

Dihydrothiamine was prepared by reduction of thiamine with trimethoxyborohydride according to the procedure of Bonvicino.[17]

The white sodium salt of the thiol form of thiamine (III), the yellow sodium salt of thiamine and thiamine monochloride were prepared according to the procedures of Zima and Williams.[6]

Reagent grade (Baker) absolute methanol was employed. Moisture was carefully excluded.

The Tricyclic (Dihydrothiachromine) Form of Thiamine.—Five grams (0.015 mole) of thiamine chloride hydrochloride was suspended in 20 ml. of cold absolute alcohol and 0.03 mole of sodium ethoxide in cold ethanol of total volume 12 ml. was added with stirring. The sodium chloride was quickly filtered off by suction on a sintered glass filter and the filtrate was allowed to stand for about 3 hours in the cold. The white crystalline solid was collected on a buchner funnel. Moisture was carefully excluded through use of a rubber dam to prevent yellowing of the product. After washing with cold alcohol and peroxide-free ether the compound was dried *in vacuo* at room temperature; yield 1.1 g., m.p. 128–129° dec. *Anal.* Calcd. for $C_{12}H_{16}ON_4S$: C, 54.5; H, 6.1; N, 21.2; neut. equiv., 264. Found: C, 54.6; H. 6.2; N, 21.3; neut. equiv., 267; molecular wt. by comparison of spectrum in 0.1 *N* HCl with that of thiamine hydrochloride, 267.

Spectral Measurements.—A Beckman DU spectrophotometer with the cell compartment thermostated at 25° in most cases and at 19.2° in some experiments was used for quantitative spectral measurements. A Cary model 12 recording spectrophotometer was employed for preliminary evaluation of spectra.

Spectra usually were measured on 1.42×10^{-4} *M* solutions of the thiazolium compounds prepared by dilution of a stock solution. Spectra in methanol were obtained by adding an aliquot of the stock solution to methanolic KOH of appropriate concentration, mixing and reading the spectrum within 5 minutes for qualitative studies and within 2–3 minutes for quantitative measurements. The absorbancy of the yellow form decreased by 1–3% during the first 6 minutes after mixing.

Spectra in aqueous solutions were measured in buffers, usually of 0.2 ionic strength and consisting of potassium phosphates at *p*H 6.8, of sodium bicarbonate and KOH from *p*H 9–10, of piperidine hydrochloride and KOH from *p*H 10 to 12, and of KOH and KCl above 12. When the spectra changed rapidly with time, 0.1 ml. of an appropriate stock solution was plunged into 3.0 ml. of buffer in the spectrophotometer cell by means of the adder-mixer of Boyer and Segal[18] which permits complete mixing within 2 seconds or less. Readings were obtained at intervals of 5 seconds beginning 10 seconds after mixing. Satisfactorily accurate readings and timing were obtained through the help of a second person in timing and recording. Some data were also collected using a Varian linear recorder to plot transmittancy *versus* time. Extrapolation of absorbancies to zero time using semi-log paper was usually precise.

Following each kinetic measurement, the temperature in the cell was measured and found to lie within the limits 19.2 ± 0.2°. The *p*H was then measured using a Beckman model G meter and the temperature of the sample in the *p*H meter noted. The *p*H was corrected to 19.2°. Although thiamine can undergo irreversible oxidative reactions in air, we have taken no precautions to exclude air. This is justified by the short time intervals involved and by the demonstrated complete reversibility of the phenomena described here when the elapsed time was kept small. It appears that in most cases, only a few per cent. of irreversible decomposition occurs in the spectrophotometer cell in periods up to two hours.

Calculations.—The methanolic KOH solutions were standardized and the basicity of the final diluted solutions expressed as the logarithm of the excess KOH concentration. When the KOH concentration was low, the amount of KOH which had reacted with the thiamine was subtracted from the total amount added to give the excess. From the spectrum the amounts of yellow form, intermediate and free base present were computed and the correction was made on the assumption that 3, 2 and 1 equivalents of base, respectively, were consumed in the production of these forms from the hydrochloride. Satisfactory accuracy in the log [KOH] values was obtainable except below log [KOH] = −4.

The curve in Fig. 3B which shows the molar absorbancy index, a_M for the neutral plus intermediate forms in methanol was computed using the following data. From Fig. 3A the limiting value for a_M at 349 mμ was taken as 7.75×10^3 and assumed to represent a_M for the yellow form (the corresponding a_M in aqueous solution is 6.52×10^3). Within experimental error, the same molar absorbancy indices were obtained for the yellow sodium salt described by Zima and Williams.[6] At 290.3 mμ the a_M for the yellow form is 3.38×10^3.

First-order rate constants for the fading of the yellow color in aqueous solutions were computed by plotting the logarithm of the absorbancy at 349 mμ against time and measuring the slope. A linear relationship was observed (except in samples of low initial absorbancies) as might be expected when the absorbancy falls to zero at equilibrium. Actually a_M did not fall to zero, but from initial values as high as 6.5×10^3 to 0.02 to 0.1 $\times 10^3$. a_M would be expected to decrease to 0.03×10^3 representing the 0.5% of yellow form still present at equilibrium. The presence of impurities and slow side reactions and the difficulty of measuring very low absorbancies accurately may account for the variation in these values. In some samples, at the lower *p*H values, only a small amount of yellow color was present and initial absorbancies were low even when the thiamine concentration was 1.42×10^{-3} *M* (10 times the usual concentration). In such cases it was necessary to plot the logarithm of the absorbancy at 349 mμ minus the final absorbancy to which the solution decayed against time in order to obtain a straight line.

The rate of pseudo-base formation from the neutral form was obtained from measurements at 255 mμ. a_M changes from 7.36 to 11.66×10^3 during the course of the reaction. The difference, $\Delta = 11.66 \times 10^3 - a_M$ (observed) at a given time was assumed to be proportional to the amount of the neutral form remaining at that time. Plots of log Δ *versus* time were linear and permitted calculation of the rate constants.

Estimates of the pK_{av} for conversion to the thiol form were also obtained from data at 255 mμ for thiamine and two sim-

Metabolite Analogs. VII. Preparation of Some Benzimidazolyl Analogs of Ethyl Pteroylglutamate

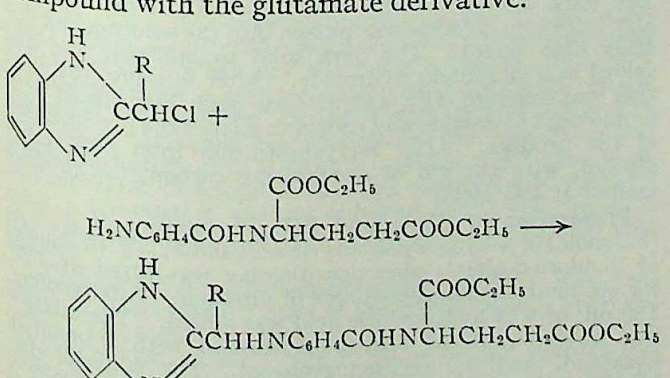
BY W. RAYMOND SIEGART AND ALLAN R. DAY

RECEIVED JANUARY 15, 1957

Some benzimidazolyl analogs of ethyl pteroylglutamate have been prepared. Substituents have been placed on the carbon atom of the methylene bridge and in the benzene ring of the benzimidazole.

Two benzimidazolyl analogs of pteroylglutamic acid have been reported previously, N-{4-[(2-benzimidazolyl)-methylamino]-benzoyl}-glutamic acid[1] and N{4-[(5-chloro-2-benzimidazolyl)-methylamino]-benzoyl}-glutamic acid. The first compound was reported to retain a certain degree of growth-promoting activity[1a] and also to be a weak growth antagonist.[1b] The 5-chloro compound was reported to be a stronger growth antagonist than the unsubstituted analog.[1b] It seemed to be desirable to extend this work, in several ways, in order to determine the possibility of obtaining strong anti-folic activity in this type of compound. In the present investigation, benzimidazolyl analogs of folic acid have been synthesized containing not only substituents in the benzene ring but also on the carbon atom of the methylene bridge. Substituents have been placed on the methylene bridge when there were no substituents on the ring and when there were substituents on the benzene ring. The choice of substituents in the benzene ring was influenced by the work of Hoover and Day.[2]

The syntheses of the benzimidazolyl analogs of pteroylglutamic acid involved four steps: (1) preparation of diethyl *p*-aminobenzoylglutamate; (2) preparation of 2-hydroxyalkylbenzimidazoles; (3) preparation of 2-chloroalkylbenzimidazoles; and (4) finally, the condensation of the chloroalkyl compound with the glutamate derivative.



p-Nitrobenzoylglutamic acid was prepared by a modified Schotten–Baumann procedure from *p*-nitrobenzoyl chloride and glutamic acid. The nitro group was reduced by catalytic hydrogenation over palladium and the corresponding aminobenzoylglutamic acid converted to its diethyl ester. Preliminary work had shown that the final products, the benzimidazolyl analogs of folic acid, were most readily isolated and purified in the form of their ethyl esters.

The 2-hydroxyalkylbenzimidazoles were prepared from the appropriate hydroxy acid and *o*-phenylenediamine by the Phillips method[3] or by fusing the reactants together. The hydroxy compounds were then converted to the corresponding chloro compounds by treatment with thionyl chloride.

In order to reduce side reactions to a minimum, the hydrochlorides of the chloro compounds were used for condensation with diethyl *p*-aminobenzoylglutamate. The condensations were carried out in dioxane solution in the presence of two equivalents of triethylamine. The main side-reaction which occurred to a greater or less extent, depending on the nature of the chloro compound, was self condensation. It had been shown earlier[4] that the 2α-chloroalkylbenzimidazoles do not always undergo normal anionic replacement reactions. They show a marked tendency to undergo self-condensation to form tetracyclic compounds. For example, 2-chloromethylbenzimidazole readily forms dibenzimidazo[1,2,-a,1′,2′,-d]piperazine. On several occasions during the course of the present work, high melting, crystalline compounds were isolated whose analyses indicated that they were tetracyclic. No attempt was made to purify these secondary products. Gummy materials also were separated from the reactions of the 2α-chloroalkylbenzimidazoles with ethyl *p*-aminobenzoylglutamate. They were assumed to be linear polymers formed from self-condensation of the chloro compounds.

For testing purposes, two benzimidazolyl analogs of the ethyl ester of pteroic acid were prepared also. They were prepared by condensing the chloroalkyl benzimidazoles with ethyl *p*-aminobenzoate.

All of the final products are being tested for physiological activity. The test results will be published elsewhere.

[a] Ref. 3. [b] Ref. 4. [c] Recryst. from 33% ethanol. [d] Recryst. from 50% ethanol. [e] Recryst. from 95% ethanol. [f] P. Mamalis, V. Petrow and B. Sturgen, *J. Chem. Soc.*, 1600 (1950).

Experimental

p-**Nitrobenzoylglutamic Acid.**—A solution of 47 g. (0.25 mole) of *p*-nitrobenzoyl chloride in 170 ml. of benzene was added slowly, with stirring and cooling, to a solution of 29.4 g. (0.2 mole) of glutamic acid and 32 g. (0.8 mole) of sodium hydroxide in 170 ml. of water. After the completion of the reaction, the aqueous layer was separated and adjusted to a *p*H of 4 to 5 with concentrated hydrochloric acid and the *p*-nitrobenzoic acid removed by filtration. The filtrate was adjusted to a *p*H of 1 and cooled overnight. The precipitated *p*-nitrobenzoylglutamic acid was removed and recrystallized from hot water; yields 75–80%, m.p. 112.5–113.5°.

p-**Aminobenzoylglutamic Acid.**—The amino compound was obtained by hydrogenation of the nitro derivative over palladium-in-ethanol solution. The crude product was recrystallized from hot water with the aid of decolorizing carbon; yield 75%, m.p. 172–173°.

Diethyl *p*-**Aminobenzoylglutamate.**—This ester was prepared by the method of Waller, *et al.*[5]; yield 70%, m.p. 143–144°.

Preparation of 2-Hydroxyalkylbenzimidazoles.—These compounds were prepared from the corresponding *o*-phenylenediamines and α-hydroxy acids. The following were made by the Phillips method[3]: 2-(1-hydroxyethyl)-benzimidazole (I), 2-(1-hydroxyisopropyl)-benzimidazole (II), 2-(1-hydroxybenzyl)-benzimidazole (III), 2-(1-hydroxyethyl)-5-chlorobenzimidazole (IV), 2-(1-hydroxyisopropyl)-5-chlorobenzimidazole (V), 2-hydroxymethyl-5-nitrobenzimidazole (VII), 2-(1-hydroxyethyl)-5-nitrobenzimidazole (VIII), 2-(1-hydroxyisopropyl)-5-nitrobenzimidazole (IX), 2-hydroxymethyl-4-nitro-6-chlorobenzimidazole (X), 2-(1-hydroxyethyl)-4-nitro-6-chlorobenzimidazole (XI), 2-hydroxymethyl-5-methylbenzimidazole (XIII), 2-(1-hydroxyethyl)-5-methylbenzimidazole (XIV), 2-(1-hydroxyisopropyl)-5-methylbenzimidazole (XV), and 2-hydroxymethyl-4-amino-6-chlorobenzimidazole (XVI).

The Phillips method did not give good yields in all cases. In the preparation of IV and VIII, after the refluxing period was completed, the solution was adjusted to a *p*H of 5. The aqueous layer was decanted from a dark oil that had formed and the solution adjusted to *p*H 8 to precipitate the benzimidazole product. The procedure was least efficient for the preparation of X, XI and XII. In these cases, after the refluxing period, the mixture was cooled and the solid removed by filtration. After washing with water, the solid was treated with 2 *N* sodium hydroxide solution and filtered. The filtrate was acidified with hydrochloric acid, neutralized with ammonium hydroxide, cooled and the solid removed. The first filtrate was made 2 *N* with sodium hydroxide and filtered. The filtrate was acidified with hydrochloric acid, neutralized with ammonium hydroxide, cooled and the precipitate removed. The two precipitates were combined and recrystallized from alcohol.

The following compounds were prepared by fusing the diamine and hydroxy acid: 2-(1-hydroxybenzyl)-5-chlorobenzimidazole (VI) and 2-(1-hydroxyisopropyl)-4-nitro-6-chlorobenzimidazole (XII).

Preparation of VI.—4-Chloro-*o*-phenylenediamine (14.25 g., 0.1 mole) was added to 13.6 g. (0.1 mole) of molten mandelic acid (125°). The reaction mixture was maintained at 125° in an atmosphere of nitrogen for two hours. The dark gummy residue was dissolved in dry ethanol. Dry hydrogen chloride was passed into the solution and dry ether then added. The dark solid so obtained was dissolved in 2 *N* sodium hydroxide. After filtering, the solution was acidified with hydrochloric acid, neutralized with ammonium hydroxide and cooled to hasten the precipitation of the product. After recrystallization from 50% ethyl alcohol, with the aid of decolorizing carbon, the product melted at 189–190.5°.

Preparation of Compound XII.—A mixture of 20.8 g. (0.2 mole) of-α-hydroxyisobutyric acid and 37.5 g. (0.2 mole) of 5-chloro-3-nitro-*o*-phenylenediamine was fused at 110° for six hours in an atmosphere of nitrogen. After cooling, 150 ml. of 4 *N* hydrochloric acid was added. The mixture was filtered and the filtrate neutralized with ammonium hydroxide and the product removed. The material that was insoluble in the hydrochloric acid was treated with 2 *N* sodium hydroxide and filtered. The filtrate was acidified with hydrochloric acid, neutralized with ammonium hydroxide, cooled and the product removed by filtration. The two products were combined and recrystallized from 50% ethyl alcohol with the aid of decolorizing carbon. Yellow needles were obtained.

Preparation of 2-Chloroalkylbenzimidazoles.—Many difficulties were encountered in attempting to convert the hydroxy compounds to the corresponding chloro compounds.

[a] Yield as hydrochloride. [b] This compound was not obtained analytically pure, but was used successfully to make the folic acid analog. [c] Gummy solid. [d] No definite m.p.; starts to decompose at 130°. [e] Starts to decompose at 45–50°.

The free bases of the 2-chloroalkylbenzimidazoles are very reactive and tend to self-condense. In four cases the pure free bases could not be obtained although the crude free bases were used successfully to make the folic acid analogs. In most cases the hydrochlorides of the 2-chloroalkyl compounds could be isolated in better yields than the free bases and they appeared to be considerably more stable.

2-(1-Chloroethyl)-benzimidazole (XVII) and 2-(1-chloroisopropyl)-benzimidazole (XVIII) were obtained as their hydrochlorides by heating the hydrochlorides of I and II, respectively, in chloroform solution for 2–3 hours with thionyl chloride.[4] After cooling, dry ether was added to precipitate the hydrochlorides. The products were thoroughly washed with ether and dried.

The hydrochloride of 2-(1-chlorobenzyl)-benzimidazole (XIX) was prepared in a similar way in 50–60% yields. The free base was obtained by dissolving the hydrochloride in the least amount of water. This solution was cooled and slowly neutralized with sodium bicarbonate solution. The crude free base was removed, washed with ice-water and dried *in vacuo*. It was recrystallized by dropping the compound into boiling acetone, decanting the acetone from a heavy red oil and cooling. White needles were obtained.

The hydrochloride of 2-(1-chloroethyl)-5-chlorobenzimidazole (XX) was prepared from 2-(1-hydroxyethyl)-5-chlorobenzimidazole hydrochloride as described above, yields 60–70%. The dry, crude free base obtained from the hydrochloride was recrystallized by adding it to boiling benzene. The benzene was decanted from a dark oil which formed and cooled. White needles were obtained.

Difficulties were encountered in preparing the hydrochloride of 2-(1-chloroisopropyl)-5-chlorobenzimidazole (XXI) from 2-(1-hydroxyisopropyl)-5-chlorobenzimidazole hydrochloride. When dry ether was added to precipitate the hydrochloride, a gummy material was obtained. It was converted to a solid by stirring it with several portions of dry ether. Attempts to recrystallize the solid from dry alcohol and ether gave a gummy material which once more was converted to a solid by treating several times with dry ether. Although it was not obtained analytically pure, it was used successfully for the preparation of the folic acid analog.

2-Chloromethyl-5-nitrobenzimidazole (XXII) was prepared by dissolving 0.1 mole of the corresponding hydroxymethyl compound in 250 ml. of boiling dioxane. The solution was cooled to 60° and 30 ml. of thionyl chloride was added with stirring. The reaction was exothermic and no further heat was applied. After the temperature dropped to room temperature, dry ether was added to complete the precipitation of the hydrochloride. After removing the hydrochloride, washing with dry ether and drying, it was dissolved in cold water. This solution was slowly neutralized with sodium bicarbonate solution. The product was removed by filtration, washed with water and dried. It was purified by dropping it into boiling benzene and filtering to remove insoluble material. On cooling slowly an oil was first separated. The benzene was decanted and further cooled to give the product (white needles).

2-(1-Chloroethyl)-5-nitrobenzimidazole (XXIII) was prepared from 0.15 mole of the hydroxyethyl compound and 80 ml. of thionyl chloride. The solution was refluxed for 1.5 hours. The free base was obtained from this solution by the same procedure used for XXII. The product could not be obtained in pure form but it formed the expected analog with diethyl *p*-aminobenzoylglutamate. The following is a typical analysis. *Anal.* Calcd. for $C_9H_8O_2N_3Cl$: C, 47.90; H, 3.58; N, 18.63; Cl, 15.71. Found: C, 49.45; H, 3.64; N, 17.60; Cl, 14.44.

2-(1-Chloroisopropyl)-5-nitrobenzimidazole (XXIV) was prepared from 2-(1-hydroxyisopropyl)-5-nitrobenzimidazole in the same manner as XXIII. The final crystallization was made from a solution containing equal amounts of benzene and petroleum ether. The analytical data were similar to those noted above but the product was used successfully to prepare the desired analog.

2-(1-Chloroethyl)-5-methylbenzimidazole hydrochloride (XXV) was prepared from the corresponding hydroxyethyl compound by the method used for the preparation of XVII. The free base could not be obtained and even the hydrochloride could not be obtained analytically pure. The latter was obtained as an oil from dry ethanol and ether. The oil was extracted several times with dry ether and placed in a vacuum desiccator over calcium chloride until solidification was complete; yields 50–63%. A typical analysis: *Anal.* Calcd. for $C_{10}H_{12}N_2Cl_2$: C, 51.96; H, 5.24; N, 12.12; Cl, 30.67. Found: C, 50.19; H, 5.71; N, 11.99; Cl, 27.43.

2-(1-Chloroisopropyl)-5-methylbenzimidazole (XXVI) was prepared from 2-(1-hydroxyisopropyl)-5-methylbenzimidazole by the same procedure used for XXV. Similar to XXV, it could not be obtained analytically pure, but was used successfully for the preparation of the corresponding folic acid analog.

Preparation of Benzimidazolyl Analogs of Diethyl *p*-Aminobenzoylglutamate. Diethyl N-{4-[1-(2-Benzimidazolyl)-ethylamino]-benzoyl}-glutamate (XXVII).—2-(1-Chloroethyl)-benzimidazole hydrochloride (54.25 g., 0.25 mole), 80 g. (0.25 mole) of diethyl *p*-aminobenzoylglutamate and 200 ml. of dry dioxane were placed in a flask. Triethylamine (50.5 g., 0.5 mole) was added and the solution refluxed for 10 hours. After standing overnight, the precipitated triethylamine hydrochloride was removed. It was washed with water and the water-insoluble residue was dried. The product was extracted with benzene and then recrystallized from alcohol–water.

Diethyl N-{4-[1-(2-Benzimidazolyl)-isopropylamino]-benzoyl}-glutamate (XXVIII).—The procedure for XXVII was used here also. In these preparations an additional small amount of product could be obtained by concentrating the original filtrate. The oil so obtained was extracted with benzene leaving a small amount of solid product.

XXXV	CH_3	H	5-Methyl	11	161.5–162.5	64.97	6.72	11.66		64.91	6.61	11.73	
XXXVI	CH_3	CH_3	5-Methyl	15	108–110	65.55	6.94	11.33		65.39	6.93	11.38	

Diethyl N-{4-[1-(2-Benzimidazolyl)-benzylamino]-benzoyl}-glutamate (XXIX).—In this preparation the free base 2-(1-chlorobenzyl)-benzimidazole was used in place of the hydrochloride and only one equivalent of triethylamine was added. Otherwise the procedure for XXVII was followed.

Diethyl N-{4-[1-(5-Chloro-2-benzimidazolyl)-ethylamino]-benzoyl}-glutamate (XXX).—The procedure for the preparation of XXVII was used in this case. To obtain the product the filtrate from the triethylamine hydrochloride was evaporated under reduced pressure and the resulting oil allowed to stand overnight under benzene to produce a solid material which was recrystallized from benzene to give a product with one molecule of benzene; m.p. 103–105°.

Anal. Calcd. for $C_{31}H_{35}O_5N_4Cl$: C, 64.29; H, 6.10; N, 9.68; Cl, 6.12. Found: C, 63.98; H, 6.13; N, 9.69; Cl, 6.22.

Several recrystallizations from carbon tetrachloride gave a pure product free of benzene; yield 18%.

Diethyl N-{4-[1-(5-Chloro-2-benzimidazolyl)-isopropyl-amino]-benzoyl}-glutamate (XXXI).—The method used for preparing XXVII was employed here also. The product was obtained from the filtrate, after removing the triethylamine hydrochloride, in the same manner that XXIX was isolated. In this case the pure, unsolvated product was obtained by recrystallization from benzene.

Diethyl N-{4-[1-(5-Nitro-2-benzimidazolyl)-methyl-amino]-benzoyl}-glutamate (XXXII).—This compound was prepared by the method used for compound XXVII except that the product was isolated from the filtrate from the triethylamine hydrochloride by evaporation under reduced pressure. The oily product so obtained was extracted with hot benzene. On cooling to room temperature some diethyl *p*-aminobenzoylglutamate separated and was removed. The analog XXXII was obtained by evaporation of the benzene filtrate under reduced pressure. It was recrystallized from 50% alcohol–water.

Diethyl N-{4-[1-(5-Nitro-2-benzimidazolyl)-ethylamino]-benzoyl}-glutamate (XXXIII).—It was prepared by the method used for XXXI from 2-(1-chloroethyl)-5-nitrobenzimidazole hydrochloride and diethyl *p*-aminobenzoylglutamate with the following modifications: (a) the triethylamine in an equal volume of dioxane was added over a period of one hour to the reaction mixture at 60°; and (b) the resulting mixture was held at 60° for 8 hours with continual stirring.

Diethyl N-{4-[1-(5-Nitro-2-benzimidazolyl)-isopropyl-amino]-benzoyl}-glutamate (XXXIV) and diethyl N-{4-[1-(5-methyl-2-benzimidazoyl)-ethylamino]-benzoyl}-glutamate (XXXV) were prepared by the method used for XXX. In these cases, however, the products were recrystallized from alcohol–water.

Diethyl N-{4-[1-(5-Methyl-2-benzimidazolyl)-isopropyl-amino]-benzoyl}-glutamate (XXXVI).—The procedure used for the preparation of XXX was used here also. In this case the final purification was accomplished by recrystallization from carbon tetrachloride.

Preparation of Benzimidazolyl Analogs of the Ethyl Ester of Pteroic Acid. Ethyl 4-[1-(2-Benzimidazolyl)-ethylamino]-benzoate.—2-(1-Chloroethyl)-benzimidazole hydrochloride (39.4 g., 0.18 mole), 29.7 g. (0.18 mole) of ethyl *p*-aminobenzoate and 125 ml. of dry dioxane were placed in a flask and 36.36 g. (0.36 mole) of triethylamine added. The solution was refluxed for 8 hours, cooled and the precipitate removed. After thorough extraction with water, the residue was recrystallized from alcohol–water; yield 34%, m.p. 213–215°.

Anal. Calcd. for $C_{18}H_{19}O_2N_3$: C, 69.88; H, 6.20; N, 13.59. Found: C, 70.08; H, 6.34; N, 13.72.

Ethyl 4-[1-(5-Chloro-2-benzimidazolyl)-ethylamino]-benzoate.—This compound was prepared from 2-(1-chloroethyl)-5-chlorobenzimidazole by the above procedure. The product was purified by recrystallization from benzene; yield 14%, m.p. 191–193°.

Anal. Calcd. for $C_{18}H_{18}O_2N_3Cl$: C, 62.87; H, 5.29; N, 12.22; Cl, 10.31. Found: C, 62.61; H, 5.37; N, 12.08; Cl, 10.27.

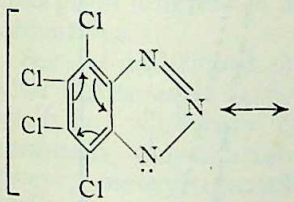
Halogenated Benzotriazoles[1]

BY RICHARD H. WILEY AND KARL F. HUSSUNG

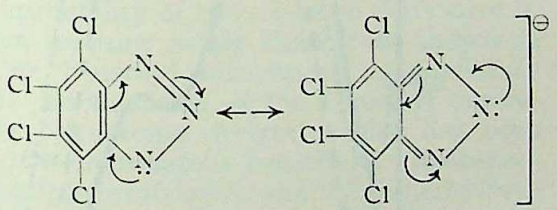
RECEIVED FEBRUARY 23, 1957

4,7- and 5,6-dichlorobenzotriazole add to conjugated systems to give 2- and 1-substituted derivatives, respectively. This establishes with more certainty the previously postulated steric effect in which 4,7-substituents direct this type of addition to the 2-position. Tetrabromobenzotriazole and 5-methyl-4,6,7-trichlorobenzotriazole also give 2-substituted conjugate addition products. The halogenation of 2-methyl-4-nitro-, 4-nitro- and 2,5-dimethylbenzotriazoles gives the 4,5,6,7-tetrachloro derivative with replacement of the bz substituent by chlorine. Some previously undescribed compounds including several tetrachlorobenzotriazole derivatives, 4-iodobenzotriazole and 2-methyl-5-nitrobenzotriazole have been prepared and characterized. Nitration of 2-methylbenzotriazole gives the 5-nitro derivative whose structure has been established by comparison with 2-methyl-4-nitrobenzotriazole, the structure of which has been established by its chlorination to 2-methyl-4,5,6,7-tetrachlorobenzotriazole.

In previous papers in this series,[2-4] we have described the structural problems which result from the possibility for 1- and 2-isomerism in the products of the conjugate addition of azoles to unsaturated systems. One of the unusual observations in these studies was that 4,5,6,7-tetrachlorobenzotriazole adds to conjugated unsaturated systems to give 2-substituted derivatives whereas benzotriazole itself gives only 1-substituted derivatives. The absence of any obvious electronic factor attributable to the chlorine substituents, which can result in the exclusive participation of



Ia

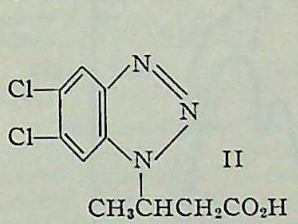


Ib Ic

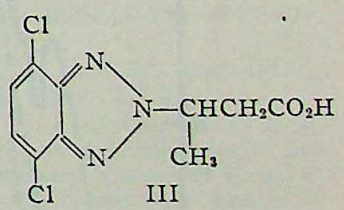
resonance structure Ic in the addition reaction, suggests that a steric factor is primarily responsible. In order to evaluate this factor in more detail the 4,7- and 5,6-dichlorobenzotriazoles, their 1- and 2-methyl derivatives and their conjugate addition products have been prepared and characterized. A variety of additional types of substituted benzotriazoles, including tetrabromobenzotriazole, have been prepared and the chlorination and bromination processes have been further characterized. The results of these studies will be discussed in this paper.

5,6-Dichlorobenzotriazole was prepared from *o*-dichlorobenzene *via* 4,5-dichloro-1,2-dinitrobenzene[5] which was reduced to the diamine and cyclized to the triazole in 50% yield. 4,7-Dichlorobenzotriazole was prepared from 2,5-dichloroaniline. The acylated aniline was nitrated and converted to 2,5-dichloro-6-nitroaniline.[6] This was reduced to 3,6-dichloro-*o*-phenylenediamine[7] which was diazotized to give the triazole in 81% yield. The 1- and 2-methyl derivatives of each were separated by recrystallization from dilute sulfuric acid in which the less basic 2-methyl derivatives are less soluble. The absorption data for the 1- and 2-methyl derivatives of 5,6-dichlorobenzotriazole show maxima at 272 and 295 and at 293 mμ, respectively. The absorption data for the 1- and 2-methyl derivatives of 4,7-dichlorobenzotriazole show the same general pattern but with more structure. The principal maxima occur at 272 and 294 and at 285 mμ, respectively, with several additional slightly less intense maxima. The complete data are given in Figs. 1 and 2.

Addition reactions with crotonic acid gave β-1′-(5′,6′-dichlorobenzotriazolyl)-butyric acid (II) and



II



III

β-2′-(4′,7′-dichlorobenzotriazolyl)-butyric acid (III). β-Phenyl-β-2′-(4′,7′-dichlorobenzotriazolyl)-propiophenone was obtained from benzalacetophenone and 4,7-dichlorobenzotriazole. The absorption maxima, summarized in Figs. 1 and 2, are consistent with these structural assignments. Both of the 2-substituted derivatives show single maxima at 286 mμ, and the 1-substituted derivative shows double maxima at 274 and 296 mμ. These data establish that the presence of the chlorine atoms in the 4,7-positions is sufficient to cause the addition reaction to take place in the 2-position and that the 5,6-chlorine substituents do not interfere with addition at the 1-position. In the absence of additional data relating this orientation to the inductive effect of the chlorine or to contributions from resonance structures related to the electron release characteristics of the chlorine, the orientation to the 2-position is assigned to a type

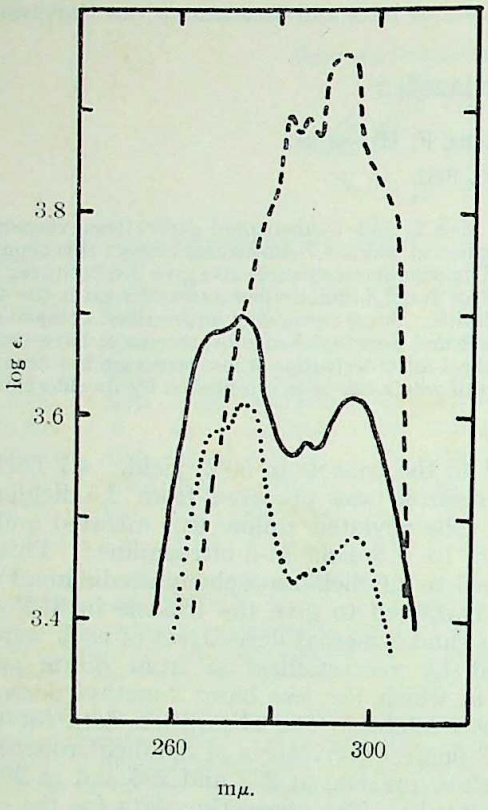

Fig. 1.—Ultraviolet absorption curves for 1-methyl-5,6-dichlorobenzotriazole (———); 2-methyl-5,6-dichlorobenzotriazole (– – – –); β-1′-(5′,6′-dichlorobenzotriazolyl)-butyric acid (. . . .).

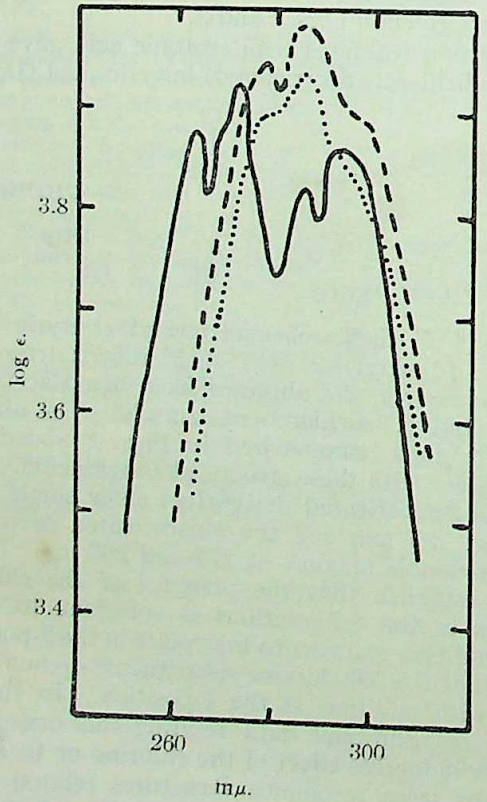

Fig. 2.—Ultraviolet absorption curves for 1-methyl-4,7-dichlorobenzotriazole (———); 2-methyl-4,7-dichlorobenzotriazole (– – – –); β-2′-(4′,7′-dichlorobenzotriazolyl)-butyric acid (. . . .).

of steric hindrance presumably characteristic of these and related systems.

The addition products obtained from tetrabromobenzotriazole are also of the 2-substituted type. Tetrabromobenzotriazole has been obtained in 54% yield from benzotriazole, bromine and concd. nitric acid. 5-Chloro-4,6,7-tribromobenzotriazole has been obtained similarly from 5-chlorobenzotriazole in 56% yields. The 1- and 2-methyl and ethyl derivatives of tetrabromobenzotriazole have been prepared by bromination of 1- and 2-alkylbenzotriazoles. The absorption data show maxima for the 1-alkyl derivatives at 278–289 and 308 mμ. The 2-alkyl derivatives show a single principal maximum at 306 mμ. The introduction of four bromo groups has produced very little, if any, bathochromic shift in these maxima as compared to the tetrachloro analog. The adduct from benzalacetophenone, β-phenyl-β-2′-(4′,5′,6′,7′-tetrabromobenzotriazolyl)-propiophenone, shows a single maximum in the 300–308 mμ range characteristic of the 2-substituted benzotriazoles. The data are given in Figure 3.

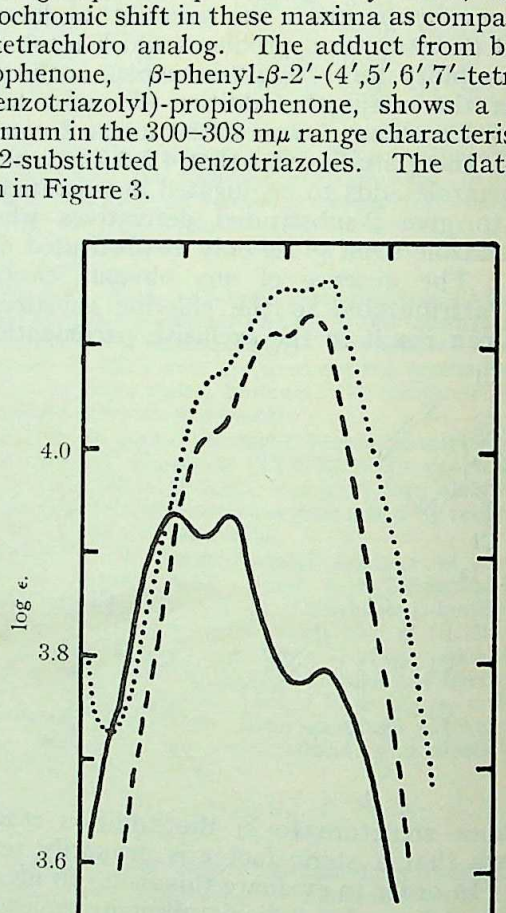

Fig. 3.—Ultraviolet absorption curves for 1-ethyl-4,5,6,7-tetrabromobenzotriazole (———); 2-ethyl-4,5,6,7-tetrabromobenzotriazole (– – – –); β-phenyl-β-2′-(4′,5′,6′,7′-tetrabromobenzotriazolyl)-propiophenone (. . . .).

Addition products obtained from 5-methyl-4,6,7-trichlorobenzotriazole[8] are also of the 2-substituted type. Chlorination of 5-methylbenzotriazole gives the trichloro derivative. Adducts from benzalacetophenone, acrylamide and acrylonitrile show single maxima in the 295–300 mμ range characteristic of the 2-substituted derivatives.

In the course of these studies several previously

undescribed derivatives of benzotriazole have been obtained. These include the methiodide and dimethochloride of 2-(2-dimethylaminoethyl)-tetrachlorobenzotriazole, 1-dimethylamino-4,5,6,7-tetrachlorobenzotriazole, β-2′-(tetrachlorobenzotriazolyl)-butyramide, β-1′-(benzotriazolyl)-butyramide and the 1- and 2-ethyl derivatives of tetrachlorobenzotriazole. 4-Iodobenzotriazole has been prepared from 4-nitrobenzotriazole[9] by reduction and replacement of the amino group. 1-Methyl-6-chlorobenzotriazole has been prepared from 4-chloro-1,2-dinitrobenzene[10] *via* 5-chloro-2-nitro-N-methylaniline,[11] reduction to the diamine and cyclization with nitrous acid. Bromination gave the tribromo derivative.

Some new observations about substitution reactions in the benzotriazole series are available. The nitration of 2-methylbenzotriazole has been shown to give 2-methyl-5-nitrobenzotriazole, m.p. 150–152°. This structure is established by comparison with 2-methyl-4-nitrobenzotriazole, m.p. 183–184°. The latter was obtained by methylation of the known 4-nitrobenzotriazole. The structure of the 4-nitro compound as that of a 2-methyl derivative is established by the fact that it gives 2-methyl-4,5,6,7-tetrachlorobenzotriazole on chlorination. The presence of the nitro group obscures the usual absorption differences between the 1- and 2-methyl derivatives.

Several additional observations about the character of the aqua regia chlorinations are also now available. Contrary to our previous report[2] the persistent chlorination of 1-methylbenzotriazole gives 1-methyltetrachlorobenzotriazole. Apparently, the incomplete chlorination results from an increased insolubility of the trichloro derivative in the reaction mixture rather than from the steric effect of the 1-methyl substituent as previously postulated. Bromination of the 1-methyl derivative to the tetrabromo derivative also has been achieved. On chlorination 2-methyl-4-nitrobenzotriazole, 4-nitrobenzotriazole and 2,5-dimethylbenzotriazole are converted to tetrachlorobenzotriazoles. In these systems the bz (but not the 2) substituents are replaced by chlorine. 2,5-Dimethylbenzotriazole was prepared by alkylation and separated by precipitation of the ether-insoluble hydrochlorides of the 1-methyl analogs.

These observations establish two new factors about the substitution reactions of benzotriazoles: (1) substitution takes place at the 5-position in the 2-substituted types and (2) replacement of nitro and methyl by chloro takes place during chlorination.

Experimental[12]

5,6-Dichlorobenzotriazole.—To a solution of 16.3 g. (0.069 mole) of 4,5-dichloro-1,2-dinitrobenzene[5] in 75 ml. of concd. hydrochloric acid was added 93.5 g. (0.414 mole) of stannous chloride dissolved in 300 ml. of concd. hydrochloric acid. The resulting solution was heated with stirring until all the dinitrobenzene was reacted as indicated by the disappearance of an orange color. The solution was cooled, filtered and the resulting product washed with concd. hydrochloric acid. The dihydrochloride of the diamine thus obtained was dissolved in water, cooled to 0° and treated with 4.75 g. (0.069 mole) of sodium nitrite in 15 ml. of water. The solid product was filtered, washed with water, recrystallized from ethanol–water and dried to give 6.5 g. (50%) of crude product. Two recrystallizations from nitromethane and one from ethyl acetate gave an analytical sample, m.p. 264–266°; λ_{max}, 265 (s = shoulder) (log ε 3.50), 270(3.53), 286(s)(3.61), 292(3.67).

Anal. Calcd. for $C_6H_3N_3Cl_2$: N, 22.35; neut. equiv., 188.0. Found: N, 22.42; neut. equiv., 188.3.

2-Methyl-5,6-dichlorobenzotriazole.—To a solution of 3.7 g. (0.02 mole) of 5,6-dichlorobenzotriazole in 100 ml. of 1 *N* sodium hydroxide was added 2.5 g. (0.02 mole) of dimethyl sulfate dropwise over a period of 10 minutes. The resulting mixture was heated on a steam-bath for 1 hr. The solid product which separated on cooling was collected on a filter, washed with water and dried to give 2.0 g. of a crude mixture of 1- and 2-methyl derivatives. Two recrystallizations from dilute sulfuric acid gave 0.75 g. (18%) of reasonably pure 2-methyl derivative. Two additional recrystallizations from methanol gave an analytical sample, m.p. 186–188°; λ_{max}, 282(3.89), 286(3.89), 293(3.95), 300(s)(3.84).

Anal. Calcd. for $C_7H_5N_3Cl_2$: N, 20.80. Found: N, 20.65.

1-Methyl-5,6-dichlorobenzotriazole.—The sulfuric acid filtrates from the recrystallization of the above mixture of 1- and 2-methyl-5,6-dichlorobenzotriazole were diluted with water to precipitate 1.25 g. (31%) of reasonably pure 1-methyl derivative. Three additional recrystallizations from nitromethane gave an analytical sample, m.p. 210–212°; λ_{max}, 268(s)(3.68), 272(3.70), 286(s)(3.57), 295 (3.62).

Anal. Calcd. for $C_7H_5N_3Cl_2$: N, 20.80. Found: N, 20.60.

β-1′-(5′,6′-Dichlorobenzotriazolyl)-butyric Acid (II).—A mixture of 1.5 g. (0.08 mole) of 5,6-dichlorobenzotriazole, 0.86 g. (0.01 mole) of crotonic acid and 20 drops of pyridine was heated for 15 hr. at 100°. The reaction mixture was poured into 100 ml. of 1.0 *N* hydrochloric acid to precipitate the crude product which was filtered, dried and washed with 100 ml. of ether to give 1.4 g. (64%) of the product. Three recrystallizations from acetic acid–water gave an analytical sample, m.p. 174–175°; λ_{max}, 268(s)(3.57), 274(3.61), 290(s)(3.45), 296(3.48).

Anal. Calcd. for $C_{10}H_9N_3Cl_2O_2$: N, 15.33; neut. equiv., 274.1. Found: N, 15.60; neut. equiv., 271.2.

4,7-Dichlorobenzotriazole.—To a solution of 25.91 g. (0.1465 mole) of 3,6-dichloro-*o*-phenylenediamine[6,7] dissolved in 245 ml. of glacial acetic acid was added 45 ml. of water. The resulting solution was cooled to 5° and 11.03 g. (0.16 mole) of sodium nitrite dissolved in 20 ml. of water was added with stirring. The precipitate from the reaction mixture was filtered, dried and recrystallized from dilute ethanol to give 22.4 g. (81%) of crude product. Three recrystallizations from nitromethane gave an analytical sample, m.p. 275–277°; λ_{max}, 264(3.82), 270(3.85), 285(3.81), 292(s)(3.79).

Anal. Calcd. for $C_6H_3N_3Cl_2$: N, 22.35; neut. equiv., 188.0. Found: N, 22.07; neut. equiv., 188.9.

2-Methyl-4,7-dichlorobenzotriazole.—To a solution of 5.64 g. (0.03 mole) of 4,7-dichlorobenzotriazole in 200 ml. of 0.5 *N* sodium hydroxide was added 3.8 g. (0.03 mole) of dimethyl sulfate dropwise with stirring over a period of 10 minutes. The resulting mixture was heated on a steam-bath for 1 hr. After cooling, the precipitated product was collected on a filter, washed with water and dried to give 3.3 g. of a crude mixture of 1- and 2-methyl derivatives. Two recrystallizations from dilute sulfuric acid gave 1.05 g. (17%) of reasonably pure 2-methyl derivative. Four additional recrystallizations from methanol gave an analytical sample, m.p. 174–176°; λ_{max}, 278(3.95), 285(3.98), 292(3.92), 296(s)(3.89).

Anal. Calcd. for $C_7H_5N_3Cl_2$: C, 41.61; H, 2.50; N, 20.80. Found: C, 41.58; H, 2.51; N, 20.30.

β-Phenyl-β-2′-(4′,7′-dichlorobenzotriazolyl)-propiophenone.—To a melt of 1.88 g. (0.01 mole) of 4,7-dichlorobenzotriazole and 2.08 g. (0.01 mole) of benzalacetophenone was added 4 drops of benzyltrimethylammonium hydroxide solution. The mixture was heated for 3 hr. at 80°, cooled and dissolved in 50 ml. of ether. Addition of petroleum ether precipitated 2.65 g. (67%) of the crude product. Three recrystallizations from ethanol gave an analytical sample, m.p. 150–151°; λ_{max}, 280(s)(3.97), 286(4.03), 298(s)(3.83).

Anal. Calcd. for $C_{21}H_{15}N_3Cl_2O$: N, 10.60. Found: N, 10.75.

4,5,6,7-Tetrabromobenzotriazole.—A solution of 11.9 g. (0.10 mole) of benzotriazole and 72.0 g. (0.45 mole) of bromine in 150 ml. of concd. nitric acid was heated for 30 hr. under reflux. The crystalline product was collected on a filter, washed and dried to give 23.5 g. (54%) of the crude product. Several recrystallizations from acetic acid gave the pure product, m.p. 262–266°; λ_{max}, 278(4.01), 285(4.03), 300(3.94).

Anal. Calcd. for $C_6HN_3Br_4$: N, 9.67; neut. equiv., 434.8. Found: N, 9.89; neut. equiv., 434.5.

5-Chloro-4,6,7-tribromobenzotriazole.—A solution of 4.6 g. (0.03 mole) of 5-chlorobenzotriazole and 21.0 g. (0.13 mole) of bromine in 60 ml. of concd. nitric acid was heated for 22 hr. under reflux. The crystalline product was collected on a filter, washed and dried to give 6.60 g. (56%) of the crude product. Several recrystallizations from methanol gave the pure product, m.p. 249–251°; λ_{max}, 277(s)(3.93), 285(3.98), 302(3.91).

Anal. Calcd. for $C_6HN_3ClBr_3$: N, 10.77; neut. equiv., 390.3. Found: N, 11.00; neut. equiv., 398.0.

1-Methyl-4,5,6,7-tetrabromobenzotriazole.—A solution of 1.33 g. (0.01 mole) of 1-methylbenzotriazole and 7.00 g. (0.044 mole) of bromine in 25 ml. of concd. nitric acid was heated for 24 hr. under reflux. The crystalline product was collected on a filter, washed and dried to give 2.20 g. (48%) of the crude 1-methyl derivative. Several recrystallizations from nitromethane gave the pure product, m.p. 225–226°; λ_{max}, 278(3.96), 289(3.95), 308(3.80).

Anal. Calcd. for $C_7H_3N_3Br_4$: N, 9.36. Found: N, 9.35.

2-Methyl-4,5,6,7-tetrabromobenzotriazole.—A solution of 1.33 g. (0.01 mole) of 2-methylbenzotriazole and 7.00 g. (0.044 mole) of bromine in 25 ml. of concd. nitric acid was heated for 8 hr. under reflux. The crystalline product was collected on a filter, washed and dried to give 3.0 g. (67%) of the crude 2-methyl derivative. Several recrystallizations from nitromethane gave the pure product, m.p. 250–253°; λ_{max}, 285(s)(3.99), 294(4.10), 299(4.10), 306(4.12).

2-Dimethylaminoethyl-4,5,6,7-tetrachlorobenzotriazole Dimethochloride.—To a solution of 3.28 g. (0.01 mole) of 2-dimethylaminoethyl-4,5,6,7-tetrachlorobenzotriazole in 75 ml. of methanol was added 1.26 g. (0.01 mole) of dimethyl sulfate. The resulting solution was then evaporated to dryness and the crude salt redissolved in a mixture of 50 ml. of water and 10 ml. of concd. hydrochloric acid. After heating to boiling, 2.44 g. (0.01 mole) of barium chloride dihydrate was added. After boiling several minutes, the hot solution was filtered to remove the barium sulfate. The filtrate was cooled and the precipitate collected on a filter, washed, dried and extracted with 100 ml. of ethanol. The filtered ethanol solution was evaporated to precipitate 3.4 g. (79%) of the crude product. Several recrystallizations from nitromethane gave the pure product, m.p. 236–237°; λ_{max}, 294(4.13), 300(4.13), 306(4.12).

Anal. Calcd. for $C_{12}H_{16}N_4Cl_6$: C, 33.59; H, 3.76. Found: C, 33.80; H, 3.77.

1-Dimethylaminoethyl-4,5,6,7-tetrachlorobenzotriazole.—To 21 g. (0.082 mole) of 4,5,6,7-tetrachlorobenzotriazole dissolved in 500 ml. of 0.5 *N* potassium hydroxide was added 11.7 g. (0.082 mole) of dimethylaminoethyl chloride hydrochloride. The resulting solution was heated for 30 minutes on a steam-bath. The oil which separated solidified on cooling. The product was collected on a filter, dried and taken up in ether. Evaporation to dryness gave 3.5 g. (13%) of the crude product. Several recrystallizations from ethanol gave an analytical sample, m.p. 93–95°; λ_{max}, 276(3.90), 283(3.92), 305(3.73).

Anal. Calcd. for $C_{10}H_{10}N_4Cl_4$: N, 17.08; Found: N, 17.16.

β-2′-(4′,5′,6′,7′-Tetrachlorobenzotriazolyl)-butyramide.—To 10 ml. of thionyl chloride was added in small portions 1.7 g. (0.005 mole) of β-2′-(4′,5′,6′,7′-tetrachlorobenzotriazolyl)-butyric acid. After solution was complete, the thionyl chloride was removed on a steam-bath. The remaining solution was added dropwise with stirring to 20 ml. of cold concd. ammonium hydroxide to precipitate 1.6 g. (95%) of crude product. Several recrystallizations from nitromethane gave the pure product, m.p. 228–229°; λ_{max}, 294(4.09), 302(4.08).

Anal. Calcd. for $C_{10}H_8N_4Cl_4O$: N, 16.38; Cl, 41.47. Found: N, 16.51; Cl, 41.50.

1-Ethyl-4,5,6,7-tetrachlorobenzotriazole.—A solution of 1.5 g. (0.01 mole) of 1-ethylbenzotriazole in 300 ml. of concd. hydrochloric acid and 100 ml. of concd. nitric acid was heated for 52 hr. under reflux. The solution was cooled and the crystalline product collected on a filter, washed and dried to give 2.3 g. (81%) of the crude product. Several recrystallizations from methanol gave the pure product, m.p. 114–117°; λ_{max}, 276(s)(3.86), 283(3.89), 304(3.71).

Anal. Calcd. for $C_8H_5N_3Cl_4$: N, 14.75; Cl, 49.77. Found: N, 14.77; Cl, 49.82.

2-Ethyl-4,5,6,7-tetrachlorobenzotriazole.—A solution of 1.5 g. (0.01 mole) of 2-ethylbenzotriazole in 300 ml. of concd. hydrochloric acid and 100 ml. of concd. nitric acid was heated for 50 hr. under reflux. The solution was cooled and the crystalline product collected on a filter, washed and dried to give 1.8 g. (63%) of the crude product. Several recrystallizations from methanol gave the pure product, m.p. 160–163°; λ_{max}, 294(4.11), 300(4.10).

Anal. Calcd. for $C_8H_5N_3Cl_4$: N, 14.75; Cl, 49.77. Found: N, 14.55; Cl, 49.80.

4-Iodobenzotriazole.—To 13.5 g. (0.06 mole) of stannous chloride in 50 ml. of concd. hydrochloric acid was added in small portions a mixture of 3.28 g. (0.02 mole) of 4-nitrobenzotriazole in 20 ml. of concd. hydrochloric acid. The resulting solution was heated to boiling and allowed to cool. The chlorostannate, which crystallized on cooling, was collected on a filter and washed with concd. hydrochloric acid. The crystalline product was dissolved in water and hydrogen sulfide bubbled through until no more precipitation of tin sulfides was evident. The tin sulfides were removed by filtration and the filtrate made strongly acidic by the addition of 50% sulfuric. The solution was cooled to 0°, and sodium nitrite was added until a slight excess existed. The clear solution was then poured into 300 ml. of ice-water, and an excess of potassium iodide in water was added slowly with stirring. The free iodine which formed was reduced with sodium sulfite, and 10 g. of sodium acetate was added. The solution was then neutralized to a *p*H 3 with 6 *N* sodium hydroxide and extracted with three 300-ml. portions of ether. The combined ether extracts were dried over sodium sulfate and evaporated to give 0.8 g. (16.3%) of crude product. Several recrystallizations from water gave the pure product, m.p. 216–218°; λ_{max}, 264 (3.95), 272(3.95), 286(3.90), 290(3.88).

Anal. Calcd. for $C_6H_4N_3I$: N, 17.15. Found: N, 17.20.

1-Methyl-6-chlorobenzotriazole.—A solution of 15.5 g. (0.083 mole) of 2-nitro-5-chloro-N-methylaniline[10,11] in 20 ml. of concd. hydrochloric acid was added in small portions to 56.4 g. (0.25 mole) of stannous chloride dissolved in 150 ml. of concd. hydrochloric acid. This solution was poured into 500 ml. of water and made distinctly basic by the addition of aqueous potassium hydroxide. The resulting solution was extracted with three 100-ml. portions of ether. The combined ether extracts were then extracted with three 100-ml. portions of 1 *N* hydrochloric acid. The aqueous extracts were combined, chilled to 10° and treated with 6.35 g. (0.092 mole) of sodium nitrite. The dark colored solution was made distinctly basic and extracted with three 100-ml. portions of ether. The combined ether extracts were dried over anhydrous sodium sulfate, the ether removed on a steam-bath and the product fractionated. There was obtained 4.0 g. (29%) of the crude 1-methyl derivative, b.p. 165° (25 mm.). Two recrystallizations of the solidified liquid from carbon tetrachloride gave the pure product, m.p. 121–123°; λ_{max}, 270(3.83), 282(3.77).

Anal. Calcd. for $C_7H_6N_3Cl$: N, 25.07. Found: N, 24.82.

2-Methyl-4-nitrobenzotriazole.—A solution of diazomethane in ether was added to 1.64 g. (0.01 mole) of 4-nitrobenzotriazole dissolved in 75 ml. of ether until a light yellow color persisted. Evaporation of the ether gave 1.7 g. (95.5%) of crude product. One recrystallization from dilute ethanol and two recrystallizations from ethyl acetate gave an analytical sample, m.p. 183–184° (light yellow needles).

Anal. Calcd. for $C_7H_6N_4O_2$: N, 31.45. Found: N, 31.52.

2-Methyl-5-nitrobenzotriazole.—A solution of 4.0 g. (0.03 mole) of 2-methylbenzotriazole in 40 ml. of water and 20 ml. of concd. nitric acid was heated for 60 hr. under reflux. The solution was cooled and the pale yellow crystalline product collected on a filter, washed and dried. There was obtained 1.7 g. (32%) of the crude product. Several recrystallizations from ethanol gave the pure product, m.p. 150–152°.

Anal. Calcd. for $C_7H_6N_4O_2$: C, 47.19; H, 3.40; N, 31.45. Found: C, 47.31; H, 3.17; N, 31.21.

2-Methyl-4,5,6,7-tetrachlorobenzotriazole from 2-Methyl-4-nitrobenzotriazole.—A solution of 0.18 g. (0.001 mole) of 2-methyl-4-nitrobenzotriazole in 39 ml. of concd. hydrochloric acid and 13 ml. of concd. nitric acid was heated under reflux for three days. The solution was cooled and diluted with water to precipitate 0.06 g. (22%) of the crude 2-methyl derivative, m.p. 179–182°. The product was recrystallized from methanol to give white needles, m.p. 182–184°. A mixed melting point with an authentic sample of 2-methyl-4,5,6,7-tetrachlorobenzotriazole showed no depression while the melting point of a mixture of the product with a pure sample of starting material was 148–157°.

1-Methyl-4,5,6,7-tetrachlorobenzotriazole by Chlorination of 1-Methylbenzotriazole.—A solution of 3.0 g. (0.0225 mole) of 1-methylbenzotriazole in 300 ml. of concd. hydrochloric acid and 100 ml. of concd. nitric acid was heated under reflux. The solid which had precipitated after 1 hr. heating was redissolved by the addition of 300 ml. of concd. nitric acid. This mixture was then refluxed for 72 hr. The solution was cooled and diluted with water to precipitate 3.5 g. (57%) of the crude product. Several recrystallizations from carbon tetrachloride gave the pure product, m.p. 193–196°. On admixture this material does not depress the m.p. of an authentic sample of 1-methyl-4,5,6,7-tetrachlorobenzotriazole.

4,5,6,7-Tetrachlorobenzotriazole from 4-Nitrobenzotriazole.—A solution of 1.2 g. (0.0075 mole) of 4-nitrobenzo-

triazole in 300 ml. of concd. hydrochloric acid and 150 ml. of concd. nitric acid was heated for one week under reflux. The solution was cooled and the crystalline product collected on a filter, washed and dried to give 1.2 g. (62%) of crude product. Recrystallization from nitromethane gave the pure product, m.p. 256–260°. On admixture this material does not depress the m.p. of an authentic sample of 4,5,6,7-tetrachlorobenzotriazole.

2-Methyl-4,5,6,7-tetrachlorobenzotriazole from 2,5-Dimethylbenzotriazole.—A solution of 1.5 g. (0.01 mole) of 2,5-dimethylbenzotriazole in 80 ml. of concd. hydrochloric acid and 80 ml. of concd. nitric acid was heated under reflux for 10 hr. The solution was cooled and the crystalline product collected on a filter, washed and dried. Three recrystallizations of this solid from methanol gave the pure product, m.p. 181–183°. On admixture this product does not depress the m.p. of an authentic sample of 2-methyl-4,5,6,7-tetrachlorobenzotriazole.

2,5-Dimethylbenzotriazole.—A solution of diazomethane in ether was added slowly to 13.3 g. (0.1 mole) of 5-methylbenzotriazole dissolved in ether until a slight yellow color persisted. The resulting solution was refluxed until the slight excess of diazomethane was removed and dried over anhydrous sodium sulfate. Dry hydrogen chloride was then bubbled through the ethereal solution. The precipitated hydrochlorides were removed by filtration. Evaporation of the ethereal solution gave 8.8 g. (60%) of crude product. Fractionation gave an analytical sample, b.p. 117° (12 mm.); λ_{max}, 276(s)(4.12), 284(4.14), 288(4.11).

Anal. Calcd. for $C_8H_9N_3$: N, 28.55. Found: N, 28.72.

β-1′-(Benzotriazolyl)-butyramide.—To 1.0 g. (0.005 mole) of β-1′-(benzotriazolyl)-butyric acid was added 4.0 ml. of thionyl chloride. After solution was complete, the mixture was added dropwise with stirring to 15 ml. of cold concd. ammonium hydroxide. The product was collected on a filter, washed with water and dried to give 0.3 g. which was 30% of the theoretical amount. Several recrystallizations from water gave an analytical sample, m.p. 104–105°; λ_{max}, 256(3.80), 262(3.80), 280(3.61).

Anal. Calcd. for $C_{10}H_{12}N_4O$: N, 27.44. Found: N, 27.42.

Ultraviolet Absorption Data.—Ultraviolet absorption measurements were made with a Beckman DU photoelectric spectrophotometer with 1.00-cm. silica cells and a hydrogen discharge lamp as the light source. The measurements were made in methanol solution. The data are recorded in the preceding Experimental sections as wave lengths at which maxima or shoulders(s) occur with the corresponding log ε in parentheses.

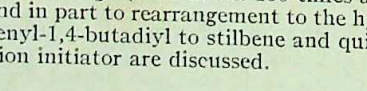
Preparation and Decomposition of a Cyclic Azo Compound. 3,6-Diphenyl-3,4,5,6-Tetrahydropyridazine

BY SAUL G. COHEN, SHU-HSI HSIAO,[1a] EUGENE SAKLAD AND CHI HUA WANG[1b]

RECEIVED MARCH 26, 1957

The azo compound I was prepared by addition of diethyl azodicarboxylate to 1,4-diphenylbutadiene-1,3, hydrogenation, hydrolysis, decarboxylation and autoxidation; λ_{max} 387 mμ, log ε 2.89, displaced from 345 mμ of *trans*-aliphatic azo compounds. Compound I decomposes in hydrocarbon solvents, including solutions containing styrene, with essentially quantitative yield of nitrogen, and about 100 times as fast at 80° as acyclic analogs. Solid I, heated at about 125°, led in part to styrene and in part to rearrangement to the hydrazone tautomer. Attempts to obtain products of addition of the biradical 1,4-diphenyl-1,4-butadiyl to stilbene and quinone failed. The mode of decomposition of I and its possible activity as a polymerization initiator are discussed.

As part of our study of the chemistry of azo compounds[2] we undertook to prepare 3,6-diphenyl-3,4,5,6-tetrahydropyridazine (I) and by its decomposition, the biradical 1,4-diphenyl-1,4-butadiyl (II), $C_6H_5\dot{C}HCH_2CH_2\dot{C}HC_6H_5$. Compound I, because of its cyclohexene type structure would be a *cis*-azo compound, while acyclic aliphatic azo compound are normally *trans*, and it seemed of interest to compare its physical properties, its ease of decomposition and its products of decomposition with those of the closely related *trans*-acyclic compounds,[3] 1-azo-bis-1-phenylethane or 1-azo-bis-1-phenylpropane, $C_6H_5-\underset{\displaystyle R}{\underset{|}{CH}}-N=N-\underset{\displaystyle R}{\underset{|}{CH}}C_6H_5$ (III), R = CH_3 or C_2H_5. The 1,4-biradical II, which might



I

be formed, would be of interest both for a study of its chemistry as such and because it is identical with the product of "tail-to-tail" reaction of two molecules of styrene which had once been proposed as the active intermediate in the initiation of the thermal polymerization of styrene,[4] but which is no longer supported.[5]

Preparation of Compound I.—The preparation of the azo compound I has been reported[6] by (1) condensation of two molecules of α-chloroacetophenone semicarbazone to a compound which appears to be 2-carbamyl-3,4,5-trihydro-3,6-diphenylpyridazine (a) followed by (2) treatment with sodium ethoxide at 160°. The product was converted to 3,6-diphenylpyridazine by treatment with bromine water and was assigned structure I. We repeated this preparation and found that the compound had an absorption maximum at 292 mμ, log ε 4.19, which has been characteristic of the hydrazones tautomeric with the acyclic azo compounds in this work,[2a,7] and end absorption in the near ultraviolet but no maximum in the range of 300–400 mμ which would be characteristic of the azo compound.[3] This, coupled with the strongly

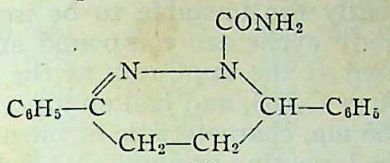
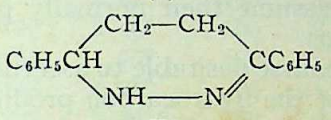
ionizing conditions of preparation, which would favor tautomerism, and the high thermal stability of the material, lead us to assign to it the tautomeric structure IV, m.p. 157–159°.



(a)

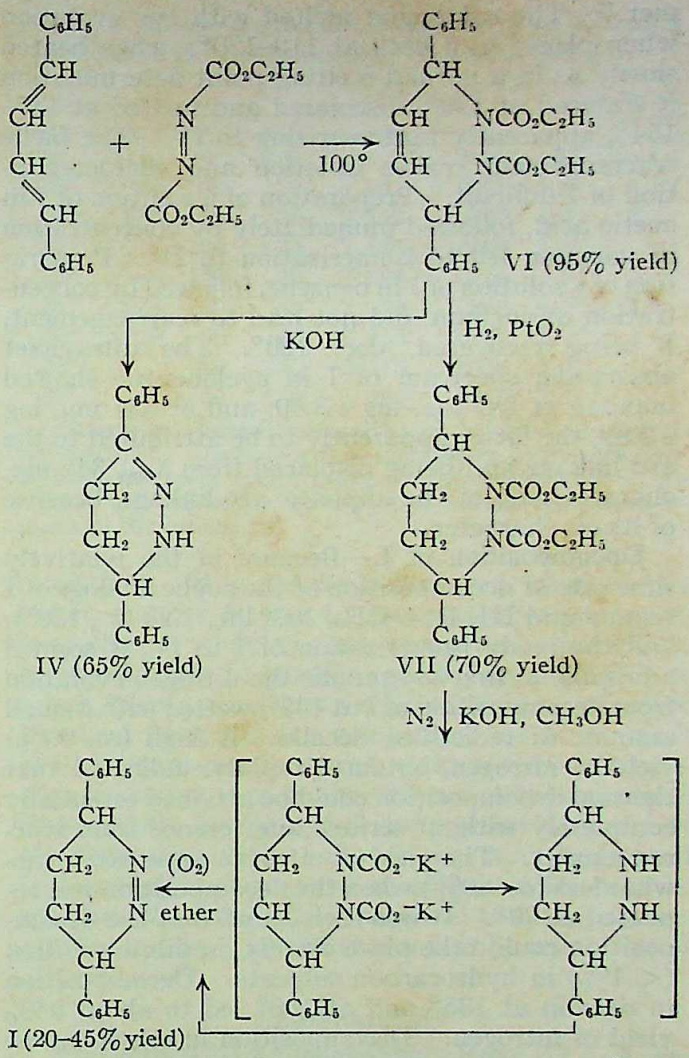


IV

Compounds of type III have been prepared by conversion of the relevant ketone C_6H_5COR to the azine, hydrogenation to the hydrazine and oxidation to the azo compound.[3] However, the reactions of γ-diketones necessary for the formation of cyclic azo compounds related to I do not proceed this simply. The reactions of 1,2-dibenzoylethane[8] and acetonylacetone[9,10] with hydrazine do not lead to isolation of the pure azine, *i.e.*, the 4,5-dihydropyridazine, but to a mixture from which the disproportionation products, the pyridazine and the tetrahydropyridazine, each substituted at the 3- and 6-positions, may be obtained. Again the conditions of formation of the tetrahydro compound would indicate that the one from dibenzoylethane is probably the more stable tautomer IV. In our work treatment of 1,2-dibenzoylethane with hydrazine led to a mixture V which was apparently not readily separated into its components. Attempted hydrogenation to the hexahydropyridazine over platinum oxide in ethanol containing hydrogen chloride led to the hydrazone IV in about 50% yield, while when the reaction was attempted in acetic acid, 3,6-diphenylpyridazine was obtained, also in about 50% yield. While we cannot rule out that these products were formed by disproportionation of the dihydro compound in the presence of the hydrogenation catalyst, they may well have comprised the crude reaction product V. Attempted reduction of the hydrazone IV or the mixture V with lithium aluminum hydride was not successful, although some of the azo compound I may have been present in the product from V. It seemed likely that more vigorous reduction, as with zinc and hydrochloric acid, would lead to cleavage of the nitrogen–nitrogen bond.[11]

The azo compound I was prepared by: (a) Diels–Alder addition of diethyl azo-dicarboxylate to 1,4-diphenylbutadiene, forming the adduct[12] VI, (b) hydrogenation[12] of the carbon–carbon double bond in VI, leading to VII, followed by (c) saponification of the hydrogenated adduct, decarboxylation and, apparently, autoxidation in ether solution to form I (Chart 1). Saponification of the adduct VI in methanol led, as reported,[12] to the tautomeric product IV instead of to the $\Delta^{4,5}$-

CHART 1



compound. While hydrogenation of VI did not, in our experiment, lead to a product of quite as sharp a melting point as reported, elementary analysis was satisfactory. Attempted acid hydrolysis of both the adduct VI and the hydrogenated adduct VII led to recovery of the respective starting materials. Alkaline hydrolysis of the hydrogenated adduct, compound VII, in glycol in the presence of air was reported[12] to lead to the tautomeric product of oxidation IV, while saponification in the absence of air led to impure hexahydrodiphenylpyridazine.[12]

In our work, alkaline hydrolysis of VII in glycol under nitrogen followed by attempted precipitation of the hydrochloride of the hexahydro compound from the ether extract of the saponification product led to the hydrazone IV. Observation of some crystals, which decomposed at 110° with gas evolution, in a portion of the product which had not been treated with hydrogen chloride led to successful synthesis of I. The hydrolysis of VII was carried out by treatment with potassium hydroxide in refluxing methanol under nitrogen, decarboxylation apparently occurring concomitantly. The solution was diluted with water and extracted with ether, either with or without prior neutralization with hydrochloric acid. Concentration of the dried ether solution led to the azo compound I, autoxidation of the hydrazo compound apparently taking place at this stage, since autoxidation during

the hydrolysis would lead to the hydrazone tautomer.[12] The compound melted with gas evolution when placed in a bath at 110–120°; when heated slowly as in a normal melting point determination it sintered at 120°, discolored and melted at 147–154°, apparently tautomerizing to IV. The facile rearrangement makes isolation and characterization of I difficult. Preparation of a solution of I in acetic acid, followed immediately by concentration in vacuum, led to isomerization to IV. Preparation of a solution of I in benzene, followed by concentration in vacuum, did not lead to rearrangement, I being recovered, dec. 120°. The ultraviolet absorption spectrum of I in cyclohexane showed maxima at 287 mμ, log ε 3.49, and at 387 mμ, log ε 2.89, the latter apparently to be attributed to the azo linkage and being displaced from λ_{max} 345 mμ, characteristic of the aliphatic azo linkage, because of its *cis* character.

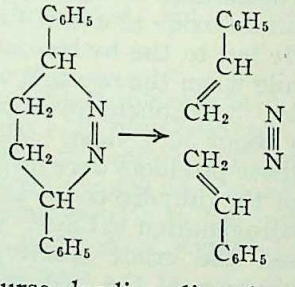
Decomposition of I.—Because of the relatively slow rate of decomposition of the acylic analogs of I (compound III, R = CH_3, half-life, 1.25 hr., 110°), and the ready isomerization of I to IV, it seemed advisable at first to examine the nitrogen evolution from decomposition of I at 135°, wetted with a small amount of redistilled decalin. A high (*ca.* 90%) yield of nitrogen, obtained rapidly, indicated that thermal decomposition could be attained essentially completely without serious interference from rearrangement. The yield of nitrogen appeared somewhat less (*ca.* 80%) when the decomposition was repeated at 90°. It was then found that the decomposition could take place cleanly, in dilute solution (< 1%) in hydrocarbon solvents. Decomposition in decalin at 135° and at 100° led to about 95% yield of nitrogen. Decomposition in ethylbenzene that had not been freshly distilled led to low, non-reproducible yields, rearrangement presumably taking place; distillation of the ethylbenzene led to high yields of nitrogen at 100°.

Since we would wish to examine compound I as an initiator of polymerization and as a source of the biradical II, a possible intermediate in the thermal polymerization of styrene, the decomposition of compound I in 3.46 moles/l. styrene in ethylbenzene was examined briefly. Nitrogen evolution was rapid and essentially quantitative both at 100 and at 80°. The data on evolution of nitrogen are summarized in Table I.

Observations made during the measurements of the evolution of nitrogen indicate that decomposition was essentially complete in about 20 minutes at 100° and that the half-life at 80° was about 20 minutes. In contrast, the half-life for decomposition of the acyclic analog $C_6H_5CH(CH_3)N{=}NCH(CH_3)C_6H_5$ (III) is about 4 hr.[3] at 100°. It may be estimated that the first-order rate constant for decomposition of I at 80° is about 6×10^{-4} sec.$^{-1}$, while that for III is about two orders of magnitude less, 4.5×10^{-6}. Apparently the *cis*-azo structure of I (possibly aided by another factor to be discussed below) leads to increased ease of decomposition, in addition to the shift in absorption maximum noted above. It will be of interest to examine the kinetics of decomposition of cyclic azo compounds of this type. Extreme instability had been reported[13] for a seven-membered cyclic azo compound, but subsequent work[14] assigned a different structure to the material. The six-membered cyclic analog of azo-bis-isobutyronitrile was apparently too unstable to be isolated.[10] A 24-membered[15] cyclic azo compound analogous to I decomposed at the same rate as the acyclic analog III (R = C_2H_5), and had an absorption maximum at 355 mμ, characteristic of the acyclic compounds; the large ring presumably allowed the azo linkages to assume their normally preferred *trans* configurations.

It was of course desirable to ascertain, if possible, the nature of the hydrocarbon products of decomposition. A sample of the azo compound I (0.053 g.) was decomposed in the solid state under nitrogen, and the residue was worked up. The rearranged product IV was obtained in 30% yield, and it appears likely and not unreasonable that the isomerization occurs to a greater extent under these conditions than in dilute solution in hydrocarbon solvents. The odor of styrene was detected readily immediately after the decomposition, and treatment of the filtrate, after removal of IV, with bromine in acetic acid led to styrene dibromide in 7% yield (based on non-rearranged I). Since this product was isolated in only 17% yield in a control experiment carried out under similar conditions, it may be that half of the azo compound which decomposes is converted to styrene. The styrene may be formed (a) in a second reaction from the biradical II or (b) directly from decomposition of the azo compound into three fragments

$$C_6H_5\dot{C}HCH_2CH_2\dot{C}HC_6H_5 \longrightarrow 2C_6H_5CH{=}CH_2 \quad \text{(a)}$$



(b)

The latter course, leading directly to three molecules and no radicals, might well contribute to the observed enhanced ease of decomposition of I. The rupture of the three bonds in process b need not be completely symmetrical, the two carbon–nitrogen bonds being more completely broken in the transition state than the carbon–carbon bond and the transition state possibly having characteristics of the transition state of both processes a and b. This would contribute to increased ease of decomposition and allow both styrene and products of the biradical to be observed.

Attempts were made to find evidence for the formation of the biradical II by carrying out the decomposition of I in the presence of unsaturated material that might react with II. In the presence of stilbene we failed to isolate the possible six-membered cyclic adduct, recovering part of the

[a] Decalin. [b] Ethylbenzene (not distilled). [c] Ethylbenzene (distilled). [d] 3.46 moles/l. styrene in ethylbenzene.

stilbene. In the presence of quinone the possible derivative of naphthohydroquinone was not found. In addition to recovered quinone and quinhydrone, a small amount of the rearrangement product IV and a considerable quantity (47% yield) of the product of dehydrogenation of I or IV, 3,6-diphenylpyridazine, were obtained.

In order to obtain preliminary information about the efficacy of this potential biradical source as a polymerization initiator, the styrene–ethylbenzene solutions in which the azo compound had been decomposed in the nitrogen evolution experiments were examined for polymer contents and compared with blank solutions treated in the same way in the absence of compound I. The data are summarized in Table II. In experiments carried out at 100° (expts. 23, 24, 25, 26), the polymer was precipitated in methanol; an undesirably high yield of polymer was found in the blank run in the absence of azo compound I. After correction for this, it appeared that about 4 molecules of styrene had been polymerized per molecule of I originally present. In experiments carried out at 80° (expts. 34, 35, 36, 37), the volatile components were removed in vacuum until the residue was brought to constant weight; satisfactory low yields were obtained in the absence of I and the small corrections were made. It appeared that about 8 molecules of styrene were rendered non-volatile per molecule of I originally present. Such a number has significance for comparison with other initiators only if (a) the rate of decomposition of the azo compound and (b) the fraction which is converted to radicals (as distinguished from styrene molecules) are known. Using the approximate rate constant, given before, and making the necessary corrections for concentration and temperature, we estimate[16] that benzoyl peroxide would polymerize about 70 molecules of styrene per molecule of peroxide under similar

[a] Sample was diluted with methanol and insoluble portion was weighed. [b] Sample was evaporated to constant weight in vacuum, room temperature. [c] Correction applied, assuming half the hydrocarbon part of the azo compound remains in the residue.

conditions. It is not clear, however, whether this larger number is due to the peroxide leading to long chains, while the azo compound through its biradical leads to smaller cyclic products,[5,17,18] or arises from a comparatively low yield of effective biradical from the azo compound, the larger part of it decomposing to styrene—the reverse of a possible initiating step in the thermal polymerization. Study of the kinetics of decomposition of I and of the properties of the polymer that may be formed in low yield are required to give indication as to whether the biradical II may lead to high polymer and be involved in the thermal polymerization of styrene.

Experimental[19]

3,6-Diphenyl-2,3,4,5-tetrahydropyridazine (IV). A.—α-Chloroacetophenone, 15.5 g. (0.1 mole), in 125 ml. of ethanol was treated with 11 g. (0.1 mole) of semicarbazide hydrochloride in 12.5 ml. of water at 40° with gradual addition of 8.5 g. (0.1 mole) of sodium bicarbonate. The mixture was boiled and cooled, and the product was collected, washed with ethanol and dried; α-chloroacetophenone semicarbazone 12.5 g. (0.059 mole), 59% yield, m.p. 151–152°, reported[20] 156°. The semicarbazone, 12.5 g., was heated under reflux for 1.2 hr. with 11 g. (0.13 mole) of sodium bicarbonate in 200 ml. of 1:1 ethanol–water. The product was collected and dried; 7.3 g. (0.026 mole), 44% yield, m.p. 213–216°, 218.5–220° after two crystallizations from benzene, reported[6] 221°. *Anal.* Calcd. for $C_{17}H_{17}ON_3$: C, 73.10; H, 6.13; N, 15.04. Found: C, 72.87; H, 5.85; N, 14.78. The product above, 2 g. (0.0072 mole), was heated for 6 hr. at 160° in a solution of 6 g. of sodium in 120 ml. of ethylene glycol and cooled. The product IV was collected and crystallized from ethanol, 1.6 g. (0.0068 mole), 94% yield, m.p. 157–159°, reported[6] 159°. No gas was evolved when it was heated to 300°. The absorption spectrum was determined in chloroform in a Beckman DU spectrophotometer and showed a small minimum at 245 mμ, log ε 3.68, a maximum at 292 mμ, log ε 4.19, which fell off rapidly to log ε 1.20 at 365 mμ and more slowly to log ε 0.45 at 400 mμ.

B.—Succinyl chloride, 20 g. (0.13 mole), in 56 ml. of thiophene-free benzene was added at room temperature over a period of 2 hr. with stirring to 25 g. (0.19 mole) of aluminum chloride in 200 ml. of benzene. The mixture was treated with ice and 20 ml. of concentrated hydrochloric

acid. The benzene solution was concentrated and the precipitate was washed and crystallized from ethanol, 1,2-dibenzoylethane, 5.0 g. (0.021 mole), 16% yield, m.p. 144–145°, reported[21] 144–145°. 1,2-Dibenzoylethane, 5 g. (0.021 mole), was dissolved in 30 ml. of ethanol and treated with 2 g. of hydrazine hydrate. A white solid V was obtained, 4.8 g., 96% yield, m.p. 140–210°. Attempted crystallization from ethanol did not lead to pure compounds.

A solution of 3 g. of the mixture V in 200 ml. of ethanol was treated with 5 ml. of ethanol saturated with hydrogen chloride, then with hydrogen over platinum oxide at 50° for 2.5 hr., filtered and cooled. Compound IV crystallized out, 0.650 g., m.p. 144–152°, 155–157°, after recrystallization from alcohol, alone and when mixed with the product from procedure A, above. The original filtrate was made alkaline, leading to an additional 1.1 g. of crude IV, m.p. 140–155°, 155–157° after several recrystallizations. The ultraviolet absorption spectrum was identical with that described in A, above.

C.—The adduct of diethyl azo-dicarboxylate and 1,4-diphenylbutadiene, compound VI below, 1 g. (0.0026 mole), was boiled in 3 ml. of 40% potassium hydroxide in methanol for 1 hr. under nitrogen. The solution was cooled, diluted with 2 ml. of water and acidified with concentrated hydrochloric acid. A solid separated, was collected, washed with water and crystallized from methanol; 0.4 g., 64% yield, m.p. 156–158°, mixed m.p. with IV, 157–159°.

3,6-Diphenylpyridazine. A.—A solution of 1.0 g. of mixture V in 10 ml. of acetic acid was treated with hydrogen over platinum oxide at 30 p.s.i. for 2 hr., filtered and concentrated in vacuum, leading to 3,6-diphenylpyridazine, 0.50 g., 50% yield, m.p. 207–219°, crystallized from ethanol, m.p. 219–220°, reported[12] m.p. 222°.

B.—A solution of IV, 0.384 g. (1.62 mmoles), in 30 ml. of acetone was treated with 6 drops of 30% hydrogen peroxide at room temperature for 16 hr. and concentrated. The residue was crystallized from ethanol, leading to 3,6-diphenylpyridazine, 0.155 g., 40% yield, m.p. and mixed m.p. 218–220°.

Attempted Reductions with Lithium Aluminum Hydride.—A: Treatment of the mixture V, 2 g., with 1.1 g. of $LiAlH_4$ in 50 ml. of ether under reflux for 6 hr. led to material melting 155–180°, 1.6 g. B: Treatment of 4.8 g. of mixture V with 1 g. of $LiAlH_4$ in di-*n*-butyl ether at 80° for 13 hr. led to 2.5 g. of material melting at 95–110°, 116–120° dec. after crystallization from methanol–water in Dry Ice. C: Treatment of the hydrazone IV, 0.5 g., with 0.1 g. of $LiAlH_4$ in 50 ml. of di-*n*-butyl ether at 80° for 13 hr. led to recovered IV, 0.3 g. D: Treatment of the hydrazone IV, 0.350 g., with 0.150 g. of $LiAlH_4$ in 30 ml. of di-*n*-butyl ether under reflux for 5 hr. led to recovered IV, 0.120 g.

1,2-Dicarboethoxy-3,6-diphenyl-1,2,3,6-tetrahydropyridazine (VI).—A: 1,4-Diphenylbutadiene[22] was prepared by condensation of phenylacetic acid (150 g., 1.10 moles) and cinnamaldehyde (169 g., 1.28 moles) in acetic anhydride (155 ml.) in the presence of lead oxide (122 g.) at 145°; 50 g., 22% yield, m.p. 152–153°, from benzene–ethanol, reported[22] 152.5–153.5°. B: Diethyl 1,2-hydrazinedicarboxylate[23] was prepared from reaction of hydrazine hydrate (78.2 g.) with ethyl chlorocarbonate (108 g., 1.00 mole) in ethanol at 0°; 47.5 g. (0.27 mole), 54% yield, m.p. 132–133° from water, reported[23] 130°. C: Diethyl azo-dicarboxylate[24] was prepared by treatment of a solution of 20 g. (0.11 mole) of diethyl 1,2-hydrazinedicarboxylate in 24 ml. of concentrated nitric acid with 4.8 ml. of fuming nitric acid at 0° for 1.5 hr. The mixture was poured into ice-water, extracted with ether, washed with sodium bicarbonate, dried and distilled; 8.3 g. (0.048 mole), 42% yield, b.p. 106–108° (13 mm.), reported[24] 106° (13 mm.). D: 1,2-Dicarboethoxy-3,6-diphenyl-1,2,3,6-tetrahydropyridazine (VI) was prepared by reaction of 9.0 g. (0.05 mole) of diethyl azodicarboxylate with 9 g. (0.044 mole) of 1,4-diphenylbutadiene in 10 ml. of toluene on the steam-bath for 3 hr. The toluene was removed in vacuum and the adduct VI was crystallized from ethyl acetate; 15.8 g., 95% yield, m.p. 134–136°, reported[12] 132°. *Anal.* Calcd. for $C_{22}H_{24}N_2O_4$: C, 69.44; H, 6.36. Found: C, 69.13; H, 6.42.

3,4,5,6-Tetrahydro-3,6-diphenylpyridazine (I). A.—The adduct VI, 5 g. (0.013 mole), was hydrogenated in 300 ml. of acetic acid over platinum oxide at 30 p.s.i. The solution was filtered and concentrated and the residue was crystallized from ethanol, 3.5 g., 70% yield, m.p. 85–87°, solid persisting to 95°, reported[12] 87°. Recrystallization from ethanol did not affect the melting range. *Anal.* Calcd. for $C_{22}H_{26}N_2O_4$: C, 69.06; H, 6.85. Found: C, 69.22; H, 6.96. Treatment of the hydrogenated adduct VII above with concentrated hydrochloric acid in methanol under reflux for 1 hr. led to recovery of VII. The adduct VI was also unaffected under these conditions.

B (1): A solution of 1.0 g. (2.6 mmoles) of VII and 1.5 g. of potassium hydroxide in 5 ml. of ethylene glycol was boiled under nitrogen for 2 hr., cooled, diluted with 25 ml. of water and extracted with peroxide-free ether. The solution was dried over magnesium sulfate and treated with dry hydrogen chloride. An oil precipitated, at first white, then turning orange, crystallization of which from ethanol and water and from ethyl acetate led to the hydrazone IV, m.p. 156–158°. Some crystals were observed in the magnesium sulfate; the latter was dissolved in water, the crystals were collected and dried, dec. 110° with gas evolution when heated rapidly, sintered 98°, melting over a range to 145° when heated slowly. (2). A second saponification was carried out in the same way. The dried ether extract was concentrated and cooled leading to long flat crystals, 0.284 g. (1.25 mmoles), 48% yield, decomposing with gas evolution at 110°. (3): Saponification of 1.0 g. of VII by 2 g. of potassium hydroxide in 5 ml. of boiling methanol was carried out similarly. The dried ether extract was concentrated and crystals were obtained and dried in a desiccator; 0.15 g. (0.64 mmole), 25% yield, dec. 110°. (4): The hydrogenated adduct VII, 1.0 g. (2.6 mmoles), was boiled for 1 hr. under nitrogen in a solution of 2.0 g. of potassium hydroxide in 5 ml. of methanol, cooled in ice, diluted with 10 ml. of water, brought to *p*H 8 with 6 *N* hydrochloric acid and extracted with ether. The ether solution was dried over magnesium sulfate, concentrated and refrigerated. Elongated plate-like crystals formed, 0.135 g., 22% yield, decomposing with gas evolution when placed in a bath at 120°. *Anal.* Calcd. for $C_{16}H_{16}N_2$: C, 81.30; H, 6.82; N, 11.85. Found: C, 81.48; H, 6.92; N, 11.75. In other runs yields varied from 20 to 45%. The ultraviolet absorption spectrum in cyclohexane showed maxima at 287 mμ, log ε 3.49, and at 387 mμ, log ε 2.89.

Rearrangement of I.—A small quantity of the azo compound I was dissolved in acetic acid and the solution was immediately evaporated to dryness in vacuum at room temperature, leading to the hydrazone IV, m.p. and mixed m.p. 155–158°.

Decomposition of I. A. Nitrogen Evolution.—The azo compound I was dissolved in a small quantity of redistilled solvent in a test-tube connected to a thermostated gas buret, the system (including the solution) was swept with oxygen-free nitrogen and leveled, the test-tube was heated at 135° or 110° for 0.5 hr. or at 100 or 90° for 1 hr. or at 80° for 2.5 hr. and brought back to the thermostat temperature (30°) and the evolved gas was measured. The interim readings were observed at the reaction temperature. The volumes measured were small and the accuracy was probably about ±5%. The data are summarized in Table I.

B. Products of Decomposition.—(1): Compound I, 0.053 g. (0.225 mmole), in a tared centrifuge-tube under nitrogen, was heated at 110° for a few minutes, then placed in an oil-bath at 125° for 5 minutes, strong nitrogen evolution ensuing and droplets condensing on the walls of the tube. The tube was opened and the odor of styrene was detected; the tube was swept again with nitrogen, stoppered and reweighed, loss of 0.008 g. being observed. The residue (solidified) was treated with 3 ml. of 95% ethanol, leading to compound IV, 0.016 g., 30% yield, m.p. 156–158°, mixed m.p. 157–158°. The filtrate was treated with 4% bromine in acetic acid until a pale yellow color persisted, diluted with 1 ml. of water and cooled, leading to styrene dibromide, m.p. and mixed m.p. 68–70°, 0.006 g. (0.023 mmole), 7% yield. Styrene, 0.100 g. (1 mmole), was dissolved in 3 ml. of ethanol and brominated as described above, [illegible] styrene dibromide, m.p. 68–70°, 0.044

g. (0.17 mmole), 17% yield, reported[25] 72–73°. The infrared spectra of the two samples were identical, showing a strong carbon–bromine bond at 695 cm.$^{-1}$.

(2) A solution of compound I, 0.050 g. (0.212 mmole), and stilbene, 0.036 g. (0.212 mmole), in 1 ml. of ethylbenzene (b.p. 134–134.5°) was heated in vacuum at 100° for 50 minutes, concentrated to dryness in vacuum and treated with methanol. Stilbene was recovered; 0.014 g., 39% yield, m.p. and mixed m.p. 123–125°. The residue was an oil.

(3) A solution of I, 0.061 g. (0.26 mmole), and freshly sublimed quinone, m.p. 114–115°, 0.221 g. (2.0 mmoles), in 6 ml. of benzene was heated under nitrogen at 90° (bath temperature) for 42 hr. The solution was concentrated and sublimed in vacuum leading to recovery of quinone and separation of some black solid, 0.020 g. melting unsharply above 160°, presumably quinhydrone. The black residue, 0.145 g., was heated with a little ethanol, leading to compound IV, 0.003 g., 5% yield, m.p. and mixed m.p. 155–157°. The residue was chromatographed on alumina, leading to 3,6-diphenylpyridazine, 0.028 g., 47% yield, m.p. and mixed m.p. 219–220°

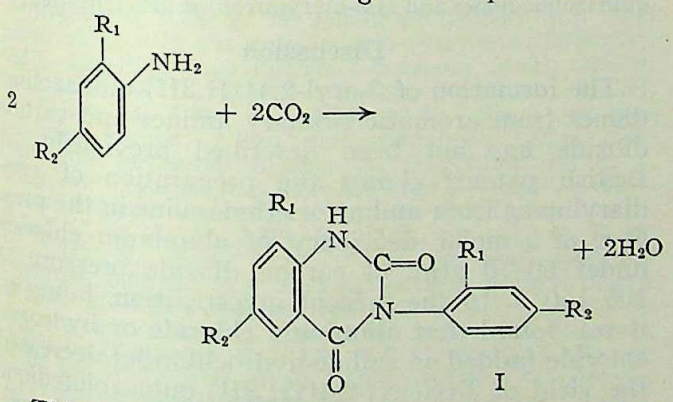
Quinazolinediones from Aromatic Amines and Carbon Dioxide

BY T. L. CAIRNS, D. D. COFFMAN AND W. W. GILBERT

RECEIVED FEBRUARY 12, 1957

The reaction of carbon dioxide with certain primary aromatic amines at 8500 atm. and 200–250° has given high conversions to 3-aryl-2,4(1H,3H)-quinazolinediones (I). A sharp pressure threshold for the reaction was found at about 3300 atm.; the quinazolinediones were not formed at lower pressures, while conversions increased to 65–70% at the highest temperatures and pressures investigated.

Previous communications[1] from this Laboratory have described investigations of the effects of pressures of 6000 to 8500 atm. on chemical reactions. This paper reports a new reaction, the high pressure synthesis of 3-aryl-2,4(1H,3H)-quinazolinediones (I) from certain primary aromatic amines and carbon dioxide according to the equation[2]



This unusual transformation has been examined in terms of the effects of temperature, pressure, solvents, catalysts and substituents. Conversions of aniline to 3-phenyl-2,4(1H,3H)-quinazolinedione (I, $R_1 = R_2 = H$) as high as 70% were obtained at temperatures above 200° at 8500 atm., but the conversion fell to zero at 150°. A sharp pressure threshold for the reaction was found at about 3300 atm. The quinazolinedione was not formed at lower pressures, and the conversion increased rapidly with increased pressures above the threshold value. The reaction occurred in the presence of either alkaline or acidic catalysts, but with acidic catalysts the yield of quinazolinedione was decreased by formation of unidentified by-products. In the uncatalyzed reaction, formation of the corresponding *sym*-diarylurea was the chief competing reaction.

Quinazolinediones were also obtained from *o*-toluidine (15% conversion, $R_1 = CH_3$, $R_2 = H$) and from *p*-toluidine (50% conversion, $R_1 = H$, $R_2 = CH_3$). Quinazolinediones were not identified among the reaction products when the aromatic amine contained nitro, halogen or hydroxyl substituents or when the amine was α- or β-naphthylamine.

Primary aromatic diamines have given complex intractable products with carbon dioxide under these conditions. These products may have been low molecular weight polymeric quinazolinediones or polymeric ureas.

Experimental

Aniline and CO_2.—Aniline (4.08 g.) and carbon dioxide (2.39 g.) were charged into a stainless steel cylinder fitted with a movable piston.[3] In some runs a small quantity of nitrogen (*ca.* 0.3 g.) was used to ensure return of the piston to its original position when the external pressure on it was released at the end of the experiment. The cylinder was placed in a Bridgman-type pressure apparatus,[4] and its contents were subjected to an initial pressure of 8500 atm. at room temperature. The entire high-pressure system was then heated to 200°. After 14 hr. the apparatus was cooled to room temperature. The final pressure was about 7900 atm. The pressure was released and the cylinder removed and vented. The reaction product was washed from the vessel with ether and collected on a filter to give 3.37 g. of crude solid, m.p. 267–268°. It was purified by recrystallization from a mixture of ethanol and benzene or by sublimation under reduced pressure to give white crystals, m.p. 275–280°.

Anal. Calcd. for $C_{14}H_{10}N_2O_2$: C, 70.57; H, 4.23; N, 11.76. Found: C, 70.76; H, 4.43; N, 11.60, 11.65.

The product was identified as 3-phenyl-2,4-(1H,3H)-quinazolinedione by hydrolysis to aniline and anthranilic

[m] Neutral fraction, 0.10 g., m.p. 50–53°. [n] Neutral fraction, 0.85 g., m.p. 30–40°. [o] *sym*-Diphenylurea, 0.29 g. [p] Some aniline recovered. [q] CO_2 formed. [r] Quantitative conversion to triphenyl isocyanurate.

In most of this work the crude reaction product was purified by suspension in ether and extraction first with 2 *N* hydrochloric acid and then with 5% sodium hydroxide solution. The 3-aryl-2,4-(1H,3H)-quinazolinediones were recovered by saturating the sodium hydroxide solution with carbon dioxide. The small neutral fraction which was sparingly soluble in ether was recrystallized from ethanol to give the *sym*-diarylurea. From aniline and carbon dioxide this urea was *sym*-diphenylurea, long white needles, m.p. 244–246°. The mixed m.p. with authentic *sym*-diphenylurea, m.p. 245–247°, was not depressed.

Examples in the table illustrate the effects of temperature, pressure, solvents, catalysts and substituents on the reactions of representative primary aromatic amines with carbon dioxide. The relative proportions of 3-aryl-2,4-(1H,3H)-quinazolinediones and *sym*-diarylureas are also indicated.[6,7,8]

Discussion

The formation of 3-aryl-2,4(1H,3H)-quinazolinediones from aromatic primary amines and carbon dioxide has not been described previously. A British patent[9] claims the preparation of *sym*-diarylureas from aniline or ethylaniline in the presence of a molar deficiency of aluminum chloride under 50–70 atm. of carbon dioxide pressure at 105–150°. In the present investigation, however, it was found that aluminum chloride or hydrogen chloride (added as aniline hydrochloride) decreased the yield of 3-phenyl-2,4(1H,3H)-quinazolinedione without giving isolable quantities of *sym*-diphenylurea. This effect was accompanied by an increased formation of unidentified, low-melting, neutral, ether-soluble side-reaction products.

It does not appear that *sym*-diphenylurea was formed first and that subsequently it underwent reaction with more carbon dioxide to give the quinazolinedione. However, the experiments to demonstrate this point are not unequivocal, since phenomena involving contact of carbon dioxide with massive crystals of *sym*-diphenylurea *vs.*

[m] Recovered 1.27 g. of cyclic urea benzimidazolone, m.p. 320°. P. Pierron[8] reported benzimidazolone, m.p. 310°. *Anal.* Calcd. for $C_7H_6N_2O$: C, 62.67; H, 4.51; N, 20.89. Found: C, 62.36; H, 4.57; N, 20.59, 20.64. [n] Recovered 2.96 g. of gray solid. Soxhlet extraction with ether, methanol, acetone and dimethylformamide gave no appreciable loss in weight of solid. *Anal.* Calcd. for $(C_{13}H_{10}N_2O)_x$ (polymeric urea): C, 74.27; H, 4.80; N, 13.33. Found: C, 73.10; H, 4.95; N, 13.54, 13.63.

finely divided urea crystals formed *in situ* from aniline and carbon dioxide might lead to entirely different rates of reaction. In the presence of a small amount of triethylamine to give a basic environment, *sym*-diphenylurea did give a detectable quantity of the quinazolinedione, but the reaction was complicated by gross amounts of unidentified by-products.

Recent work by Kizber and Glagoleva[6] indicated that *sym*-diphenylurea when heated with potassium carbonate for 5 hr. at 250–260° under 50–55 atm. carbon dioxide pressure underwent modest conversions to *p*-aminobenzoic acid, anthranilic acid and 3-phenyl-2,4(1H,3H)-quinazolinedione. Further the potassium salt of anthranilic acid was converted to the quinazolinedione by heating in a sealed tube at 230–240° for 8 hr. *sym*-Diphenylurea was also cleaved by potassium carbonate and carbon dioxide in 8 hr. at 160–170°, giving 80–85% of the potassium salt of phenylcarbamic acid. The latter on heating above 180° in carbon dioxide was converted to potassium salts of *p*-aminobenzoic and anthranilic acids.

Conditions in the present reaction system do not favor the formation of phenyl isocyanate, which, incidentally, at 250° and 8500 atm. was quantitatively trimerized to triphenyl isocyanurate, m.p.

265–270°.[10] The aniline salt of phenylcarbamic acid, $C_6H_5NHCOOH \cdot H_2NC_6H_5$, might be stable even in the presence of water under carbon dioxide pressure. This salt might be capable of rearranging under the combined agencies of heat and carbon dioxide pressure to give the aniline salt of anthranilic acid in analogy to the reported results with the potassium salt. This mechanism appears consistent with the observed lower conversions in the presence of aluminum chloride and aniline hydrochloride. Other possible intermediates in the transformation to the quinazolinedione are indicated in the diagram.

(10) N. W. Hofmann, *Ber.*, **18**, 764 (1885). Triphenyl isocyanurate, m.p. 275°, was prepared by heating phenyl isocyanate (5 moles) with potassium acetate (1 mole) at 100°.

Acknowledgments.—The authors are pleased to acknowledge the assistance given by Dr. N. E. Searle who supplied known samples of *sym*-di-*o*-tolyl- and di-*p*-tolylurea. We would like to thank Drs. W. W. Prichard, E. L. Jenner, J. R. Roland and A. L. Barney, and Messrs. A. W. Larchar, H. S. Young and P. J. Rennolds for stimulating discussions and helpful suggestions.

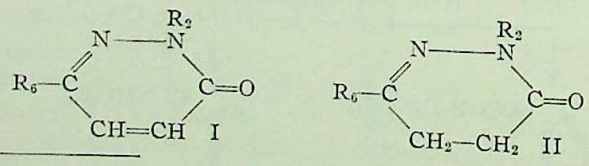
Absorption Spectra of Heterocyclic Compounds. VII.[1] Some 3(2H)-Pyridazones

BY EDGAR A. STECK AND FREDERICK C. NACHOD

RECEIVED MARCH 2, 1957

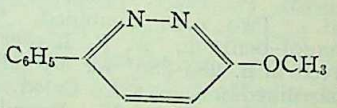
The absorption spectra of a series of 3-pyridazones have been reported and interpreted.

Pyridazine derivatives may be considered to contain a potential hydrazine unit in the 1,2-diazine ring and hence are not readily obtainable from biochemical transformations involving nitrogen. In fact, this ring system has not been found to occur in natural products, a sharp distinction from the other diazines. This heterocyclic type has not been investigated as thoroughly as the pyrimidines and pyrazines, and relatively few reports of physicochemical studies on pyridazines have appeared in the literature.[2–14] Some work has been done[3,9,13] on the absorption spectra of 3(2H)-pyridazones, which are cyclic hydrazones. Our interest in the 6-substituted 3(2H)-pyridazones as chemotherapeutic agents[15,16] and intermediates for the preparation of other potential pharmaceuticals has led us to study the absorption spectra of this type (I) and also the related 4,5-dihydro compounds II.



I II

The range of structures which may be chosen for 3(2H)-pyridazones and related dihydro compounds is limited sharply by the non-equivalence of the two formulas possible for pyridazine.[5,7] Thus, comparison of the absorption spectra of 6-phenyl-3(2H)-pyridazone (I, R_2 = H, R_6 = C_6H_5) with those of 2-methyl-6-phenyl-3-pyridazone (I, R_2 = CH_3; R_6 = C_6H_5) and 3-methoxy-6-phenylpyridazine (III) clearly substantiates the formulation of the first-mentioned compound as (I). The spectra of the three compounds in 95% ethanol are shown in Fig. 1.



III

Absorption spectra of 6-(2-thienyl)-3(2H)-pyridazone and the related 4,5-dihydro compound in 95% ethanol, 0.01 *N* sodium hydroxide and 0.01 *N* hydrochloride are presented in Fig. 2. 4,5-Dihydro-6-(2-thienyl)-3(2H)-pyridazone shows little difference in pattern of spectra in the three solvents. While the spectra of 6-(2-thienyl)-3(2H)-pyridazone in ethanol and acid are identical, the absorption in basic solutions is more closely related in effect to those obtained with the dihydro compound. This indicates that the sodium enolate, which may be formed through keto–enol tautomerism in this type of the pyridazone, is more or less closely related to the dihydropyridazone (*cf.* ref. 13). However, the behavior in neutral or acid solution shows that 6-(2-thienyl)-3(2H)-pyridazone may not exist in keto form (in those solvents) as evident by comparison of Fig. 2 with Fig. 1.

In Table I, the comparison of spectral absorption of 6-substituted 3(2H)-pyridazones in neutral, alkali and acid solutions is presented. A chlorine in the *p*-position of the phenyl group produced a slight batho- and hyperchromic effect, this being more pronounced when ethanol was the solvent. This behavior is not unexpected, nor was a similar shift in the case of the 6-(2-thienyl)-3(2)-pyridazone

absorption spectra of 6-substituted 4,5-dihydro-3(2H)-pyridazones obtained in ethanolic, basic and acidic solutions. The general interrelationships in these cases were of the same character as observed for the 6-substituted 3(2H)-pyridazones.

(17) E. A. Steck, G. W. Ewing and F. C. Nachod, THIS JOURNAL, 71, 238 (1949).

It may be noted that the dihydro compounds exhibit bathochromic and hypsochromic displacement with respect to the related 3(2H)-pyridazones. This is a consequence of the fact that a greater number of contributors may be formulated for the dihydro type which contain conjugation permissible for such a system having non-equivalence of structural forms.

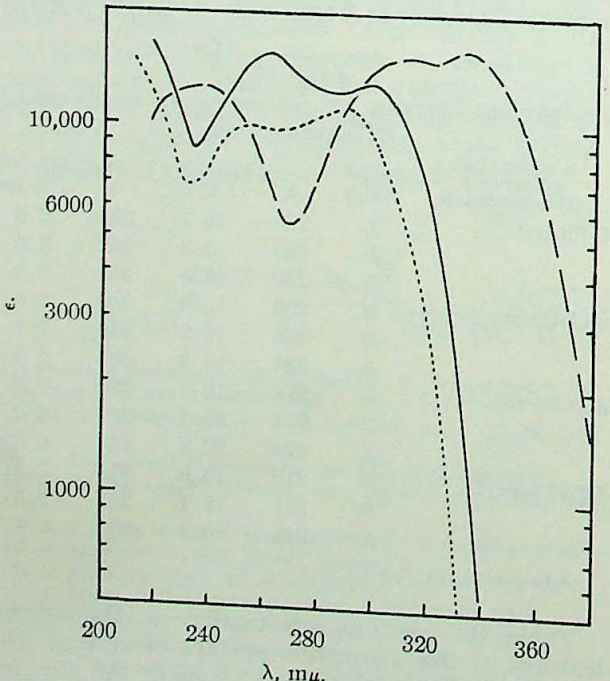

Fig. 3.—Absorption spectra of 2-(4-chlorophenyl)-4,5-dihydro-6-phenyl-3(2)-pyridazone; —, in 95% ethanol; - - - -, 0.01 *N* HCl; — —, 0.01 *N* NaOH.

hydrochloric acid was used to dissolve 2-(4-chlorophenyl)-6-phenyl-3-pyridazone. The effect of varying the 6-substituent of 2-(4-chlorophenyl)-4,5-dihydro-3-pyridazones also was studied, with the substituent involved being a phenyl, a 4-chlorophenyl or a 2-thienyl group. Figure 3 gives detailed information on 2-(4-chlorophenyl)-4,5-dihydro-6-phenyl-3-pyridazone, with the spectra run in ethanol, base and acid. In the case of the 6-phenyl compound, it is to be noted that a marked bathochromic shift occurred when 0.01 *N* sodium hydroxide was used as solvent rather than ethanol or 0.01 *N* hydrochloric acid. This alteration is obviously a result of an increase in conjugation, possibly through formation of IV (as sodium salt). The presence of a 4-chlorophenyl or a 2-thienyl group in position 6 of the 2-(4-chlorophenyl)-4,5-dihydro-3-pyridazones did not lead to such definite spectral evidence. In each of these latter cases, there is an inflection in the region in which a bifurcation was found for the 6-phenyl compound (*cf.* Fig. 3). It is to be noted that the dihydro-3-pyridazones bearing a substituent in position 2 follow the general aspects found in 3(2H)-pyridazones, with the additional expected complexity.

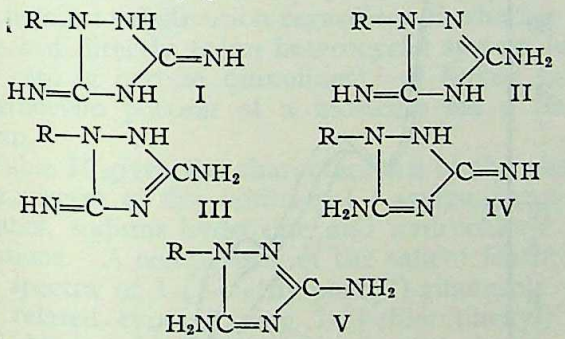
Absorption Spectra of Heterocycles. VIII.[1] Some Guanazole Derivatives

BY EDGAR A. STECK AND FREDERICK C. NACHOD

RECEIVED MARCH 9, 1957

The ultraviolet absorption spectra of several 1-arylguanazoles have been determined and their relation with structure treated. As a result of chemical and physical considerations, it has been suggested that 1-arylguanazoles be formulated as 3(5)-amino-1-aryl-5(3)-imino-1,2,4-triazolones (III) or (IV) rather than as 1-aryl-3,5-diimino-1,2,4-triazolidines (I).

The investigation of guanazole derivatives as potential pharmaceuticals[2] led to the preparation of certain 1-aryl-, 1-aryl-2-substituted and 1-aryl-3-substituted guanazoles which showed interesting structural aspects. Stollé and Dietrich[3] have noted that five structures (I-V) may be assigned to 1-substituted guanazoles, but no further treatment of this matter has been reported. The present discussion is based upon the ultraviolet absorption spectra of the 1-arylguanazoles and derivatives.



The reaction of arylhydrazines with cyanoguanidine might result in the formation of 1-arylguanazoles having several possible structures, as indicated by formulas I-V. These types represent the relationship of these 1,2,4-triazoles with guanidines and biguanides where arrangement of the atoms may be considered as being formed of two amidine groups. In these electrically neutral structures it is seen readily that the greatest degree of conjugation is present in V; forms III and IV show less conjugation, and no conjugation occurs in I and II. A study was made of the various proton donor and acceptor forms possible for those 1,2,4-triazole derivatives known as guanazoles; a summary of these considerations is shown in Table I. The contribution of the non-conjugated forms exceeds those of either conjugated type; this is in harmony with the experimental findings.

In Fig. 1 are shown the spectra of 1-phenylguanazole in acid, base and ethanol. For purposes of comparison, the spectrum of biphenyl in hexane[4] is also included since, as will be seen later in the case of 1-(4-xenyl)-guanazole (Fig. 3), there is a typical super-position of the component spectra in the solvent studied. It may be noted that the highest maximum in the spectrum of 1-phenylguanazole is attained in alcoholic solution. There is a related shift in the spectrum to longer wave lengths in neutral solution, whereas the spectra in solutions of both high and low *p*H are found to

occur at shorter wave lengths. This, too, is in agreement with our above-noted considerations. To test the idea further, it was decided to determine the influence of *p*H upon the extinction coefficients in the spectrum of 1-phenylguanazole. Figure 2 shows the results of spectral studies made with a number of buffer solutions. This demonstrates clearly that a maximum in conjugation, as may be attributable to forms III-V, results at neutral *p*H

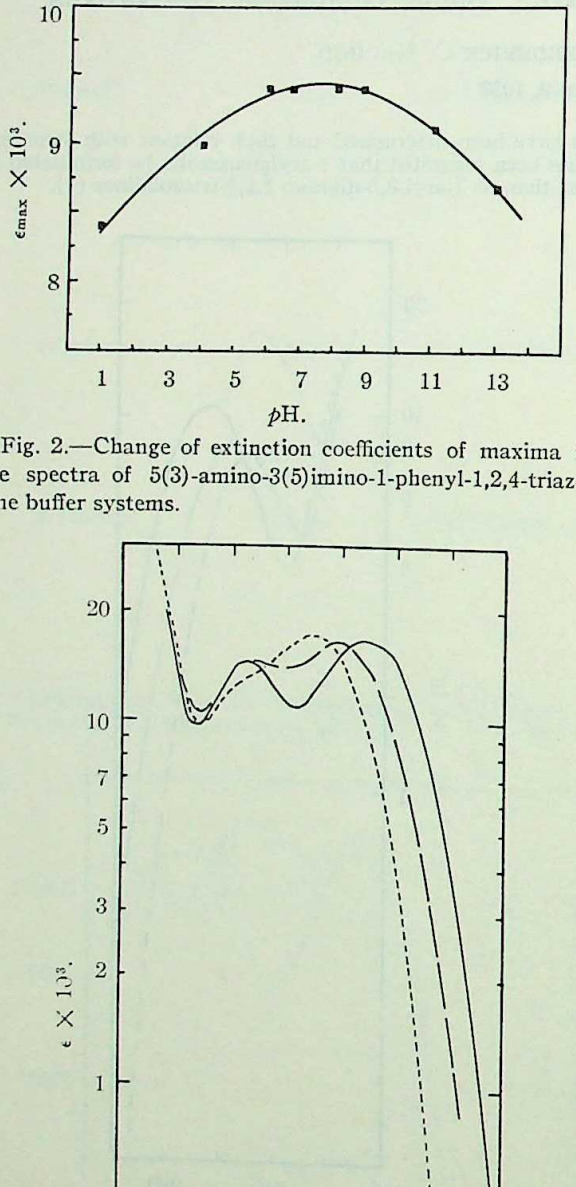

Fig. 2.—Change of extinction coefficients of maxima in the spectra of 5(3)-amino-3(5)imino-1-phenyl-1,2,4-triazolone buffer systems.

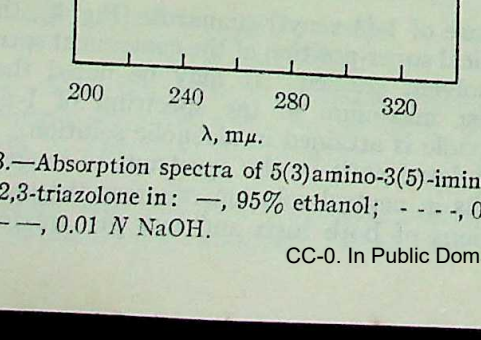

Fig. 3.—Absorption spectra of 5(3)amino-3(5)-imino-1-*p*-xenyl-1,2,3-triazolone in: —, 95% ethanol; - - - -, 0.01 *N* HCl; — —, 0.01 *N* NaOH.

range. Moreover, it should be noted that the hyperchromic effect in ethanolic solution (Fig. 1) is to be ascribed to an additional solvent effect.

The spectra for 1-(4-xenyl)-guanazole in ethanol, acid and base are shown in Fig. 3. There are two maxima in the spectral curves determined with use of solutions in sodium hydroxide and ethanol; the relative positions of the curves are in the expected order and magnitude. In acid solution the maximum obtained for 1-(4-xenyl)-guanazole is to be seen to occur at the same wave length as for biphenyl in hexane solution[4] (Fig. 1), namely, 248 mμ. A characteristic curve with a single maximum is the result of the influence of the non-conjugated aromatic and heterocyclic contributors in 1-(4-xenyl)-guanazole.

Figure 4 shows the spectra for 1-(2-naphthyl)-guanazole in the three customary solvents. The pattern of these data obtained in acidic, basic and neutral solutions reflects the individual contributions of the aromatic and heterocyclic moieties in-

volved. The maxima contributed by the 1,2,4-triazole nucleus appear again in the 260 mμ region for the three solvents, while the naphthalenic substituent shows its strong and characteristic absorption in the 220 mμ region (for a comparison with the spectra of 2-naphthol and 2-naphthylamine, *cf.* refs. 5 and 6). In the case of the absorption spectrum obtained when ethanol was the solvent, there is to be seen the expected bathochromic shift with relation to the other two solvents. It is also to be noted that the characteristic triplet was maintained in the spectrum of 1-(2-naphthyl)-guanazole in alcohol but was nearly obliterated in acidic and alkaline solvents, only a memory of it remaining in the respective inflection points.

The influence of a para-halogen substituent upon the absorption spectrum of 1-phenylguanazole is indicated in Fig. 5. The expected batho- and hyperchromic shifts upon transition from the fluoro to the iodo grouping is indeed realized. It should be noted, however, that there is little change in character from 1-(4-chlorophenyl)-guanazole to the related bromo compound. The development of an additional maximum in the short wave region first appears in 1-(4-bromophenyl)-guanazole and is again evidenced with a concomitant bathochromic shift in the case of the spectrum of the iodo compound. These effects appear to be caused by the halogen substitution regardless of whether it is attached directly to an heterocyclic system (as in the case of certain quinolines),[7] or linked to the heterocyclic portion of a molecule *via* a phenyl group.

Table II gives the characteristics of the absorption spectra of five additional 1-arylguanazoles in ethanol, sodium hydroxide and hydrochloric acid solutions. A comparison of the salient features of the spectra of 1-(4-methylphenyl)-guanazole with the related types having 1-(3-chlorophenyl) and 1-(3-chloro-4-methylphenyl) groups shows that substitution of position 3 by a chloro group has less influence upon the spectrum of 1-(3-chloro-4-methylphenyl)-guanazole than does the 4-methyl group. This is presumably due to the interaction of position and inductive effects.[8] Also given in Table II are characteristic portions of the spectra of 1-[4-(4′-methylphenoxy)-phenyl]-guanazole and 1-[4-(4′-methylphenylthio)-phenyl]-guanazole, which may likewise be compared with 1-(4-methylphenyl)-guanazole. The interposition of the phenoxy group between the methyl and phenyl radicals results only in an intensification but not a shift in the respective spectra of 1-[4-(4′-methylphenoxy)-phenyl]-guanazole from those of the related 1-(4-methylphenyl) compound. However, the replacement of the oxygen by the heavier sulfur atom in 1-[4-(4′-methylphenylthio)-phenyl]-guanazole not only leads to further intensification but also to a bathochromic shift of *ca.* 21–25 mμ. This is to be expected, as the sulfur atom has a

guanazole. The 2-methyl group obliterates not only the effects based upon tautomerism in the 1-phenylguanazole but, presumably, also that of some of the ionic contributions. As a consequence, the original pattern is really lost, and a faint memory is apparent only at the inflection points.

The 1-aryl-3,5-diimino-1,2,4-triazolidine structure (*i.e.*, I) for the 1-arylguanazoles has been preferred by Pellizzari.[14] This diimino formula does not readily explain the loss of only one nitrogen atom when 1-phenylguanazole is treated with caustic[15] and the behavior on acetylation.[15] The formation of monohydrochlorides and picrates[14,15] by the 1-arylguanazoles may not necessarily be considered in this matter, for it is well known that the mutual proximity of potentially basic groups may prevent the full showing of the basic properties. As examples of this behavior, one may cite certain polynitrogen heterocycles which form only monosalts.[16–18] Mann and Watson[19] have discussed salt formation in polyamine types, and they comment, *inter alia*, "it is suggested that the positive pole created by the initial salt formation exerts a strong electronic attraction, and this attraction, relayed by the inductive or mesomeric effect, may virtually immobilize the lone pair of electrons on a neighboring nitrogen atom and so deactivate this atom." Evidence here presented renders it desirable that the 1-substituted guanazoles should be considered to have the amino-imino structures indicated as III or IV rather than as diimino compounds as I. It does not appear to be possible to exclude the possibility of structure V, use of which has been made in the formulation of the products obtained from 1-phenylguanazole and isothiocyanates.[20]

1-Arylguanazoles.—All guanazoles were prepared as described in another publication.[2]

Absorption Spectra.—The spectrophotometric studies were all carried out with a Beckman quartz spectrophotometer, model DU, serial no. D-377. The method and solvents used have been described in other contributions from these laboratories.[5,6]

Acknowledgments.—To Dr. E. J. Lawson we owe much for his helpful counsel and patience in discussions concerning the potential ionic configurations in 1-arylguanazoles. A considerable portion of the spectrophotometric studies have been due to the efforts of Mrs. M. Becker and Mr. M. Priznar.

Some 9-Amino-3-nitroacridine Derivatives

BY EDGAR A. STECK, JOHANNES S. BUCK[1] AND LYNN T. FLETCHER

RECEIVED MARCH 9, 1957

A series of 9-amino-3-nitroacridine types bearing hydroxylated side-chains was prepared for investigation as potential chemotherapeutic agents. In most cases, the 6,7-positions of the acridine nucleus were substituted, as by dimethoxy, methylenedioxy and ethylenedioxy groups; two derivatives of 9-amino-7-butoxy-3-nitroacridine also were made.

It appears that the investigation of 9-amino-3-nitroacridine derivatives has been largely neglected because little antimalarial activity has been found in this type[2]; the most interesting property in the group lies in their activity against microörganisms, which is even exhibited by 9-amino-3-nitroacridine itself.[3–6a] 9-(3-Diethylamino-2-hydroxypropylamino)-6,7-dimethoxy-3-nitroacridine (I), also known as Nitroakridine 3582 (Hoeschst) and 3043B for Entozon (Entozon is a mixture of I with 6,9-diamino-2-ethoxyacridine, Rivanol, and urea), and its salts have been the most carefully studied of the 9-amino-3-nitroacridines.[1,6–11] It has been claimed that this compound, and certain salts and combinations containing it, possess activity against

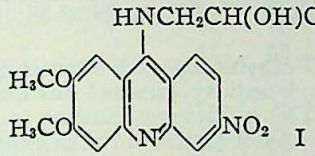
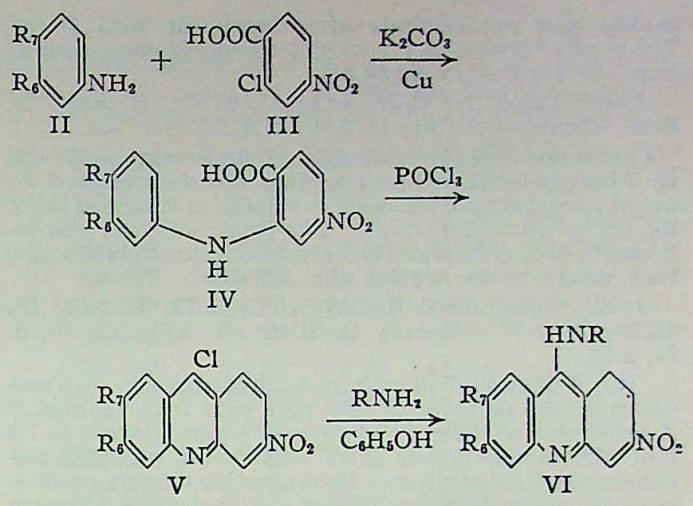
bacteria,[9–12] rickettsia,[5,13–15] viruses,[6,16–20] trichomonads[21] and babesiidae.[9] While certain antibiotics have ranges of activity which include those mentioned, this investigation was begun before such were well studied and was particularly concerned with those bearing an hydroxylated basic chain attached to position 9 of a 3-nitroacridine nucleus with at least one alkoxy group in position 6 or 7 or with a methylenedioxy- or ethylenedioxy group bridging positions 6 and 7.



I

The synthesis of the 9-chloro-3-nitroacridines required for reaction with the various amines was accomplished by the Ullmann reaction[22] as modified by Leśniański.[23,24] In this procedure, the intermediate N-arylanthranilic acids (*e.g.*, IV) prepared from an aniline (II) and a 2-halobenzoic acid (*e.g.*, III) undergo cyclization to the 9-chloroacridine (*e.g.*, V) by the action of phosphorus oxychloride. In the reactions of 2-chloro-4-nitrobenzoic acid with 3,4-dimethoxyaniline, 3,4-methylenedioxyaniline and 3,4-ethylenedioxyaniline, methanol or ethanol were satisfactory solvents, but with 4-butoxyaniline it was necessary to use pentanol (*cf.* refs. 25–27). The purified N-arylanthranilic acids were all cyclized without difficulty by use of phosphorus oxychloride in toluene.

The reaction of the 9-chloro-3-nitroacridines (V) with aliphatic amino compounds bearing hydroxyl groups, in phenol as a solvent (*cf.* refs. 27, 28), was exothermic but readily controlled; this produced the type VI of which I is an example. 7-Butoxy-9-chloro-3-nitroacridine, 9-chloro-6,7-methylenedioxy-3-nitroacridine and 9-chloro-6,7-ethylenedioxy-3-nitroacridine were caused to react with 3-diethylamino-2-hydroxypropylamine (VII) and N-(2-



hydroxyethyl) ethylenediamine (VIII). 9-Chloro-6,7-dimethoxy-3-nitroacridine was caused to react with these amines (in the case of VII, compound I being produced) and also N-(2-hydroxypropyl)-ethylenediamine (IX), N-(2-hydroxy-2-methylpropyl)-ethylenediamine (X), N-(2-hydroxyethyl)-1,3-propanediamine (XI), N-(2-hydroxy-2-methylpropyl)-1,3-propanediamine (XII) and N-(2-hydroxyethyl)-1,7-heptanediamine (XIII). The compounds produced by use of the amine VII were, ordinarily, the most difficult to purify. Since the hydrochlorides of the 9-amino-3-nitroacridines (Table I) lost hydrogen chloride readily upon drying at elevated temperatures, it was advisable to dry the products at room temperature. Several of the compounds thus obtained were hydrated. It was of interest that, while several of the intermediates did not give concordant values for nitrogen by the Dumas method,[29] most of the final products offered little difficulty.

The testing of the compounds herein described will be reported subsequently by other members of this Institute.

Experimental[30]

A. 9-Chloro-3-nitroacridines. I. 7-Butoxy-9-chloro-3-nitroacridine.—4-Butoxynitrobenzene was obtained in 68.5% yield by the action of butyl bromide upon potassium 4-nitrophenolate in butanol.[31] Use of butyl iodide gave yields of 54–58%.[32] The reduction of the nitro compound to 4-butoxyaniline in methanol with Raney nickel catalyst (25°, 80 atm.) gave a conversion of 92.5%; b.p. 95–98° (1 mm.).

Thirty-three grams (0.2 mole) of 4-butoxyaniline, 35.3 g. (0.26 mole) of powdered, anhydrous potassium carbonate, 36.3 g. (0.18 mole) of 2-chloro-4-nitrobenzoic acid[33] and 0.5 g. of copper powder in 150 cc. of pentanol were stirred and refluxed for 5 hr. The excess amine and solvent were steam distilled, the residues diluted to 500 cc. with water, boiled with Darco G-60 and filtered. Acidification of the cooled filtrates gave 56.0 g. (85% yield) of crude greenish product, m.p. 170–174°. To obtain pure N-(4′-butoxyphenyl)-4-nitroanthranilic acid from the crude, it was necessary to crystallize from 85% ethanol, dissolve the greenish solid in

caustic and re-precipitate after treatment with Darco. The product crystallized from 80% ethanol as orange blades, m.p. 197.3–197.8°, yield 64.5%.

Anal. Calcd. for $C_{17}H_{18}N_2O_5$: C, 61.81; H, 5.49; N, 8.48. Found: C, 61.81; H, 5.60; N, 8.27.

Cyclization of N-(4′-butoxyphenyl)-4-nitroanthranilic acid to 7-butoxy-9-chloro-3-nitroacridine was accomplished by use of phosphorus oxychloride in toluene as described below for the 6,7-dimethoxy type. The pure compound was obtained in 69% yield after three crystallizations from heptane; long, golden-brown needles, m.p. 159–160°.

Anal. Calcd. for $C_{17}H_{15}ClN_2O_3$: C, 61.73; H, 4.51; Cl, 10.72; N, 8.47. Found: C, 61.60; H, 4.51; Cl, 10.79; N, 8.52.

II. **9-Chloro-6,7-dimethoxy-3-nitroacridine.**[34]—4-Nitroveratrole was prepared in 75% pure yield from veratrole.[35] A suspension of 450 g. (2.46 mole) of 4-nitroveratrole in 1.4 l. of ethanol was reduced at 25° and 50 atm. with 10% palladium–charcoal catalyst. The reduction mixture containing 4-aminoveratrole was filtered and kept under nitrogen. A mixture of 337 g. (2.44 moles) of anhydrous potassium carbonate, 492 g. (2.66 moles) of 2-chloro-4-nitrobenzoic acid and 0.5 l. of water at 60° was prepared, then the solution of 4-aminoveratrole, 25 g. of copper powder and 25 g. of Filter-cel were added. The mixture was stirred vigorously and the alcohol removed until the still temperature reached 92°, then refluxed for 5 hr. The solids which were collected were extracted with 2 l. of boiling water after mixing with 25 g. of Darco G-60 and 50 g. of Filter-cel; the filter-cake was re-extracted with the boiling liquors, then chilled. The potassium salt of N-(3,4-dimethoxyphenyl)-4-nitroanthranilic acid was collected from the extracts (357 g.) and the liquors concentrated. A total yield of 392 g. (45%) of the salt was obtained; acid isolated from the salt melted at 221–223.5°.

A mixture of 356.3 g. (1.0 mole) of potassium N-(3,4-dimethoxyphenyl)-4-nitroanthranilate and 3.5 l. of toluene was stirred while *ca.* 0.5 l. of distillate was collected to ensure anhydrous conditions before the addition of 220 cc. (368 g., 2.4 moles) of phosphorus oxychloride during 15 minutes. The well-stirred mixture was refluxed for 3 hr. and then 0.5 l. of distillate removed *in vacuo*. Cooling of the residue gave the phosphorus salt of 9-chloro-6,7-dimethoxy-3-nitroacridine, which was collected, then washed with toluene and ether. The complex was decomposed by gradually adding it to a well-stirred mixture of 310 cc. of 35% sodium hydroxide solution, 1300 cc. of water and 1300 g. of ice and stirring for 2 or 3 hr. at 0°. A brownish product resulted; this was washed free of alkali, air-dried and washed with benzene. The 9-chloro-6,7-dimethoxy-3-nitroacridine was boiled with 4 l. of ethylene dichloride for 2 hr., cooled and the light yellow product dried. A yield of 230 g. (72%) resulted, m.p. 246–248° dec.

III. **9-Chloro-6,7-methylenedioxy-3-nitroacridine.**—A portion of the required 3,4-methylenedioxyaniline was obtained in 88% yield, b.p. 85–86° (1 mm.) (m.p. 44.5–45.5°), from the reduction of 3,4-methylenedioxynitrobenzene in methanol with Adams catalyst at 3 atm. hydrogen pressure. The nitro compound was a by-product from the preparation of 6-nitropiperonal[36] or made from 1,2-methylenedioxybenzene[37] by nitration.[38] Some had been prepared earlier by a Hofmann degradation of piperonylamide.[39]

The reaction of 3,4-methylenedioxyaniline, 2-chloro-4-nitrobenzoic acid and potassium carbonate in the presence of copper powder and Filter-cel was carried out after the method described for 4-aminoveratrole. A 91% yield of crude N-(3,4-methylenedioxyphenyl)-4-nitroanthranilic acid (m.p. *ca.* 210°) was collected; two crystallizations from 60% methanol (charcoal) gave a 60% yield of pure compound. The beautiful garnet plates melted at 246–247°.

Anal. Calcd. for $C_{14}H_{10}N_2O_6$: C, 55.63; H, 3.34; N, 9.27. Found: C, 55.52; H, 3.36; N, 9.40.

Conversion of the above acid to 9-chloro-6,7-methylenedioxy-3-nitroacridine followed the same pattern as the related types. The crude material was crystallized from chlorobenzene to give the desired compound as fluffy yellow needles, m.p. >300°, in a purified yield of 63%.

Anal. Calcd. for $C_{14}H_7ClN_2O_4$: C, 55.55; H, 2.33; Cl, 11.71; N,[29] 4.63. Found: C, 55.51; H, 2.33; Cl, 11.82; N,[29] 4.57.

IV. **9-Chloro-6,7-ethylenedioxy-3-nitroacridine.**—1,4-Benzodioxane (1,2-ethylenedioxybenzene) was made by the method of Ghosh.[40] The nitration according to the directions of Vorländer[41] was not particularly satisfactory, but the modification of Heertjes, *et al.*,[42] readily gave 80% yields of pure 4-nitro-1,2-ethylenedioxybenzene even with large batches.

The reduction of pure 4-nitro-1,2-ethylenedioxybenzene with Adams catalyst at 40° and 3 atm. was run in methanol. The filtered reduction liquors were employed in the same manner as described above for the 3,4-dimethoxyaniline; N-(3,4-ethylenedioxyphenyl)-4-nitroanthranilic acid was isolated in 69% yield (after one crystallization from dilute ethanol with use of Darco G-60; m.p. *ca.* 235°). Further crystallization gave the pure compound in the form of golden needles, m.p. 249–250.5°.

Anal. Calcd. for $C_{15}H_{12}N_2O_6$: C, 56.96; H, 3.83; N,[29] 4.43. Found: C, 57.23; H, 3.53; N,[29] 4.32.

Interaction of the anthranilic acid type with phosphorus oxychloride in toluene was accomplished in the usual manner. The 9-chloro-6,7-ethylenedioxy-3-nitroacridine isolated after one crystallization from xylene melted *ca.* 285° (86.5% yield). Further crystallization from chlorobenzene (followed by extraction with boiling ether to remove the adhering solvent) produced the pure compound; orange microcrystals, m.p. 298.7–299.5° (76% yield from the acid).

Anal. Calcd. for $C_{15}H_9ClN_2O_4$: C, 56.88; H, 2.87; Cl, 11.19; N,[29] 4.43. Found: C, 56.96; H, 2.92; Cl, 11.23; N,[29] 4.23.

B. **Side-Chains. 3-Diethylamino-2-hydroxypropylamine (VII) and N-(2-hydroxyethyl)-ethylenediamine (VIII)** were redistilled commercial products.

N-(2-Hydroxypropyl)-ethylenediamine (IX), b.p. 88–91° (3 mm.), $n^{25}D$ 1.4744, was obtained in 48% yield from ethylenediamine and propylene oxide.[43] The by-product, N,N′-bis-(2-hydroxypropyl)-ethylenediamine, was isolated in 21.5% yield; shimmering white platelets from ethanol, m.p. 147–147.5°.

Anal. Calcd. for $C_8H_{20}N_2O_2$: C, 54.51; H, 11.44; N, 15.90. Found: C, 54.80; H, 11.41; N, 15.88.

N-(2-Hydroxy-2-methylpropyl)-ethylenediamine (X), b.p. 89–93° (2 mm.), $n^{25}D$ 1.4670, was prepared (58.5% yield) from ethylenediamine and isobutylene oxide.[43] N,N′-Bis-(2-hydroxy-2-methylpropyl)-ethylenediamine was also formed (22.5% yield); it crystallized from hexane as white blades, m.p. 69.5–70°.

Anal. Calcd. for $C_{10}H_{24}N_2O_2$: C, 58.79; H, 11.84; N, 13.72. Found: C, 58.74; H, 11.12; N, 13.60.

N-(2-Hydroxyethyl)-1,3-propanediamine (XI) resulted when 2-(2-hydroxyethyl)-propionitrile was catalytically reduced in ammoniacal ethanol[44,45]; b.p. 105–107° (1 mm.), $n^{25}D$ 1.4837.

N-(2-Hydroxy-2-methylpropyl)-1,3-propanediamine (XII) was obtained by catalytic reduction of the related propionitrile in ammoniacal ethanol[46]; b.p. 102–106° (4 mm.), $n^{25}D$ 1.4672.

(34) This procedure was devised by Dr. B. F. Tullar of the Development Laboratories of this Institute during 1945. It was partly based upon experiments of Drs. C. E. Kwartler, W. Boehme and E. A. Steck. The over-all yield obtained from veratrole and 2-chloro-4-nitrobenzoic acid was uniformly about 24%, while the procedure of Miller and Wagner[7] would produce 9-chloro-6,7-dimethoxy-3-nitroacridine in *ca.* 13% yield.

N-(2-Hydroxyethyl)-1,7-heptanediamine (XIII).—Pimelonitrile[47] was reduced in 10% ammoniacal ethanol with Raney nickel catalyst at 60 atm. and 90°. An 88% yield of 1,7-heptanediamine was collected at 52–54° (1 mm.); this compound was prepared[48] earlier by sodium–ethanol reduction of pimelonitrile.

A solution of 33.3 g. (0.26 mole) of 1,7-heptanediamine in 100 cc. 90% methanol was stirred at 0° in a flask equipped with condenser through which brine was circulated at −10°. To this there was added 12 cc. (10.6 g., 0.24 mole) of liquefied ethylene oxide contained in a jacketed dropping funnel having brine circulated through the jacket. When addition had been completed (*ca.* 0.5 hour), the reaction mixture was allowed to warm to room temperature, and reaction caused the temperature to rise to 40°. The mixture was stirred for 3 hr., then refluxed for 1 hr. before fractionation. A yield of 20.9 g. (47%) of N-(2-hydroxyethyl)-1,7-heptanediamine (XIII) was collected at 164–168° (1 mm.), $n^{25}D$ 1.4751.

Anal. Calcd. for $C_9H_{22}N_2O$: N, 16.08. Found: N, 16.10.

C. 9-Amino-3-nitroacridines.—The 9-amino-3-nitroacridine derivatives which were prepared by the reaction of the appropriate 9-chloro-3-nitroacridine and amine in phenol melt have been presented with pertinent data in Table I. Indication of the procedure employed is given in the preparation of 9-(3-diethylamino-2-hydroxypropylamino)-6,7-dimethoxy-3-nitroacridine, for this is somewhat different in certain respects from those published.[7,8]

I. 9-(3-Diethylamino-2-hydroxypropylamino)-6,7-dimethoxy-3-nitroacridine Dihydrochloride.—A melt comprised of 440 g. of phenol and 220 g. (0.69 mole) of 8-chloro-6,7-dimethoxy-3-nitroacridine was stirred under reflux at 70°. The heat was removed and 123 g. (0.84 mole) of 3-diethylamino-2-hydroxypropylamine was added at such a rate that the temperature did not exceed 95°. At the end of the addition, heating was resumed for 1 hr.; the mixture was cooled to 40° and poured into a well-stirred solution of 120 cc. of concd. hydrochloric acid in 4 l. of acetone at 20°, then stirred for an hour or two. A brick-red hydrochloride resulted and was leached well with acetone to remove phenol. The crude product was dissolved in 1 l. of water at 70–75° and charcoaled. The filtrates were at 40–45° when 350 cc. of concd. hydrochloric acid was added and thereafter cooled very slowly, then collected, slurried the product with acetone, washed with acetone and ether. This scarlet dihydrochloride was dried *in vacuo* below 50° to avoid loss of HCl; m.p. 223–225° dec. The product weighed up to 250 g. and contained some 5–9.5% moisture; the yield, on the dry basis, was 56–65%. Miller and Wagner[7] have reported a product containing 6.8% water; Hurst[19] employed a sample containing *ca.* 8% moisture.[49]

In the case of most compounds listed in Table I, the method detailed for the preparation and purification of 9-(3-diethylamino-2-hydroxypropylamino)-6,7-dimethoxy-3-nitroacridine dihydrochloride was that followed. However, in the case of the types bearing the 3-diethylamino-2-hydroxypropylamine chain (VII), variations were desirable. In most cases the phenol melt was quenched in acetone–40% ethanolic hydrogen chloride mixture, and the crude products crystallized from ethanol–ether. A pure sample of 9-(3-diethylamino-2-hydroxypropylamino)-6,7-methylenedioxy-3-nitroacridine dihydrochloride was most readily obtained by merely extracting the crude with boiling ethanol and drying the residue. The products were, ordinarily, dried *in vacuo* over phosphoric anhydride, sodium hydroxide pellets and wax. Use of high temperatures for drying led to considerable loss of hydrogen chloride, which was sometimes difficult to replace. All determinations of water content were done by the Karl Fischer method.

Acknowledgment.—The authors wish to express their appreciation to Mr. M. E. Auerbach and Mr. K. D. Fleischer and their groups in the Analytical Laboratories for the analyses.

The Ultraviolet Absorption Spectra of Stereoisomeric 1,2,3,4,9,10,4a,9a-Octahydroacridines and Related Compounds[1]

BY TADASHI MASAMUNE

RECEIVED JANUARY 21, 1957

The near ultraviolet absorption spectra of *cis*- and *trans*-1,2,3,4,9,10,4a,9a-octahydroacridines and related stereoisomeric bases were measured in isoöctane, ether and alcohol. The absorption maximum of each *cis* isomer was situated at a longer wave length than that of the corresponding *trans* isomer in isoöctane and in ether; this shift was especially remarkable in alcohol. The solvent effect of alcohol on simple derivatives of aniline was examined and was found to be mainly attributable to the formation of hydrogen bonding between amine and alcohol, which depended upon the strength of the basicity and upon their steric configuration. This explanation was applied to the absorption spectra of four pairs of stereoisomeric tricyclic bases with success, it being emphasized that the formation of hydrogen bonding may be strongly influenced by the geometry of the bases. The ultraviolet absorption spectra of these bases were furthermore examined in 0.1 *N* hydrochloric acid and a characteristic peak was found to exist near 320 mμ.

Introduction

During the course of an investigation of the dehydrogenation of hydrogenated acridines,[2] it became desirable to study their ultraviolet absorption spectra in order to identify small amounts of dehydrogenated products. It was found that the absorption maximum of *cis*-1,2,3,4,9,10,4a,9a-octahydroacridine was situated at a longer wave length than that of the corresponding *trans*-base in alcohol. In the present work, the absorption spectra of those compounds were measured in isoöctane or in ether. The difference of absorption spectra of the stereoisomers in alcohol is believed principally due to the difference in solvation.

There are available many reports on the relation between geometrical form and absorption spectra of organic compounds.[3] However, no attention has been paid to the problem of whether or not the solvent effect on absorption spectra is affected by a difference in the molecular configuration of the solute. In the present article it will be shown that such a solvent effect does exist. For example, *trans*-tetrahydro-2,3-trimethylenequinoline exhibits a distinct blue shift in alcohol,[4] while the corresponding *cis* isomer shows a red shift in the same medium. A similar difference in solvation was observed in several other cases such as isomers of octahydroacridine and related compounds.

Experiments and Results

Materials.—The following stereoisomeric tricyclic bases were prepared by procedures described in the literature. Solid compounds were recrystallized to constant melting point from the solvents indicated and liquids were freshly redistilled before use: *cis*-hexahydrocarbazole,[5] m.p. 98–99° (alcohol); *trans*-hexahydrocarbazole,[5] m.p. 128–130° (alcohol); *cis*-octahydroacridine,[6] m.p. 71–72° (benzine); *trans*-octahydroacridine, m.p. 80–81° (petroleum ether); *cis*-tetrahydro-2,3-trimethylenequinoline,[7] oil, benzoyl derivative, m.p. 159–160° (acetone); *trans*-tetrahydro-2,3-trimethylenequinoline,[8] m.p. 66–68° (petroleum ether); *cis*-tetrahydro-2,3-pentamethylenequinoline,[8] oil, benzoyl derivative, m.p. 145–146° (alcohol); *trans*-tetrahydro-2,3-pentamethylenequinoline,[8] m.p. 59–60° (petroleum ether).

Ultraviolet absorption measurements were made using a Beckman quartz spectrophotometer, model DU; the following four solvents were used: ethanol, ether, isoöctane (dried over phosphorus pentoxide) and 0.1 *N* hydrochloric acid. The spectrum was examined at 0.5 mμ intervals near maximum and at 3 mμ intervals in another region of 215 to 350 mμ.

Basicity measurements were carried out at 15° according to the method of Thomson[9]: that is, because of the low solubility of the bases in water, solutions in 50% aqueous ethyl alcohol were used, and in view of uncertainty as to the value of K_w in those alcoholic solutions, the result was expressed as pK_a for the conjugated acids (calculated by means of the simple Henderson equation $pK_a = pH + \log(\text{salt})/(\text{base})$. Solutions were prepared as follows: in "50% alcohol" by dissolving *a* g. of the base in rather less than 10 cc. of ethanol, adding *b* cc. of 0.113 *N* aqueous

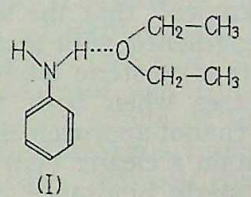
hydrochloric acid, then adding (12.5 − *a*) cc. of distilled water and making the volume up to 25 cc. with ethanol in a standard flask.

Results.—The values of λ_{max}, $\Delta\lambda_{ether}$ or $\Delta\lambda_{alc}$ (displacement of the λ_{max} in alcohol or ether relative to that in isoöctane) and $\Delta\lambda_{iso}$ (difference of λ_{max} between *cis* and *trans* isomers) of the near ultraviolet absorption spectra (Doub's "secondary" band)[10] of all the compounds included in this study are shown in Table I with data of their ϵ_{max}. The λ_{max} was estimated with reference to the intensity of absorption maximum, as λ_{max} was most easily measured and most often recorded to evaluate the solvent effect, which will be discussed in the following section. On the other hand, the values of λ_{max} and ϵ_{max} of absorption spectra of those bases in 0.1 *N* hydrochloric acid are given in Table III with basicity.

Discussion

The experimental results given in Table I may be summarized under the following two points. (1) The near ultraviolet absorption band of each *cis* compound of four pairs of stereoisomeric tricyclic bases was situated at a longer wave length than that of the corresponding *trans* compound. This red shift of the absorption maximum of each *cis* compound was observed in isoöctane and in ether; the effect was especially remarkable in alcohol. (2) In either *cis* or *trans* compounds, the absorption curve of each base in ether was found to be displaced always toward the visible side in isoöctane ($\Delta\lambda_{ether}$ positive). On the other hand, anomalous displacements were found in alcohol. In the case of *trans* isomers the absorption maximum shifted toward the shorter wave length ($\Delta\lambda_{alc}$ negative) or remained unchanged, while in the *cis* isomers the shift occurred toward the longer wave length side ($\Delta\lambda_{alc}$ positive), the only exception being *cis* hexahydrocarbazole. It is to be noted, however, that the blue shift of the *cis* compound of the latter was much less pronounced than that of the *trans* isomer.

The Solvent Effect on Near Ultraviolet Absorption Spectra.—Several papers,[11-13] have recently appeared in which solvent effects on organic spectra are correlated with various properties of the solute and the solvent. For example, Coggeshall and Lang[14] in dealing with the spectra of phenols have discussed effects due to the dipole–dipole interaction, to hydrogen bonding and to the polarization effect between solvent and solute. From among the above three effects Nagakura and Baba[15] directed special attention to the hydrogen bonding in explaining the shift of near ultraviolet absorption spectra of aniline in solutions. They observed that the solvent effect of ether upon the spectra was unusually large when compared with that in hexane. Their explanation of this abnormal behavior is as follows: On the formation of hydrogen bonds[16] shown in diagram (I), semi-ionic structures with the positive charge at the N atom come to have extra energies of stabilization.[17,18] Consequently the degree of electron migration from the N atom to the benzene ring increases, producing an abnormal red shift.



(I)

The red shifts of absorption ($\Delta\lambda_{ether}$ positive) in ether of all compounds examined in the present work (see Tables I and II) are found to be essentially the same as the results of Nagakura and Baba. This suggests that the observed shifts[19] for these compounds are due to the hydrogen bonding between the H atom of the imino group of the solute and the O atom of the solvent.

The spectroscopic behavior in alcohol is different from that in ether. In contrast to ethereal solutions, two types of hydrogen bonds are believed to be formed between amine and alcohol. One is formed between the H atom of the imino group and the O atom of alcohol, while the other is

[a] These values were measured at 25° in aqueous solution by N. F. Hall and M. R. Sprinkle, THIS JOURNAL, 54, 3469 (1932). [b] This value has never been measured, but the base is easily supposed to be stronger in basicity than *p*-toluidine on the basis of induction and resonance.

between the N atom of amine and the H atom of hydroxyl group. Solvent effects associated with the former are expected to produce the shift toward red the same way as in ethereal solutions. The situation becomes just the opposite in the latter case. With the formation of the latter type of hydrogen bond, the lone-pair electrons at the nitrogen atom will become displaced toward the hydrogen atom of alcohol. This displacement would increase the effective electron affinity of the nitrogen atom. Consequently, the magnitude of electron migration from the nitrogen atom into the benzene ring decreases, thus resulting in the blue shift of absorption maximum.

There are available several examples[20] which show the displacement of absorption spectra due to the hydrogen bonding of the latter type. Furthermore, it is known[21] that the solvent effect of this type is strengthened with increasing basicity of amines, if there is no steric hindrance; that is, excepting the cases when both the amino and hydroxyl groups cannot approach each other.

In order to obtain a clearer view on the relation of basicity and steric hindrance, the near ultraviolet absorption spectra of various simple derivatives of aniline were measured in isoöctane and in alcohol. The results obtained are given in Table II together with data on their basicity. In aromatic primary amines, which were supposed not to suffer from the steric hindrance, the degree of the displacement toward shorter wave lengths became greater with increasing basicity. This tendency will be seen at a glance at the values of $\Delta\lambda_{alc}$ or more clearly at those of $\Delta\lambda_{sol}$. Contrary to the above, the shifts toward the visible are produced in secondary amines. Moreover, no change of absorption maxima of tertiary amines occurs with variation of solvent ($\Delta\lambda_{alc}$ null).

The striking differences observed between the primary and tertiary (or secondary) amines might be explained as follows. The energy of the hydrogen bond is markedly less than the usual bond energy. Consequently, the existence of methyl groups on the N atom more strongly inhibits the formation of hydrogen bond with the use of the nitrogen atom concerned.

(20) G. J. Brealey and M. Kasha, THIS JOURNAL, 77, 4462 (1955); T. Kubota, *J. Pharm. Soc. Japan*, 74, 831 (1954).
(21) M. Tsuboi, *J. Japan. Chem.*, 7, 611 (1953).

Further support of the above view may be found in the behavior of methylaniline, dihydroindole and tetrahydroquinoline given in Tables I and II. The blue shift of the absorption maximum in alcohol relative to that in isoöctane increases in the order of methylaniline, tetrahydroquinoline and dihydroindole. This order agrees with the order of decrease in steric hindrance of methylene groups. As was elaborated by Arnold[22] and others[23] the methylene group in five-membered ring offers less steric hindrance than that in a six-membered ring, while the latter offers less than that in an aliphatic normal chain.

The Influence of Conformation of Tricyclic Bases on their Near Ultraviolet Absorption Spectra.—Attempts were made to consider conformations of four pairs of stereoisomeric tricyclic bases and to explain why the near ultraviolet absorption spectrum of the *cis* compound should produce a smaller blue shift in alcohol as compared with that in isoöctane than that of the corresponding *trans* isomer ($\Delta\lambda_{alc}$ of *cis*-base − $\Delta\lambda_{alc}$ of *trans*-base, positive). A glance at the results given in Table I and the strength of basicity given in Table II will show for these displacements that there is no relationship with the strength of basicity. These shifts, therefore, have to be interpreted from the viewpoint of stereochemistry. As an example, the conformations of octahydroacridine will be discussed in the following.

Conformations of Octahydroacridine.—Tetrahydroquinoline is regarded as an analog of tetralin with substitution of nitrogen for carbon at position 1 and consequently with only slight distortion of the ring. Arguments similar to those given in the case of tetralin by Barton[24] and others[25] may, therefore, be applicable to derivatives of tetrahydroquinoline. Since 1,2,3,4,9,10,4a,9a-octahydroacridine is regarded as a 2,3-tetramethylene derivative of tetrahydroquinoline, its *trans* isomer may be assigned a conformation with the tetra-

methylene group equatorial in positions 2 and 3 of tetrahydroquinoline. A conformation with both the substituents axial can be excluded by steric considerations. There may, moreover, be considered two conformations concerning the nitrogen atom, as represented in diagrams II and III, respectively, one having the lone-pair electrons in the quasi-axial position and the other in quasi-equatorial. In contrast to piperidine analogs in which the latter is considered to exist predominantly,[26] it is assumed that tetrahydroquinoline has another conformation (the former type) with the lone-pair electrons in quasi-axial position. There is an evidence for the above assumption: on account of the overlap between the π-orbits of the benzene ring and the p-orbital of the nitrogen atom, the structure with the electrons in quasi-axial position should be stabilized. Further support may be found in the existence of the "secondary" absorption band of octahydroacridine and other aromatic amines treated in this study, in the decrease in basicity as compared with aliphatic amines, and in also several chemical reactions.[27]

Two conformations are possible for *cis*-octahydroacridine, as shown in diagrams IV and V, since those having the lone-pair electrons in quasi-axial position are excluded from consideration. In conformation IV, the methylene group at C_3 exists in an axial position and that at C_2 in equatorial one, whereas in V their positions are reversed.

In the former, the tetramethylene group produces steric compression over the p-orbital of a nitrogen atom whereas in the latter, the substituent shields the quasi-axial hydrogen atom at C_4. Little attention has been directed to steric influence due to the lone-pair electrons. This appears to be less than the steric hindrance caused by the hydrogen atom. By the above reason conformation IV may be inferred to be more predominant than the latter. On the basis of these likely assumptions it seems reasonable to assign conformations II and IV for *trans*- and *cis*-octahydroacridines,[28] respectively. Similar interpretation may be developed to assign conformations for *trans* and *cis* isomers of tetrahydro-2,3-trimethylenequinoline and of tetrahydro-2,3-pentamethylenequinoline.

The Difference $\Delta\lambda_{sol}$.—In order to account for the solvent effect in alcohol more definitely, the concept $\Delta\lambda_{sol}$ will be proposed, being defined as $\Delta\lambda_{alc} - \Delta\lambda_{ether}$. Since the size of the ether molecule is almost the same as that of the alcohol molecule, the value of $\Delta\lambda_{ether}$ is considered to indicate the solvent effect afforded only by hydrogen bonding between the H atom of the imino group and the O atom of the alcohol. Consequently, the term $\Delta\lambda_{sol}$ displays the solvent effect resulting from only hydrogen bonding between the N atom of the amine and the H atom of the alcohol. Examination of Table I shows that the term $\Delta\lambda_{sol}$ was particularly small in each of three *cis* derivatives of tetrahydroquinoline. This means that no hydrogen bonding is formed between the N atom of amine and the H atom of alcohol. The conformations of these *cis* isomers suggested in the previous paragraph are in good agreement with these facts: tri-, tetra- or pentamethylene substituent dominates so much space over the p-orbital of the nitrogen atom that the polymethylene groups will obstruct the proximity of ethanol molecules and will thus block the formation of hydrogen bonding.

On the other hand, the three *trans* isomers are supposed to suffer steric hindrance to only a slight degree in the formation of hydrogen bonding between the N atom of the amine and the H atom of the alcohol, as shown by negative values of the term $\Delta\lambda_{sol}$ given in Table I. It is to be noted that the value of $\Delta\lambda_{sol}$ in *trans*-tetrahydro-2,3-trimethylenequinoline (-4.5 mμ) was smaller than that in the other two *trans* isomers (-2.0 and -2.5 mμ), being consistent with the observation[22] by Arnold and his associates as mentioned above.

Conformations of hexahydrocarbazole will be discussed next. As it is well known that cyclohexane fused with a five-membered ring consists mainly of the chair form,[29] conformation VI will be suitable to be assigned for *trans*-hexahydrocarbazole and VII or VIII for the *cis* isomer, each corresponding to those, II, V and IV, of octahydroacridine. The conformation VI is formed when each of two equatorial hydrogen atoms on the two adjacent carbon atoms of cyclohexane is substituted by amino and phenyl radical of aniline, respectively. In conformation VII, the *cis* isomer has a configuration with the amino and phenyl radicals in the equatorial and axial position of adjacent carbon atoms of cyclohexane, respectively, whereas in conformation VIII they are in axial and equatorial position, respectively. Similar argument to that described in the case of *cis*-octahydroacridine cannot be applied to the stability between conformations VII and VIII. However, it will be reasonable to consider that *cis*-hexahydrocarbazole consists chiefly of conformation VII, because the p-orbital of nitrogen atom is screened with the tetramethylene group in conformation VIII but, on the contrary, conformation VII hardly suffers steric hindrance as is also true in the case of the *trans* isomer. Examination of Table I indicates that the value of $\Delta\lambda_{sol}$ of *cis*-hexahydrocarbazole was not very different from that of the *trans* isomer, as expected from a consideration as above outlined.

The Difference $\Delta\lambda_{ether}$.—In addition to the term of $\Delta\lambda_{sol}$, the values of $\Delta\lambda_{ether}$ must, therefore, be discussed in order to elucidate the difference of absorption maxima of the *cis* and *trans* isomers of tricyclic bases in alcohol, and the following will be proposed as an explanation. The positive values of $\Delta\lambda_{ether}$ are due mainly to the formation of hydrogen bonding between the H atom of the imine and the O atom of the ether. It seems to require a carbon atom at the β-position in relation to the nitrogen atom (called β-carbon) or a hydrogen atom attached to the carbon (called β-hydrogen) to display a serious steric influence on the proximity

of the ether molecule. In each of conformations II and IV of *cis*- and *trans*-octahydroacridines, a quasi-equatorial hydrogen atom of an imino group runs almost parallel to the equatorial β-hydrogen atom, and those atoms with the nitrogen atom and β-carbon atom lie approximately coplanar with the benzene ring. The latter steric relation was extended to both *cis* and *trans* isomers of tetrahydro-2,3-pentamethylenequinoline with slight change due to transformation from a six-membered ring to a seven-membered ring. Therefore, in each of the two pairs both the *cis* and *trans* isomers are able to form the hydrogen bonding with ether molecule to the same degree, and as the result the difference of $\Delta\lambda_{ether}$ between isomers is supposed to be almost nothing.

On the other hand, the position is different in the other two pairs of stereoisomers where a five-membered ring combines with a six-membered ring. While the above-mentioned relation comes to each of two *trans*-isomers of those bases, each of two *cis*-isomers behaves differently: that is, each β-carbon atom, and more important each β-hydrogen atom, is forced out of coplanarity with tetrahydroquinoline or dihydroindole, because each atom of a five-membered ring is coplanar. As a result, it would be expected that the approach of an ether molecule toward the hydrogen atom of imino group is easier in each *cis* isomer, and the value of ($\Delta\lambda_{ether}$ of *cis* isomer $-$ $\Delta\lambda_{ether}$ of *trans* isomer) is expected to be positive. The values of $\Delta\lambda_{ether}$ given in Table I were found to fit in with these considerations.

One might conclude that the experimental results given in Table I are in good agreement qualitatively with what might be expected from both the conformational analysis for tricyclic bases and the inferences on the solvent effect of alcohol developed by division into terms of $\Delta\lambda_{ether}$ and of $\Delta\lambda_{sol}$. This inference of the solvation of alcohol may be extended with some reason to simple derivatives of aniline included in Table II; it may be pointed that the effect caused by the hydrogen bonding between the N atom of the aromatic amine and the H atom of the alcohol is large and depends remarkably on steric hindrance as well as on strength of basicity; however, on the contrary, that between the amino H and the alcohol O is comparatively small and is probably influenced only by steric hindrance and not by basicity.

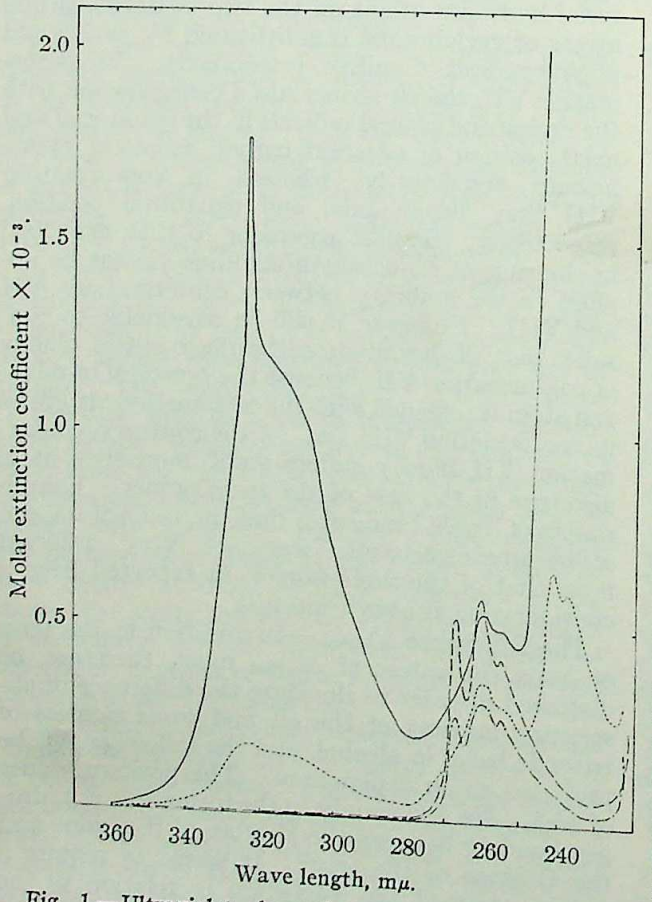

Fig. 1.—Ultraviolet absorption spectra of tricyclic bases in 0.1 *N* hydrochloric acid, concn. $M \times 10^{-3}$: ———, *cis*-hexahydrocarbazole; —·—·—, *trans*-hexahydrocarbazole; - - - - -, *cis*-octahydroacridine; ———, *trans*-octahydroacridine.

Ultraviolet Absorption Spectra of Tricyclic Bases in 0.1 *N* Hydrochloric Acid and their Basicity.—It is well known that the absorption spectra of derivatives of aniline in acidic solution agree closely with the spectrum of benzene.[30] This rule was recognized in stereoisomeric hexahydrocarbazoles in this study. But absorption spectra of the other three pairs of stereoisomers of tricyclic bases exhibited characteristic peaks at longer wave lengths (near 320 mμ), as shown in Fig. 1 and in Table III. Especially, *trans*-octahydroacridine displayed an absorption peak with extraordinary strong intensity in this region. While a rational explanation could not be offered for these phenomena, which probably result from distortion of the benzene ring by ring formation of substituents, attention should be drawn to the association of intensity of those

[a] The figures in parentheses refer to molecular extinction coefficient. [b] The basicity was measured at 15° in 50% aqueous alcohol.

absorption spectra with basicity. In each of four pairs cited in Table III, absorption maxima agree within the limit of 1 mμ, but those intensities were different among stereoisomers. Each of the bases possessing absorption bands of higher intensities was found to be a stronger base than the corresponding isomer. This correlation might be assumed because the strength of basicity of aromatic amines is closely associated with the resonance state of benzene, but no generalization would be safe from the few examples treated in this study. The problem will be kept under further investigation.

Acknowledgments.—The present research was conducted under the supervision of Professor Harusada Suginome, President of Hokkaido University. The author is also indebted to Professor Ken-iti Higasi for his help in revising the manuscript. Thanks are due to Mr. Seiya Suzuki for help with some of the measurements.

The Preparation and Dichromate Oxidation of Certain 6-Substituted Phenanthridines

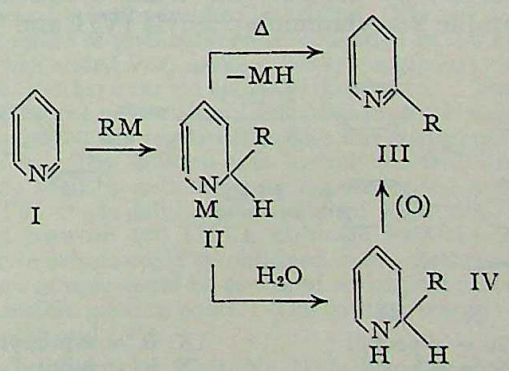
BY HENRY GILMAN AND JOHN EISCH

RECEIVED MARCH 7, 1957

The preparation of 6-substituted phenanthridines and their 5,6-dihydro derivatives by the organometallic alkylation of phenanthridine has been examined. It was found that not only do organolithium compounds (*n*-butyl- and *o*-tolyllithium) attack phenanthridine readily, but active Grignard reagents such as benzylmagnesium chloride can also add to the azomethine linkage. Finally, even ordinary Grignard reagents such as *n*-propylmagnesium bromide alkylate this heterocycle if the reaction time is protracted.

The dichromate oxidation of 6-*n*-propyl- and 6-*n*-butylphenanthridines gave, in addition to phenanthridinone, the corresponding 6-acylphenanthridines. This reaction is suggested not only to be diagnostic for 6-alkylphenanthridines but also to be a preparative method for 6-acylphenanthridines.

Although the aza-aromatic heterocycles previously studied, pyridine, quinoline and isoquinoline, are readily alkylated by organolithium compounds,[1] they react with organomagnesium compounds only with difficulty.[2] To obtain even mediocre yields, workers have resorted to such stringent reaction conditions as autoclave technique, higher-boiling solvents or dioxane media. The course of the reaction, however, seems quite analogous for organolithium and organomagnesium compounds, *i.e.*, addition of RM (M = Li, MgX) to the nitrogen heterocycle in a 1,2- or 1,4-manner. The interaction of pyridine (I) and an organometallic compound (RM) may be viewed as typical[3]



The resulting adduct II may either split out MH to give III thermally, or the dihydro compound IV obtained upon hydrolysis may be dehydrogenated.

Recent investigations have demonstrated that dibenzopyridines such as phenanthridine exhibit a high order of reactivity toward allylmagnesium

(2) For a general review of the interaction of Grignard reagents with aza-aromatic heterocycles, see M. Kharasch and O. Reinmuth, "Grignard Reactions of Nonmetallic Substances," Prentice–Hall, Inc., New York, N. Y., 1954, p. 1257 *et seq.*

(3) The predominating isomer from the reaction between pyridine and organolithium compounds is the 2-isomer, whereas the action of benzylmagnesium chloride leads in small yield to a 4:1 mixture of 4- benzyl- and 2-benzylpyridines (R. A. Benkeser and D. Holton, THIS JOURNAL, **73**, 5861 (1951)). With allylmagnesium bromide the main product has been shown to be 4-allylpyridine; smaller amounts of 2-allylpyridine which may have been formed could not be isolated (ref. 4).

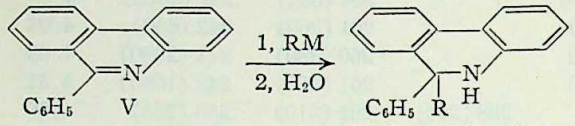
bromide in ether, in comparison to that of benzopyridines or pyridine itself.[4] Moreover, phenanthridine gives high yields of 6-arylphenanthridines with organolithium compounds,[5] and even 6-phenylphenanthridine (V) can add phenyllithium[5] or allylmagnesium bromide to give VI.[6]



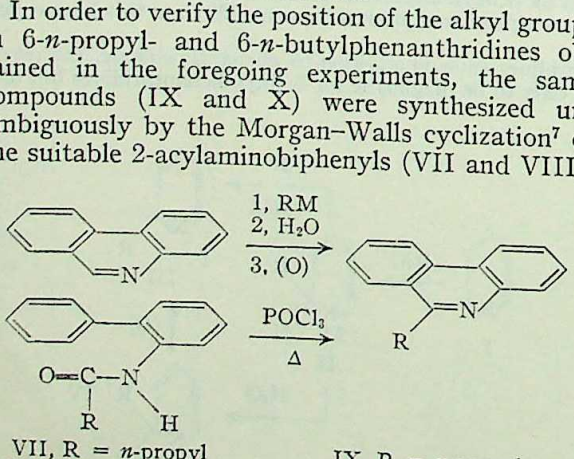
VI, R = C_3H_5, C_6H_5

In the present study it was of interest to learn whether this enhanced reactivity of phenanthridine would be reflected in its behavior toward ordinary Grignard reagents and whether organometallic alkylation was feasible for the synthesis of 6-substituted phenanthridines of various types.

Although Ziegler and Zeiser[1] have reported that *n*-butyllithium adds readily to various nitrogen bases, this reaction has not been reported for phenanthridine. Indeed, it was found that phenanthridine was immediately alkylated at −50° to give 6-*n*-butylphenanthridine in essentially quantitative yield. It may be noted that 6-*n*-butylphenanthridine could not be freed entirely of its dihydro form, as is indicated by the NH band in its infrared spectrum and the orange-yellow cast of its picrate.

A second illustration of phenanthridine's superior reactivity is its behavior with *n*-propylmagnesium bromide in ether. By prolonging the reaction time, but without use of customary "forcing" conditions, an 84% yield of 6-*n*-propylphenanthridine was secured. The excellent yield with this ordinary Grignard reagent suggests that in certain cases the organomagnesium compound may replace the organolithium compound when the latter is difficultly accessible.

In order to verify the position of the alkyl groups in 6-*n*-propyl- and 6-*n*-butylphenanthridines obtained in the foregoing experiments, the same compounds (IX and X) were synthesized unambiguously by the Morgan–Walls cyclization[7] of the suitable 2-acylaminobiphenyls (VII and VIII).



VII, R = *n*-propyl
VIII, R = *n*-butyl

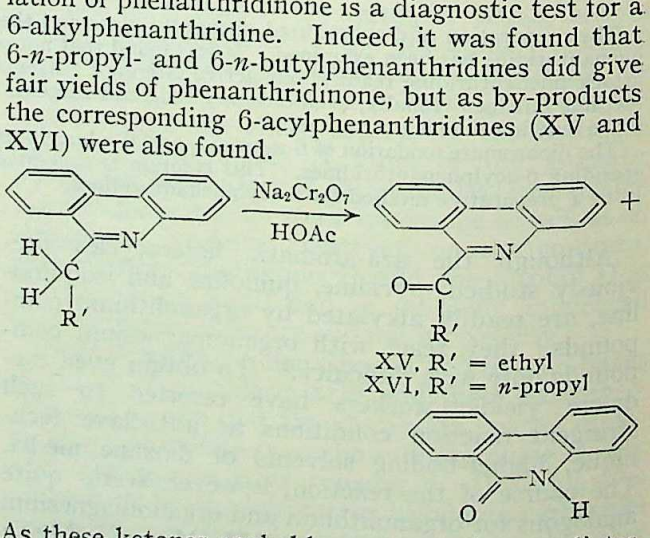
IX, R = *n*-propyl
X, R = *n*-butyl

Third, a more reactive, allylic Grignard reagent such as benzylmagnesium chloride, analogous to allylmagnesium bromide,[4] attacked phenanthridine readily to give the 6-benzyl-5,6-dihydro derivative XI in 78% yield. Since the product was not amenable to purification by crystallization, it was identified by dichromate oxidation to the known 6-benzoylphenanthridine (XII) in high yield.

Finally, a somewhat hindered aryllithium system, such as *o*-tolyllithium, added readily to the azomethine linkage in phenanthridine. Also quite significant is the fact that here the dihydro derivative XIII could be isolated as a moderately stable solid. It could be dehydrogenated smoothly by palladium in boiling mesitylene to the 6-*o*-tolyl derivative XIV which was isolated as a low melting picrate.

The above illustrated Morgan–Walls cyclization[7] of 2-acylaminobiphenyls has represented, since its introduction in 1931, the most general method for preparing 6-substituted phenanthridines. However, the use of organolithium compounds or organomagnesium reagents (when the latter are more accessible) on phenanthridine offers an attractive alternative, especially since newer methods have made phenanthridine more available in organic synthesis.[8] In addition, organometallic alkylation may be the preferred method when 6-substituted-5,6-dihydrophenanthridines themselves are desired. The latter are of interest for their potential physiological activity.[9]

The dichromate oxidation of 6-methylphenanthridines first carried out by Walls[10] led to excellent yields of phenanthridinones. The pre ent authors examined the behavior of 6-*n*-propyl- and 6-*n*-butylphenanthridines toward sodium dichromate in glacial acetic acid to learn if the formation of phenanthridinones was general for 6-alkylphenanthridines. As phenanthridine itself was essentially unaffected by the dichromate oxidation procedure, it could then be concluded that the isolation of phenanthridinone is a diagnostic test for a 6-alkylphenanthridine. Indeed, it was found that 6-*n*-propyl- and 6-*n*-butylphenanthridines did give fair yields of phenanthridinone, but as by-products the corresponding 6-acylphenanthridines (XV and XVI) were also found.



XV, R′ = ethyl
XVI, R′ = *n*-propyl

As these ketones probably represent intermediates in oxidizing 6-alkylphenanthridines to phenanthridinones, it is feasible to prepare 6-acylphenanthridines in this way by employing milder conditions. As has been mentioned previously, the impure 6-benzyl-5,6-dihydrophenanthridine was

transformed by this method to 6-benzoylphenanthridine in 72% yield.

Experimental

The melting points were determined on an electrically heated copper block and are corrected. All operations involved in the preparation and reaction of organometallic compounds were conducted under an atmosphere of dry, oxygen-free nitrogen.

6-*n*-Butylphenanthridine (X). Method A. From 2-Valeraminobiphenyl (VIII) and Phosphorus Oxychloride.[7]—A 500-ml., round-bottomed flask was equipped with an air condenser bearing a calcium chloride tube and the latter tube connected to a hydrogen chloride gas trap. The reaction flask was charged with 25.5 g. (0.10 mole) of 2-valeraminobiphenyl and 42 g. (0.27 mole) of phosphorus oxychloride, and this solution was heated cautiously until coloration appeared and gas evolution began. The heating was then discontinued and the reaction allowed to proceed spontaneously. When the vigorous reaction subsided, the solution was heated at the reflux temperature for 2 hr. The excess phosphorus oxychloride was removed at reduced pressure, and the residue extracted portionwise with 200 ml. of hot 6 *N* hydrochloric acid. After filtration through glass wool, the extracts were treated with excess sodium hydroxide. The liberated base was taken up in an ether–benzene mixture and dried with anhydrous sodium sulfate. After removal of the solvent the 6-*n*-butylphenanthridine distilled at 182–184° (4.0 mm.), 14.0 g. (60%). It was a pale yellow, viscous liquid, $n^{20}D$ 1.6369.

Anal. Calcd. for $C_{17}H_{17}N$: N, 5.96. Found: N, 6.06.

The picrate recrystallized from a dioxane–ethanol pair as fine, yellow needles, m.p. 195.5–197°.

Anal. Calcd. for $C_{23}H_{20}N_4O_7$: N, 12.06. Found: N, 12.11.

Method B. From Phenanthridine and *n*-Butyllithium.—In a 500-ml., three-necked flask fitted with a sealed stirrer, addition funnel and low-temperature thermometer and flushed with nitrogen, 20.0 g. (0.112 mole) of phenanthridine was suspended in 200 ml. of dry ether. After the contents of the flask were cooled to −45° by means of an acetone–Dry Ice-bath, 0.11 mole of freshly prepared *n*-butyllithium[11] in 120 ml. of ether was added to the stirred suspension during 20 minutes. The temperature was then lowered to −50° and held there for 15 minutes, during which time the reaction mixture formed a fluorescent green solution. Thereupon the solution was poured rapidly onto a slurry of Dry Ice in dry ether. After the mixture had warmed up to room temperature, it was extracted with 200 ml. of 5% potassium hydroxide solution. Separation and careful acidification of the aqueous layer gave no precipitated acid.

The ethereal layer of the carbonated mixture was dried over anhydrous sodium sulfate, filtered and the solvent removed. The residual orange liquid was heated with 30 ml. of nitrobenzene for 20 minutes to oxidize the dihydro derivative. After the nitrobenzene was distilled under water-pump vacuum, the residue was distilled at the oil-pump. The main fraction of pale orange liquid (23.7 g., 90%) boiled at 177–178° (3.4 mm.). That some dihydro form was still present was indicated by an N–H band at 3.0 μ in the infrared spectra and by the formation of an orange picrate. The product was redistilled through a short column, and a pale yellow liquid was obtained at 184° (4.0 mm.). The melting point of the picrate prepared from this fraction agreed well with that of the picrate prepared in method A, but still had an orange-yellow cast. A mixture melting point of the picrates was not depressed. The infrared spectra of the two preparations also were almost superimposable, except for the presence of an N–H band in the preparation from method B.

6-*n*-Propylphenanthridine (IX). Method A. From 2-Butyraminobiphenyl (VII) and Phosphorus Oxychloride.[7]—Analogous to the procedure detailed in method A above for the preparation of 6-*n*-butylphenanthridine, 23.9 g. (0.10 mole) of 2-butyraminobiphenyl and 38 g. (0.25 mole) of phosphorus oxychloride reacted to give, upon work-up, 16.0 g. (73%) of pale yellow 6-*n*-propylphenanthridine, b.p. 164–166° (2.0 mm.), $n^{20}D$ 1.6552.

Anal. Calcd. for $C_{16}H_{15}N$: N, 6.33. Found: N, 6.69.

The picrate formed fine, bright yellow needles from a dioxane–ethanol pair, m.p. 196–197.5°.

Anal. Calcd. for $C_{22}H_{18}N_4O_7$: N, 12.44. Found: N, 12.23.

Method B. From Phenanthridine and *n*-Propylmagnesium Bromide.—In a 500-ml., three-necked flask equipped with a sealed stirrer, addition funnel and reflux condenser were placed 21.1 g. (0.117 mole) of phenanthridine and 150 ml. of dry ether. Then 0.247 mole of *n*-propylmagnesium bromide in 120 ml. of ether was introduced, and the resulting yellow suspension stirred at the reflux temperature for 100 hr., during which time most of the solid dissolved to form a dark solution. The reaction mixture was hydrolyzed with ammonium chloride solution and the separated organic layer dried with anhydrous sodium sulfate. After filtration and distillation of the ether, the residual oil was heated with 30 ml. of nitrobenzene for 0.5 hr. The nitrobenzene was distilled at the water-pump and the remaining orange oil fractionated under reduced pressure. The main fraction consisted of 18.4 g. of yellow liquid, b.p. 163–164° (1.9 mm.), $n^{20}D$ 1.6525. Redistillation of the forerun gave an additional 3.4 g. of product for a total crude yield of 84%. The picrate prepared from this crude product melted at 194–195°. Admixed with the 6-*n*-propylphenanthridine picrate prepared in method A, the mixture melted at 194–197°. Moreover, the infrared spectra of this product and its picrate were almost superimposable with those of 6-*n*-propylphenanthridine and its picrate (method A), respectively.

2-Butyraminobiphenyl (VII).—A 500-ml., round-bottomed flask was equipped with a short air condenser which in turn bore a bent tube leading to a receiver. The reaction flask was charged with 33.9 g. (0.20 mole) of 2-aminobiphenyl, 35.4 g. (0.40 mole) of butyric acid and 0.1 g. of zinc dust. The contents were so heated during a 6 hr. period that a mixture of water and butyric acid slowly distilled into the receiver. Thereupon the warm mixture was poured into ice and the solidified product filtered off. After recrystallization from dilute ethanol, 38.2 g. (80%) of white product was obtained, m.p. 83–85°. The analytical sample was obtained from petroleum ether (b.p. 60–70°) as long, white needles, m.p. 86–86.5°.

Anal. Calcd. for $C_{16}H_{17}NO$: N, 5.87. Found: N, 5.80.

2-Valeraminobiphenyl (VIII).—By extension of the above procedure for 2-butyraminobiphenyl, 2-valeraminobiphenyl was prepared from 33.9 g. (0.20 mole) of 2-aminobiphenyl, 40.9 g. (0.40 mole) of valeric acid and 0.1 g. of zinc dust by an 8 hr. heating period. Recrystallization of the crude solid from dilute ethanol gave 41.8 g. (82%) of white product, m.p. 68–70°. The analytical sample consisted of long, white needles obtained from petroleum ether, m.p. 73–74.5°.

Anal. Calcd. for $C_{17}H_{19}NO$: N, 5.53. Found: N, 5.41.

6-Benzyl-5,6-dihydrophenanthridine (XI).—To 32.3 g. (0.180 mole) of phenanthridine suspended in 100 ml. of dry ether was added 0.26 mole of benzylmagnesium chloride in 190 ml. of ether over the course of 30 minutes. The initially formed bright yellow slurry slowly changed to a dark green solution when the reaction mixture was stirred under reflux for 24 hr. The solution was hydrolyzed with ammonium chloride solution and the resulting suspended solid filtered off. The crude white solid weighed 38.2 g. (78%) and melted between 130–133°. Although well-formed glistening white prisms could be obtained from an ethanol–benzene pair, no sample could be procured which had a consistently reproducible melting point. The melting points ranged between 125 and 134°.

Anal. Calcd. for $C_{20}H_{17}N$: N, 5.17. Found: N, 5.41.

The infrared spectrum had a pronounced N–H band at 3.05 μ. That the product was actually 6-benzyl-5,6-dihydrophenanthridine in intimate mixture with perhaps 6-benzylphenanthridine and some starting material was demonstrated by oxidation to the known 6-benzoylphenanthridine in high yield.

6-Benzoylphenanthridine (XII).—In 100 ml. of warm glacial acetic acid were dissolved 6.8 g. (0.025 mole) of impure 6-benzyl-5,6-dihydrophenanthridine melting over the range 129–133°. In the course of 20 minutes, 14.3 g. (0.047 mole) of solid sodium dichromate was introduced. The resulting green solution was refluxed for 90 minutes and then poured

(11) H. Gilman, J. A. Beel, C. G. Brannen, M. W. Bullock, G. E. Dunn and L. S. Miller, THIS JOURNAL, 71, 1499 (1949).

Digitized by Arya Samaj Foundation Chennai and eGangotri

into water. Cooling and filtration gave 7.0 g. (99%) of pale yellow solid, melting over the range 140–147°. From ethanol 5.1 g. (72%) of white solid melting at 150–152° was obtained. Another crystallization yielded white plates, m.p. 152–154°. The product gave a positive test for the carbonyl group with 2,4-dinitrophenylhydrazine and exhibited an intense infrared band at 6.0 μ. Ritchie reports that 6-benzoylphenanthridine melts at 152°.[12]

6-*o*-Tolyl-5,6-dihydrophenanthridine (XIII).—To 30.0 g. (0.168 mole) of phenanthridine suspended in 200 ml. of dry ether was added 0.196 mole of *o*-tolyllithium in 180 ml. of ether during 50 minutes. (The *o*-tolyllithium was previously prepared from 3.3 g., 0.50 g. atom, of lithium wire and 39.3 g., 0.230 mole, of *o*-bromotoluene in 88% yield.) The reaction mixture was stirred at room temperature for 7 hr. and the resulting green solution subsequently hydrolyzed. The suspended solid upon filtration and drying melted over the range 134–138° and weighed 9.3 g. The ethereal layer upon evaporation yielded an additional 26.7 g. of product of the same melting range. One recrystallization from an ethanol–benzene pair gave 31.5 g. (64%) of slightly tan crystals, m.p. 140–141°. The presence of a dihydro grouping was indicated by the blue fluorescence of an alcoholic solution.[9a] The analytical sample consisted of cream-colored crystals, m.p. 140.5–141.5°, which became light brown when left in the air.

Anal. Calcd. for $C_{20}H_{17}N$: N, 5.17. Found: N, 5.14.

6-*o*-Tolylphenanthridine Picrate (XIV).—The product obtained in the preceding experiment was dehydrogenated catalytically. One gram (0.0073 mole) of 6-*o*-tolyl-5,6-dihydrophenanthridine, 100 mg. of palladium-on-Darco (5% palladium) and 5 ml. of mesitylene were refluxed for 1 hr. while a rapid stream of nitrogen was swept through the reaction vessel. At the end of this time, the initial blue fluorescence of the solution had disappeared. The reaction mixture was filtered and the catalyst washed with 10 ml. of ether. The mesitylene was distilled from the filtrate, leaving an oily yellow residue. Since only an oil was obtained from 95% ethanol, the base was converted to the picrate, a crystalline yellow solid melting at 165–167°, 1.6 g. (87%). 6-*o*-Tolylphenanthridine picrate formed bright yellow prisms from 95% ethanol, m.p. 167.5–168.0°.

Anal. Calcd. for $C_{26}H_{18}N_4O_7$: N, 11.24. Found: N, 11.41.

Oxidation of 6-*n*-Butylphenanthridine.[10]—In a 250-ml., three-necked flask fitted with a condenser, stirrer and solids funnel were placed 7.8 g. (0.033 mole) of 6-*n*-butylphenanthridine and 100 ml. of glacial acetic acid. While the solution was held at incipient reflux, 14.3 g. (0.047 mole) of sodium dichromate was introduced portionwise during 75 minutes. The orange solution turned dark green during the following 2-hr. reflux period. The solution was poured into water and the precipitated tan solid was collected. When dry, the solid was extracted with two 100-ml. portions of ether. The residual tan solid weighed 2.3 g. (36%) and melted over the range 289–292°. A mixed melting point determination with an authentic specimen showed this product to be phenanthridinone.

Removal of solvent from the ether extracts left 4.0 g. (49%) of a dark yellow solid melting over the range 85–95°. Recrystallizations from 95% ethanol (Norit A) gave silky, white needles, m.p. 108–109°. This solid proved to be 6-butyrylphenanthridine (XVI) as its infrared spectrum showed an intense carbonyl band at 5.95 μ. Moreover, it formed derivatives with 2,4-dinitrophenylhydrazine and with picric acid.

Anal. Calcd. for $C_{17}H_{15}NO$: N, 5.62. Found: N, 5.52.

The 2,4-dinitrophenylhydrazone was prepared in the conventional manner. Successive recrystallizations from an ethanol–ethyl acetate pair and then a chloroform–ethanol pair gave light orange, matted needles, m.p. 158.5–161°.

Anal. Calcd. for $C_{23}H_{19}N_5O_4$: C, 64.32; H, 4.46. Found: C, 64.30; H, 4.61.

The picrate crystallized from a dioxane–95% ethanol pair as stout, yellow needles, m.p. 198–199°.

Anal. Calcd. for $C_{23}H_{18}N_4O_8$: N, 11.71. Found: N, 11.62.

Oxidation of 6-*n*-Propylphenanthridine.[10]—In a manner similar to the preceding experiment 7.3 g. (0.033 mole) of 6-*n*-propylphenanthridine in 100 ml. of glacial acetic acid was heated for 3 hr. with 14.3 g. (0.047 mole) of sodium dichromate. Dilution of the reaction mixture with water and extraction of the collected solid with ether gave a 3.4-g. (53%) residue of phenanthridinone, m.p. 292–293°.

Evaporation of the ether extracts gave 2.3 g. (30%) of impure 6-propionylphenanthridine (XV) melting from 53–57°. Recrystallizations from 95% ethanol gave white needles melting from 73–76°. This sample showed a pronounced carbonyl band at 5.9 μ in its infrared spectrum. Further purification was carried out by preparing the 2,4-dinitrophenylhydrazone. By recrystallization from a chloroform–ethanol pair this derivative formed compact orange prisms, m.p. 225.5–227.5°.

Anal. Calcd. for $C_{22}H_{17}N_5O_4$: C, 63.85; H, 4.12. Found: C, 63.61; H, 4.26.

The picrate was obtained as chartreuse-colored needles from a dioxane–ethanol pair, m.p. 195.5–197°.

Anal. Calcd. for $C_{22}H_{16}N_4O_8$: N, 12.08. Found: N, 12.34.

Attempted Oxidation of Phenanthridine.—Phenanthridine (6.6 g., 0.033 mole) was heated with 14.3 g. (0.047 mole) of sodium dichromate in 100 ml. of glacial acetic acid for 24 hr. The red solution darkened somewhat during this time. The cooled solution was poured into water and the precipitated orange solid was collected and dried. Probably this was the dichromate salt of phenanthridine, for treatment with sodium hydroxide solution regenerated phenanthridine, 6.8 g., melting from 106–111°. When heated with 50 ml. of dilute hydrochloric acid, the phenanthridine dissolved almost completely, leaving only 0.1 g. of residue.

Acknowledgments.—The authors are grateful to Dr. V. A. Fassel and Mr. R. McCord of the Institute for Atomic Research for the infrared determinations. Also, it is a pleasure to acknowledge that this work was supported in part by the United States Atomic Energy Commission under Contract No. AT(11-1)-59.

Oxidative Reactions of Hydrazines. IV. Elimination of Nitrogen from 1,1-Disubstituted-2-arenesulfonhydrazides[1-4]

BY LOUIS A. CARPINO

RECEIVED MARCH 28, 1957

Alkaline degradation of 1,1-dibenzyl-2-benzenesulfonhydrazides leads to the formation of bibenzyls. The reaction is represented as proceeding through an intermediate formed by α-elimination of the elements of benzenesulfinic acid. A new method of introducing the very conveniently removed carbo-*t*-butoxy group is described involving acylation by *t*-butyl azidoformate.

Generally, the oxidation of 1,1-disubstituted hydrazines leads to the formation of the corresponding tetrazenes (eq. 1).[5] However, in several cases,

$$R_2NNH_2 \xrightarrow{[O]} R_2NN{=}NNR_2 \qquad (1)$$

as yet relatively unexplored, other products have been obtained. Oxidation of 1,1-dibenzylhydrazine with mercuric oxide was first noted by Busch and Weiss[6] to yield bibenzyl, and recently Overberger and Marks achieved the same result using bromine in ethanol or *t*-butyl hypochlorite as oxidizing agents. Busch and Lang[7] studied the mercuric oxide oxidation of numerous 1-aryl-1-benzylhydrazines and obtained either the tetrazenes or substituted benzaldehyde arylhydrazones. Kenner and Knight[8] postulated that the Busch–Weiss reaction involved the formation of the intermediate Ia which subsequently underwent decomposition

$$(C_6H_5CH_2)_2NNH_2 \xrightarrow{[O]} \underset{\text{Ia}}{[(C_6H_5CH_2)_2\dot{N}{-}\ddot{N}:} \longleftrightarrow$$

$$\underset{\text{Ib}}{(C_6H_5CH_2)_2\overset{+}{N}{=}\ddot{\overset{-}{N}}:]} \longrightarrow C_6H_5CH_2CH_2C_6H_5 + N_2 \qquad (2)$$

to bibenzyl (eq. 2). Intermediates such as I[9] are clearly analogous to the aliphatic diazo compounds except that they lack the resonance stabilization possible with the latter. The present study is designed to obtain evidence relative to the postulation of Kenner and Knight. In view of the analogy between the postulated intermediates such as I and aliphatic diazo compounds it would appear that many of the syntheses of the latter could be modified to provide new routes to bibenzyls and to shed more light on this novel and potentially useful reaction. The first such process to be examined was that of Bamford and Stevens[10] who found that phenyldiazomethane was obtained by treatment of the benzenesulfonhydrazone of benzaldehyde with alkali (eq. 3, Z = CH). As an α-elimination[11] of the elements of benzenesulfinic acid this reaction is related to the conversion of the corresponding triazene to the azide[12] (eq. 3, Z = N). These results suggested that alkaline degradation of 1,1-dibenzyl-2-benzenesulfonhydrazide should yield bibenzyl if the postulation of Kenner and Knight is correct (eq. 4). This reaction did, in fact, yield bibenzyl in 85% yield suggesting that the same intermediates might intervene in the two cases.[13]

$$C_6H_5Z{=}NNHSO_2C_6H_5 \xrightarrow{OH^-} \underset{Z = N, CH}{C_6H_5Z{=}\overset{+}{N}{=}\overset{-}{N}} \qquad (3)$$

$$(C_6H_5CH_2)_2NNHSO_2C_6H_5 \xrightarrow{OH^-} (C_6H_5CH_2)_2\overset{-}{N}NSO_2C_6H_5 \longrightarrow$$

$$\underset{+\ -}{[(C_6H_5CH_2)_2N{=}N]} \longrightarrow C_6H_5CH_2CH_2C_6H_5 \qquad (4)$$

(6) M. Busch and B. Weiss, *Ber.*, **33**, 270 (1900). A preliminary account of an investigation of the scope of the Busch–Weiss reaction has been given by R. L. Hinman and K. L. Hamm, Abstracts of the 130th National Meeting of the American Chemical Society, Sept. 18, 1956, p. 17-O. The reaction has seen only limited use as a preparative method [see J. Kenner and J. Wilson, *J. Chem. Soc.*, 1108 (1927), and F. G. Mann, I. T. Miller and B. B. Smith, *ibid.*, 1130 (1953)].

(7) M. Busch and K. Lang, *J. prakt. Chem.*, [2] **144**, 291 (1936). References to other anomalous results are given by Overberger and Marks.[5]

(8) J. Kenner and E. C. Knight, *Ber.*, **69**, 341 (1936).

(9) The name *azamine* has been suggested for the parent substance, $H_2N^+{=}N^-$ (ref. 4 and reference cited therein). Recently W. R. McBride and H. W. Kruse [THIS JOURNAL, **79**, 572 (1957)] have presented evidence for the existence of stable azaminiun salts, $[R_2N{=}NH]X$, obtained through the oxidation of 1,1-disubstituted hydrazines.

(10) W. R. Bamford and T. S. Stevens, *J. Chem. Soc.*, 4335 (1952).

(11) Most α-eliminations yield unstable substances which either react with the environment or achieve stabilization by rearrangement. For leading references to such postulated cases of α-elimination see S. J. Cristol and R. F. Helmreich, THIS JOURNAL, **77**, 5034 (1955); J. Hine, *ibid.*, **72**, 2438 (1950); R. L. Letsinger and D. F. Pollart, *ibid.*, **78**, 6079 (1956). While α-elimination of the elements of benzenesulfinic acid is rare the corresponding β-elimination is relatively common. For examples see O. Piloty, *Ber.*, **29**, 1565 (1896); A. Hantzsch and R. Glogauer, *ibid.*, **30**, 2555 (1897); E. L. Holmes and C. K. Ingold, *J. Chem. Soc.*, 1305 (1926); A. Michael and A. M. Comey, *Am. Chem. J*, **5**, 116 (1883). When there is a choice between α- or β-elimination of HX from alkyl halides, reaction rarely, if ever, goes by the former route. The possibility exists that this preference may be reversed in the sulfonhydrazide series due to the acidity of the α-hydrogen and the presence of an unshared electron pair on the atom beta to the leaving group. The implications of this possibility are being pursued further. There does not appear to be any evidence as to whether labile 3-ring intermediates (gamma elimination) intervene in the formation of the diazo and azido groups by reactions such as 3. The diazo and azido groups are known to be linear (see K. Clusius and H. Hürzeler, *Helv. Chim. Acta*, **37**, 383 (1954), and earlier work by these authors and others).

(12) A. Key and P. K. Dutt, *J. Chem. Soc.*, 2053 (1928).

(13) Alkaline degradation of 1-phenyl-2-benzenesulfonhydrazide has been postulated [M. L. Dhar, E. D. Hughes, C. K. Ingold, A. M. M. Mandour, G. A. Maw and L. I. Woolf, *J. Chem. Soc.*, 2093 (1948)] to involve β-elimination to yield phenyldiimide ($C_6H_5N{=}NH$) which subsequently decomposes to benzene and nitrogen. The results reported in the present paper suggest that α-elimination with the formation of the azamine ($C_6H_5\overset{+}{N}H{=}\overset{-}{N}$) may represent a second possibility

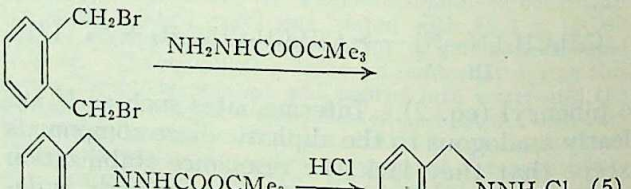
[a] Nitromethane was used as recrystallization solvent for all of the hydrazides. [b] 1,1-Bis-(o-bromobenzyl)-hydrazine was prepared by the method of Kenner and Wilson, ref. 6. [c] Yield of crude product is given in parentheses. [d] Alkaline degradation of the sulfohydrazides appeared to proceed equally as well with 5% as with 20% aqueous alkali. With the p-bromo and p-methoxy derivatives use of the more concentrated alkali caused separation of a solid, presumably the sodium sulfinate, which hindered further reaction.

Nitrogen elimination and coupling of benzyl groups also proceeds readily with the sulfonyl derivatives of 1,1-bis-(p-nitrobenzyl)- and 1,1-bis-(o-bromobenzyl)-hydrazine. By utilizing the cyclic hydrazide, 1-p-toluenesulfonamido-2,7-dihydro-3,4,5,7-dibenzazepine, 9,10-dihydrophenanthrene may be obtained in 95% yield (final step).[14] The synthetic usefulness of this reaction has been reported previously.[2] As yet no non-benzyl 1,1-disubstituted hydrazines have been found to undergo the reaction.

A brief study has been made of the effect of substitution in the benzenesulfonyl moiety on the decomposition–rearrangement since ease of loss of the benzenesulfinate anion might be expected to parallel the acidity of the corresponding sulfinic acid.[15,16] No gross differences were observed in the decomposition when 1,1-dibenzyl-2-p-bromo-, p-fluoro- or p-methoxybenzenesulfonhydrazides were compared with the unsubstituted compound. However, a marked effect was observed in the case of the o- and p-nitrobenzenesulfonhydrazides. When the reaction between p-nitrobenzenesulfonyl chloride and 1,1-bis-(p-nitrobenzyl)-hydrazine was carried out at ice-bath temperatures an unstable solid was obtained which decomposed with gaseous evolution on repeated crystallization yielding 4,4′-dinitrobibenzyl. A nitro-substituted hydrazide was isolated in a state of analytical purity by reaction of o-nitrobenzenesulfonyl chloride with 1,1-dibenzylhydrazine. Addition of either p- or o-nitrobenzenesulfonyl chloride to 1,1-dibenzylhydrazine at room temperature in the presence of triethylamine resulted in immediate gas evolution and direct formation of bibenzyl (55 and 16.5%, respectively).

Trichloromethanesulfonyl chloride similarly converted, 1,1-bis-(p-nitrobenzyl)-hydrazine directly to the bibenzyl (25–35% yield) and operation at low temperatures did not serve to yield an intermediate hydrazide.[17] For general synthetic work the p-toluenesulfonyl derivatives are preferred since these usually crystallize more readily than the benzenesulfonyl compounds.

The 1,1-disubstituted hydrazines have in general been prepared by alkylation of hydrazine or substituted hydrazines. Because of the possibility of polysubstitution, it has been found convenient in some cases to employ t-butyl carbazate in place of hydrazine. For example, N-t-butyloxycarbonyl-aminodihydroisoindole was prepared readily from α,α'-dibromo-o-xylene and t-butyl carbazate in 57% yield (eq. 5) whereas N-aminodihydroisoindole could not be isolated from the reaction of the dibromide and hydrazine hydrate or free hydrazine although a variety of experimental procedures were examined; resins appeared to be formed. Removal of the carbo-t-butoxy group occurred in a few minutes when the carbazate was added to concentrated hydrochloric acid. The use of the t-butyl compound proved decidedly superior to the use of benzyl carbazate,[18] both from the point of view of the initial condensation and the subsequent cleavage to the N-amino compound.[19]



(5)

which should be considered. Work is underway by which we hope to distinguish between these two processes. It also has been suggested [F. Raschig, *Z. angew. Chem.*, **23**, 972 (1910)] that benzenesulfonhydrazide itself undergoes β-elimination of benzenesulfinic acid under alkaline conditions yielding diimide which then undergoes decomposition to equimolar amounts of nitrogen and hydrogen.

A variety of other reactions have been postulated to yield diimide as an intermediate followed by subsequent decomposition to (a) nitrogen and hydrazine and (b) ammonia and hydrazoic acid [A. Angeli and Z. Jolles, *Ber.*, **62**, 2099 (1929); F. O. Rice and M. Freamo, THIS JOURNAL, **73**, 5529 (1951), **75**, 548 (1953); R. E. Kirk and A. W. Browne, *ibid.*, **50**, 337 (1928); J. Thiele, *Ann.*, **271**, 127 (1892)]. Conclusive evidence for the occurrence of diimide in any of these reactions is not available and the contradictory results suggest that other intermediates may be involved.

(14) Reference 2; experimental details are included in the present paper.

(15) Hydrazides which have been prepared but are not covered in the Experimental section are listed in Table I. The method of preparation followed that given for 1,1-dibenzyl-2-benzenesulfonhydrazide.

(16) The acidity constants of only a few benzenesulfinic acids have been determined. The unsubstituted compound has an ionization constant of approximately 3×10^{-2} [R. R. Coats and D. T. Gibson, *J. Chem. Soc.*, 442 (1940)].

(17) This reaction may proceed not through the hydrazide but rather by virtue of the oxidizing properties associated with "positive halogen" compounds. According to M. Battegay and W. Kern [*Bull. soc. chim. France*, **41**, 34 (1927)] this chloride acts as an oxidizing agent even toward ammonia and other amines. Recently trifluoromethanesulfonyl chloride has been prepared and found to react normally with amines [T. Gramstad and R. N. Haszeldine, *J. Chem. Soc.*, 173 (1956); R. N. Haszeldine and J. M. Kidd, *ibid.*, 2901 (1955); 4228 (1954)]. This compound was not available at the time of our work although trifluoromethanesulfonhydrazides would be of considerable interest since the corresponding sulfinic acid would undoubtedly be comparable to a mineral acid in strength.

(18) See the Experimental section.

(19) Mercuric oxide oxidation of N-aminodihydroisoindole as well as alkaline degradation of the corresponding p-toluenesulfonhydrazide will be the subject of a future communication.

In this and the previous paper[3] the very conveniently removed carbo-*t*-butoxy group[20] has been introduced indirectly by means of isocyanate or carbazate reactions. However, it was recorded[3] that *t*-butyl hydrazodiformate could be obtained through use of a crude sample of *t*-butyl azidoformate.[21] In view of the relative instability of *t*-butyl chloroformate and the lack of knowledge concerning the acylating power of azidoformates, representative amino compounds have been treated with the azide, which has now been obtained pure by vacuum distillation. The azide reacts readily with aqueous ammonia, hydrazine, phenylhydrazine, *t*-butyl carbazate and benzylamine yielding the expected carbamates. The reaction with aniline is more sluggish, requiring about two weeks standing in pyridine in order to give a 50–60% conversion to the carbanilate. These results suggest that the azide will be generally useful for the acylation of amino derivatives which are at least as basic as aniline. Attempted acylation of acetamide under the conditions described for aniline gave no isolable acylation product. We have not examined the acylation products of amino acids or their esters although these probably would be useful in peptide synthesis. No studies in these areas are contemplated.

$$Me_3COCON_3 \xrightarrow{RNH_2} RNHCOOCMe_3$$

Experimental[22,23]

1,1-Dibenzyl-2-benzenesulfonhydrazide.[1a]—A solution of 10.6 g. of 1,1-dibenzylhydrazine in 40 ml. of dimethylformamide and 6.95 ml. of triethylamine was cooled in an ice-bath and treated dropwise with 6.4 ml. of benzenesulfonyl chloride. After the mixture had stood for 15–20 min. it was diluted with water and acidified with hydrochloric acid. The oil which separated solidified in a few minutes and was dried prior to recrystallization from nitromethane which gave 13.2 g. (75%) of small yellowish needles, m.p. 138–140° dec. For analysis, see ref. 2.

An attempt to prepare this compound by the action of benzyl chloride on benzenesulfonhydrazide in the presence of triethylamine in hot dimethylformamide gave an alkali-stable solid which was recrystallized from nitromethane, m.p. 149–150.5°. This appeared to be benzyl phenyl sulfone (lit.[24] m.p. 148°) as would be expected if the unsubstituted hydrazine were first converted to the triethylamine salt of benzenesulfinic acid. The yield was 70–80%.

Anal. Calcd. for $C_{13}H_{12}SO_2$: C, 67.24; H, 5.18. Found: C, 67.40; H, 4.98.

Alkaline Decomposition of 1,1-Dibenzyl-2-benzenesulfonhydrazide.[1a]—A solution of 25 ml. of 20% sodium hydroxide was warmed to 70–80° and 5 g. of 1,1-dibenzyl-2-benzenesulfonhydrazide was added in 2–3 portions. When the evolution of nitrogen slowed down the mixture was warmed to 90° for a few minutes until the evolution stopped. The mixture was diluted with 75 ml. of water and cooled whereupon the oil solidified and was filtered and recrystallized from methanol which yielded 2.2 g. (85%) of tiny white crystals, m.p. 51–52.5°. A second recrystallization from ethanol raised the melting point to 51.5–53.5°. A mixed melting point with an authentic sample of bibenzyl showed no depression. The 1,3,5-trinitrobenzene complex melted at 100–102° (lit.[25] m.p. 102°). From the aqueous alkaline filtrate after filtration of the bibenzyl there was isolated a crystalline white solid, m.p. 80–83° (lit.[26] m.p. of benzenesulfinic acid 85°).

1,1-Dibenzyl-2-*o*-nitrobenzenesulfonhydrazide.[1a]—A solution of 2.21 g. of 1,1-dibenzylhydrazine in 10 ml. of dimethylformamide and 1.39 ml. of triethylamine was cooled in an ice-bath and a similarly cooled solution of 2.22 g. of *o*-nitrobenzenesulfonyl chloride[27] in 2.5 ml. of dimethylformamide was added dropwise. After allowing the mixture to stand for four hours, 50 ml. of water was added and the resulting mixture stored in an ice-box for five days whereupon partial solidification occurred and was completed by trituration with ethanol. Recrystallization from methanol yielded 2.2 g. (55.4%) of yellow solid which softened at 88° and melted at 91–92° dec. After three further recrystallizations from methanol the powder softened at 92° and had m.p. 95–97° dec.

Anal. Calcd. for $C_{20}H_{19}N_3O_4S$: C, 60.44; H, 4.82. Found: C, 60.30; H, 4.99.

The hydrazide evolved gas on contact with aqueous sodium hydroxide at room temperature or by heating alone in solvents such as dimethylformamide. A similar reaction was run with *p*-nitrobenzenesulfonyl chloride but the crude hydrazide (m.p. 88–92° dec.) was decomposed on attempted recrystallization from methyl ethyl ketone.

1,1-Bis-(*p*-nitrobenzyl)-hydrazine.[1a]—A modification of the method of Busch and Weiss[6] was used. A solution of 35 g. of α-chloro-*p*-nitrotoluene and 4.6 g. of 64% hydrazine in 250 ml. of warm ethanol was treated all at once with 37.8 ml. of triethylamine. A solid began to precipitate after two hours and was filtered after two days standing. The crude product amounted to 20 g. (66.3%), m.p. 115–117°. Recrystallization from nitromethane gave 12 g. (39.8%) of tiny bright yellow crystals, m.p. 135–137° (lit.[6] m.p. 137–138°).

Thermal Decomposition of 1,1-Bis-(*p*-nitrobenzyl)-2-methanesulfonhydrazide.[1a]—The hydrazide (crude, 79.5%, m.p. 139–149°) was prepared as given for the dibenzyl compound and recrystallized from nitromethane which gave tiny yellow crystals, m.p. 154–155° dec., yield 58%.

Anal. Calcd. for $C_{15}H_{16}N_4SO_6$: C, 47.36; H, 4.24. Found: C, 47.48; H, 4.46.

Heating of this hydrazide for 1–2 min. at 145–150° in ethylene glycol gave 4,4′-dinitrobibenzyl (70%), m.p. 182–184° (lit.[6] m.p. 179°). Treatment of the corresponding benzenesulfonhydrazide with 20% aqueous sodium hydroxide gave only 40% of the bibenzyl, possibly because of decomposition due to the nitro groups.

Reaction between 1,1-Dibenzylhydrazine and *p*-Nitrobenzenesulfonyl Chloride.[1a]—A solution of 2.12 g. of 1,1-dibenzylhydrazine in 10 ml. of dimethylformamide and 2.8 ml. of triethylamine was treated over a period of 3–4 minutes with 2.2 g. of *p*-nitrobenzenesulfonyl chloride (Eastman Kodak Co.) while allowing the reaction mixture to warm up spontaneously. The mixture was then held at a temperature just below its boiling point for 5 minutes, diluted with 250 ml. of water, acidified with phosphoric acid and steam-distilled. The yield of bibenzyl collected in 1 liter of distillate was 1.0 g. (54.9%), m.p. 50–51°. The same procedure applied to *o*-nitrobenzenesulfonyl chloride gave only 16.5% of bibenzyl.

(20) Observations to be published shortly in coöperation with Mr. Paul J. Crowley indicate that a wide spectrum of protective groups of the carboalkoxy and thiocarboalkoxy types is available which can be cleaved selectively under anhydrous conditions by acids of varying strengths.

(21) Repetition of the acylation of *t*-butyl carbazate using a distilled sample of the azide led to the isolation (80%) of a white solid, m.p. 124.5–125.5° (see Experimental section), which had the correct analysis for the expected hydrazo compound. The compound previously obtained, m.p. 103–105°, which also gave a correct analysis, has not been obtained since. The compound, m.p. 124.5–125.5°, was characterized by N-bromosuccinimide oxidation to the azo derivative and reconversion of the latter by reduction with hydrazine to the hydrazide. Unfortunately at the time of preparation of the compound m.p. 124.5–125.5°, none of the lower melting substance was available for direct comparison although it was noted that an attempt to oxidize the compound m.p. 103–105°, by exactly the same procedure used for the higher melting compound was not successful.

(22) All boiling and melting points are uncorrected.

(23) Analyses are by Geller Laboratories, Hackensack, N. J., and Drs. Weiler and Strauss, Oxford, England.

Preparation of N-(*t*-Butyloxycarbonylamino)-dihydroisoindole.[1b]—A solution of 39.6 g. of *o*-xylylene dibromide[28] and 19.8 g. of *t*-butyl carbazate in 100 ml. of dimethylformamide was warmed to 50° and 41.7 ml. of triethylamine was added during 5–8 minutes while maintaining the temperature at 50–60° by slight tap-water cooling, if necessary. After complete addition the mixture was allowed to stand at room temperature for three hours and diluted with water to a final volume of 400 ml. After standing for one hour the amorphous white solid was filtered and on air-drying amounted to 31 g. (88.5%), m.p. 103–113° (previous softening at 98°). Recrystallization from the minimum amount of nitromethane gave 20 g. (56.9%) of tiny crystals, m.p. 115.5–117.5° (very slight previous softening at 110°). The analytical sample (from nitromethane) melted at 119–120°.

Anal. Calcd. for $C_{13}H_{18}N_2O_2$: C, 66.64; H, 7.74. Found: C, 66.35; H, 7.77.

Preparation of N-Aminodihydroisoindole Hydrochloride.[1b]—At room temperature 4.6 g. of N-(*t*-butyloxycarbonylamino)-dihydroisoindole was added during 1–2 minutes to 6 ml. of concentrated hydrochloric acid (d. 1.18). After standing for one hour the mixture, from which the crystalline hydrochloride had begun to separate, was evaporated with a water aspirator (17 mm.) from a water-bath (65–70°) until the residue was dry (1.5–2 hours). The crystalline hydrochloride (3.32 g., 62.6%, m.p. 150–180°) was washed onto a funnel with ether and recrystallized twice by solution in the minimum amount of hot ethanol followed by precipitation with ether: I, amount 2.77 g. (52.3%), m.p. 185–195° after previous softening at 160°; II, amount 2.55 g. (48%), m.p. 203–205.5° (lit.[29] m.p. 190–194°). The benzal derivative melted at 129.5–131° (lit.[29] m.p. 127–129°).

N-Benzyloxycarbonylaminodihydroisoindole.[1b]—This compound was obtained as indicated above for the corresponding *t*-butyl derivative by substituting benzyl carbazate[30] for *t*-butyl carbazate except that after addition of the triethylamine the mixture was heated for two hours on a steam-bath prior to precipitation with water. The product, which was difficult to purify, was recrystallized from dimethylformamide and then nitromethane, yield 31%, m.p. 134–135°.

Anal. Calcd. for $C_{16}H_{16}O_2N_2$: C, 71.62; H, 6.01. Found: C, 71.52; H, 5.84.

Cleavage by means of hydrogen bromide in nitromethane gave a tacky brown solid which was not easily purified although it gave a benzal derivative, m.p. 129.5–131°.

N-*p*-Toluenesulfonamidodihydroisoindole.[1b]—A solution of 1.35 g. of the hydrochloride of N-aminodihydroisoindole in 5 ml. of warm dimethylformamide was treated with 1.4 ml. of triethylamine and the resulting mixture cooled in an ice-bath and treated during 1–2 minutes with 0.95 g. of *p*-toluenesulfonyl chloride. After 15 minutes standing in the ice-bath, dilution with water gave a tan-colored solid which was recrystallized at once by solution in hot acetone and precipitation with water. The yield was 1.3 g. (67%), m.p. 130–132° dec. (previous darkening at 126°). A second recrystallization in the same way gave 0.9 g. (46.4%) of yellow crystals, m.p. 135–136° dec. The analytical sample, m.p. 136–138° dec., was recrystallized from acetone. Recrystallization from higher-boiling solvents caused considerable decomposition.

Anal. Calcd. for $C_{15}H_{16}N_2SO_2$: C, 62.47; H, 5.59. Found: C, 62.50; H, 5.54.

1-Amino-2,7-dihydro-3,4,5,7-dibenzazepine Hydrochloride.[1b]—*o*-Bitolyl was prepared and converted to *o,o'*-bis-(bromomethyl)-biphenyl according to the procedures of Wenner.[31] The *m*-tolidine used was a commercial sample[32] of a salt having "54% contained amine." A warm solution (50–60°) of 4.15 g. of *o,o'*-bis-(bromomethyl)-biphenyl and 1.61 g. of *t*-butyl carbazate in 10 ml. of dimethylformamide was treated slowly (2–3 minutes) with 3.42 ml. of triethylamine. After standing for 3–4 hours the solution was diluted with water and the oily semi-solid extracted with methylene chloride. Removal of solvent from the dried ($MgSO_4$) solution by means of a water aspirator yielded an oil which would not crystallize and was cleaved by addition of 10 ml. of concd. hydrochloric acid. The remainder of the procedure followed that given for the corresponding dihydroisoindole. The crude hydrochloride, after one precipitation from ethanol by means of ether, amounted to 1.8 g. (60%), m.p. 213–220° A second precipitation gave 1.5 g. (50%), m.p. 226–228°. The analytical sample[2] was recrystallized from nitromethane–ethanol (1:1), m.p. 230–231°.

1-*p*-Toluenesulfonamido-2,7-dihydro-3,4,5,7-dibenzazepine.[1b]—This derivative was prepared as indicated for the corresponding dihydroisoindole compound. The yield of pure hydrazide, m.p. 149.5–151.5° dec., recrystallized from ethanol–nitromethane (2:1), was 50%. For analysis, see ref. 2.

9,10-Dihydrophenanthrene.[1b]—The azepine described directly above was decomposed as given for the 1,1-dibenzyl compound. The crude product (m.p. 33–35°, 94.5%) was recrystallized from methanol, yield 67.5%, m.p. 34.5–35.5° (lit.[33] m.p. 34.5–35°).

***t*-Butyl Azidoformate.**[1c]—*t*-Butyl phenyl carbonate was prepared as indicated previously[3] except that tap-water cooling of the reaction mixture was dispensed with, the acid chloride being added at a rate such that the temperature remained between 38–41°. *t*-Butyl carbazate was prepared in the manner previously reported[3] although the yield was 89–94% rather than 68.3% as previously indicated. Conversion of the carbazate to the azide followed the earlier method except that the water-washed, $NaHCO_3$-washed ether extracts were dried (magnesium sulfate) and the solvent removed from a water-bath at 40–45° with a water aspirator pressure of 140–150° mm. The azide was then distilled by raising the bath temperature to 90° and lowering the pressure to 70 mm. where the azide collected as a water-white liquid, b.p. 73–74° (70 mm.), yield 80%.[34]

Anal.[35] Calcd. for $C_5H_9N_3O_2$: C, 41.95; H, 6.34. Found: C, 41.90; H, 6.29.

***t*-Butyl 2-Phenylcarbazate.**[1c]—A mixture of 2.86 g. of *t*-butyl azidoformate, 2.16 g. of phenylhydrazine, 2.78 ml. of triethylamine and 5 ml. of water was placed on a continuous shaking machine for 40 hours. Filtration gave 3.2 g. (80.4%) of yellow-orange solid which was washed with water and air-dried, m.p. 85–91°. Recrystallization from ligroin (60–90°) gave 2.75 g. (69.1%) of cream-colored crystals, m.p. 91–93°. The analytical sample, recrystallized from the same solvent, melted at 92–93.5°.

Anal. Calcd. for $C_{11}H_{16}O_2N_2$: C, 63.44; H, 7.75. Found: C, 63.56; H, 7.56.

Other Acylations Using *t*-Butyl Azidoformate.[1c]—*t*-Butyl 2-phenylcarbazate also was prepared by allowing a solution of the reactants in methylene chloride to stand overnight, although the product was less easily purified (yield 40–50%). *t*-Butyl carbamate[36] was prepared by allowing the azide to stand in contact with concd. aqueous ammonia for 16 hours with occasional shaking. The yield was 80%, m.p. 108–109.5° (1:1, 60–90° ligroin–benzene). Hydrazine (64%) converted the azide back to *t*-butyl carbazate with spontaneous warming (yield 83.3%). Acylation of benzylamine occurred with spontaneous warming when 2.86 g. of the azide, 4.28 g. of the amine and 5 ml. of pyridine were mixed and allowed to stand overnight. Precipitation with water gave 3.8 g. (91.8%) of white solid, m.p. 54–57°. Recrystallization from ligroin (b.p. 60–90°) gave 3.5 g. (84.6%) of ***t*-butyl N-benzylcarbamate**, m.p. 57–58°.

Anal. Calcd. for $C_{12}H_{17}NO_2$: C, 69.53; H, 8.27. Found: C, 69.30; H, 8.20.

Acylation of aniline by means of the azide was more difficult to achieve than that of more basic amino compounds. The method used for the acylation of phenylhydrazine gave

Mechanism of Trimethylene Oxide Formation from 3-Chloropropyl Acetate

BY DONALD C. DITTMER, WALTER R. HERTLER AND HERBERT WINICOV

RECEIVED FEBRUARY 20, 1957

Evidence has been obtained that the better yields of trimethylene oxide from 3-chloropropyl acetate than from 3-chloropropanol may be caused by a protective effect of the acetate group and not by a fundamentally different mechanism. Oxide prepared from carbonyl O^{18}-labeled ester contained no excess O^{18}; this result rules out any mechanism for trimethylene oxide formation in which the two acetate oxygens are equivalent. Trimethylsilyl 3-chloropropyl ether gave as high a yield of oxide as the acetate, and 3-chloropropyl thiolacetate gave only trimethylene sulfide.

Yields of trimethylene oxide obtained by treatment of 3-chloropropyl acetate with strong base have been reported to be much greater than yields from 3-chloropropanol.[1] A similar result has been reported for the preparation of ethylene oxide from 2-chloroethyl acetate.[2]

$$ROCH_2CH_2CH_2Cl \xrightarrow{OH^\ominus} \begin{matrix} CH_2 & CH_2 \\ | & | \\ CH_2 & O \end{matrix} \qquad (1)$$

R = H–, CH_3CO–

Since in the concentrated base used the acetate presumably would be hydrolyzed to the same chlorohydrin anion, $^\ominus OCH_2CH_2CH_2Cl$, as the one formed from 3-chloropropanol, the yields of trimethylene oxide, if they proceeded from this alkoxide, would not be expected to be as different as they are between acetate and chlorohydrin.

To explain the disparity in yields between chlorohydrin and chloroacetate, a protective effect of the acetate group or a different mechanism may be invoked. The chloroacetate may yield the chlorohydrin anion at a slower rate than it is produced from the chlorohydrin. Since the concentration of alkoxide from chloroacetate at any time would be smaller than from chlorohydrin, conditions might be more favorable for intramolecular cyclization than for intermolecular reaction which would produce a polymeric ether. In other types of ring closure, high dilution of the reactants is necessary to prevent intermolecular reactions since the extent of intermolecular reaction depends on the concentration of the reactants while that of the intramolecular reaction does not.[3]

$$^\ominus OCH_2CH_2CH_2Cl \longrightarrow (OCH_2CH_2CH_2)_x \qquad (2)$$

Indeed, a linear polymeric ether, $(C_3H_6O)_x$, has been isolated as a by-product in the preparation of trimethylene oxide from 3-chloropropanol.[4] Excellent yields (70–80%) of 3,3-dichloromethyloxetane have been reported from trichloropentaerythritol and potassium hydroxide.[5] Here, the intermolecular reaction involves a displacement reaction on a neopentyl-type system which would be expected to be very slow.

$$(ClCH_2)_3CCH_2OH \xrightarrow{OH^\ominus} \begin{matrix} (CH_2Cl)_2 & \\ | & \\ C & CH_2 \\ | & | \\ CH_2 & O \end{matrix} \qquad (3)$$

70–80%

Other side products from 3-chloropropanol were said to be allyl alcohol and allyl chloride.[1a] It is not expected that acetylation of the hydroxyl group would have much effect on these olefin-producing side reactions.

If the production of trimethylene oxide from 3-chloropropyl acetate involved a different mechanism other than the straightforward intramolecular displacement of chloride ion by the alkoxide part of the molecule,[6] higher yields of oxide might be expected if the free energy of activation for the new mechanism were less than that for the old

$$CH_3\overset{O}{\overset{\|}{C}}OCH_2CH_2CH_2Cl \xrightarrow{OH^\ominus} CH_3\overset{O^\ominus}{\overset{|}{C}}OCH_2CH_2CH_2Cl$$

mechanism, thereby reducing the importance of side reactions. A possibility exists that the carbonyl group of the ester could displace chloride ion to give an intermediate, I, which decomposes to trimethylene oxide.

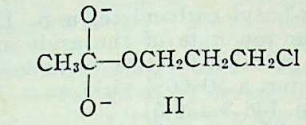
The attack by hydroxide ion on the carbonyl carbon may be concerted with the displacement of chloride ion by the carbonyl oxygen, intermediate I being formed directly. The intermediate I might go to trimethylene oxide by a concerted elimination of acetate with ring closure.

The displacement of chloride ion by the oxygen anion derived from a carbonyl group has an analogy in the Darzens glycidic ester reaction.[7] Participation of acetate carbonyl in displacements of neighboring groups is well known.[8] A displacement of bromide ion by an ester carbonyl oxygen has been suggested to occur in the pyrolysis of γ-bromoesters.[9] A cyclic *ortho* ester analogous to I has been prepared from the monotrichloroacetate of ethylene glycol,[10] and a similar *ortho* ester has been suggested as an intermediate in the preparation of *trans*-2-chlorocyclohexanol from *cis*-1,2-diacetoxycyclohexane.[11] The reaction of the acetate of 3-bromo-2,2-dimethyl-1-propanol with potassium iodide in acetone is 38 times faster than the reaction of neopentyl bromide which indicates a participation by the acetoxy group.[12]

Results

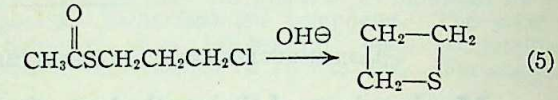
The possibility of a different mechanism of trimethylene oxide formation from 3-chloropropyl acetate was investigated by preparing the oxide from carbonyl O^{18}-labeled 3-chloropropyl acetate which was made by hydrolysis of 3-chloropropyl iminoacetate with H_2O^{18}. If the reaction scheme 4 were correct, excess O^{18} should appear in the trimethylene oxide since in I the two oxygens are equivalent. No excess O^{18} was found in the trimethylene oxide. This result is apparent in Table II in the Experimental section.

Some loss of O^{18} from the ester might occur by the scheme proposed by Bender for ester hydrolysis.[13] The concentration of base used by Bender was 0.001–0.007 *M* while the concentration of base used in the preparation of trimethylene oxide was approximately 200 *M*. The formation of the conjugate acid of the ester-hydroxide ion adduct, $CH_3C(OH)_2OR$, as proposed by Bender would seem to be rather unlikely in such strong base, although the formation of the dianion II is a possibility. Nevertheless, if the dianion were formed, at least 25% of the O^{18} in the original ester should be found in the trimethylene oxide if the latter were formed as shown in equation 4.



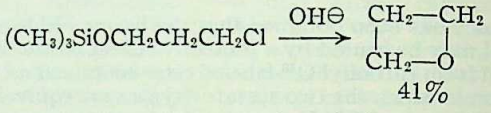
II

Only trimethylene sulfide could be isolated from the reaction of 3-chloropropyl thiolacetate with base. Trimethylene sulfide has been prepared in the same way by Bordwell and Hewett.[14]



(5)

Trimethylsilyl 3-chloropropyl ether on treatment with potassium hydroxide gave a yield of trimethylene oxide comparable to the yields from 3-chloropropyl acetate.



41%

Attempts to prepare trimethylene oxide from 3-hydroxypropyl acetate, 3-hydroxypropyl chloroacetate, 3-hydroxypropyl trichloroacetate and 3-hydroxypropyl *p*-toluenesulfonate were not successful.

Trimethylene oxide could be prepared in 24% yield from 3-chloropropyl chloroacetate and potassium hydroxide, but 3-chloropropyl trifluoroacetate and 3-chloropropyl trichloroacetate gave no oxide.

Discussion

The lack of evidence for participation of the ester carbonyl group of 3-chloropropyl acetate in the formation of trimethylene oxide seems to show that the effect of acetylation of chlorohydrins in improving yields of cyclic oxides is not to change the basic mechanism but possibly to minimize side reactions such as the intermolecular Williamson ether synthesis illustrated by equation 2. The fact that the trimethylsilyl ether of 3-chloropropanol gives about the same yield of trimethylene oxide as does the acetate implies that there is nothing special about the function of acetate.

With the silyl ether as with the acetate, the reaction with hydroxide to produce the chlorohydrin anion is slow in comparison with the abstraction of a proton from the chlorohydrin. This slow hydrolysis in both cases decreases the concentration of the anion so that, by this "dilution" effect, the cyclization to trimethylene oxide is favored at the expense of the intermolecular reaction.

Where the intermolecular reaction is hindered as in the reaction of trichloropentaerythritol with base, higher yields of oxide are observed.[5] However, a substituted chlorohydrin also may have a lower free energy of activation for ring closure than its unhindered analog.[15] Steric hindrance in intramolecular reactions has been said to be less than for intermolecular reactions.[16]

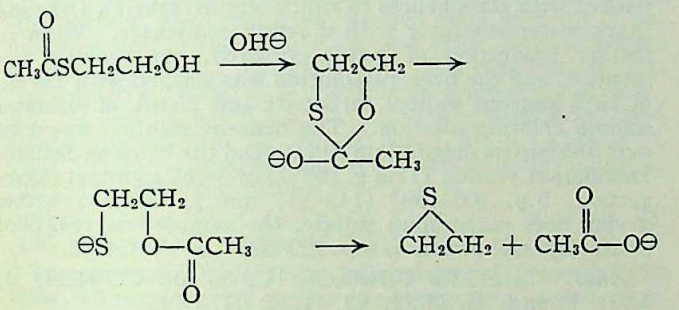
Another explanation for the higher yields from 3-chloropropyl acetate and from 3-chloropropyl trimethylsilyl ether is that the attack by hydroxide ion on the carbonyl carbon or on silicon is concerted with ring closure, there being no intermediates involved.

The synthesis of trimethylene sulfide in 24% yield from 3-chloropropyl thiolacetate and the absence of detectable trimethylene oxide did not necessarily rule out a cyclic intermediate, since in the intermediate it might be expected that the carbon–sulfur bond would break preferentially to the carbon–oxygen bond. Ethylene sulfide is prepared in 25% yield from the S-acetate of 2-mercaptoethanol by treatment with base.[17] The analogy to equation 4 is apparent.



Mono-*p*-toluenesulfonates of 1,2-glycols give good yields of epoxides on treatment with base.[18] Our finding that the mono-*p*-toluenesulfonate of 1,3-propanediol gave no trimethylene oxide on treatment with potassium hydroxide agrees with an earlier result.[19]

The failure of monoesters of trimethylene glycol to give trimethylene oxide does not necessarily rule out the mechanism of equation 4 since intermediate I could conceivably go directly to trimethylene oxide by a concerted process. The use of sodium to produce the alkoxides was not very satisfactory since there was evidence of reduction of the ester group.

Experimental

3-Chloropropanol was prepared according to Marvel and Calvery.[20]

3-Chloropropyl Iminoacetate Hydrochloride.—The procedure was based on that by McElvain and Schroeder.[21]

To a mixture of 94.5 g. (1.0 mole) of 3-chloropropanol, 42.2 g. (1.0 mole) of acetonitrile (Eastman Kodak Co. practical grade, redistilled and dried over Drierite) in 50 ml. of anhydrous ether and 5 ml. of reagent-grade chloroform, was added about 40 g. (1.1 moles) of anhydrous hydrogen chloride gas. The reaction mixture was placed in a refrigerator for 12 hr. after which a layer of about 25 ml. of anhydrous ether was placed carefully on top of the viscous solution. The iminoacetate hydrochloride precipitated after 2 to 4 more days in the refrigerator. The crystals were filtered rapidly by reduced pressure and dried in a desiccator over Drierite, potassium hydroxide and paraffin chips. The yield was 158 g. (0.9 mole, 90%), m.p. 75–77° dec. Infrared analysis (potassium bromide disk) showed characteristic bands at 1558 and 1635 cm.$^{-1}$. Ionic chloride was determined by the Volhard method.

Anal. Calcd. for $C_5H_{11}Cl_2NO$: ionic Cl, 20.64. Found: ionic Cl, 20.54.

3-Chloropropyl Acetate (Carbonyl-O^{18}-labeled).—The 3-chloropropyl iminoacetate hydrochloride (120 g., 0.7 mole) was dissolved in 25 g. (1.4 moles) of water containing greater than 1.4% O^{18} (Stuart Oxygen Co., 211 Bay St., San Francisco, Cal.). Heat was evolved and ammonium chloride precipitated. The flask was cooled under a cold water tap until heat was no longer evolved and then was warmed under a hot water tap for 15 to 20 minutes and allowed to stand for 4 hr. at room temperature. About 100 ml. of ether was added and the ammonium chloride removed by filtration and washed several times with ether. The combined ether solutions were dried over anhydrous magnesium sulfate for 24 hr. After the removal of the magnesium sulfate, the ether was evaporated and the crude 3-chloropropyl acetate was distilled through a 25-cm. column packed with glass helices to give 85.4 g. (0.62 mole, 88%) of the carbonyl-O^{18}-labeled ester.

The unlabeled ester was prepared in a similar manner except that ordinary water was used. It also was prepared from 3-chloropropanol and acetyl chloride.

Trimethylene Oxide.—The procedure of Noller was followed,[1b] in which the O^{18}-labeled 3-chloropropyl acetate was treated with hot potassium hydroxide. The trimethylene oxide was distilled as it was formed and was collected in a flask equipped with a Dry Ice condenser. The crude oxide was dried over potassium hydroxide and distilled through a small column to give 10 g. (38%) of material, b.p. 47–48°, $n^{25}D$ 1.3906. The oxide was dried over sodium metal and redistilled after removal of the sodium. Two fractional distillations of the oxide directly from sodium metal were carried out, followed by a final distillation, b.p. 47.0–47.2°, $n^{25}D$ 1.3896.

Unlabeled trimethylene oxide was prepared in a similar manner from unlabeled 3-chloropropyl acetate.

Mass Spectrometric Analyses.—Mass spectra of the labeled and unlabeled 3-chloropropyl acetates and samples of trimethylene oxide prepared from each were taken on a Consolidated model 21-101 (modified) mass spectrometer at an ionizing current of 10 amperes and an ionizing voltage of 70. Table I gives the abridged mass spectra of the labeled and unlabeled acetates and Table II of the trimethylene oxide from the respective acetates.

were careful to use in their calculations only those peaks for which only one fragment could be written for the O^{16}-containing isotope and for which only the enriched species of the same fragment was possible for a mass number two units higher. Since the natural O^{18}/O^{16} ratio is 0.002 (0.2%) for a fragment containing only one oxygen, the ratio of the relative intensity of the mass number two units higher to the relative intensity of the mass number for this fragment should be 0.002. For a fragment containing two oxygen atoms the ratio would be 0.004, and for a fragment containing two oxygen atoms one of which is enriched to 1.4% in O^{18}, the ratio would be 0.016.

Since none of the presumed oxygen-containing fragments gave a ratio of 0.002 or 0.004 (with the exception of mass 103) but gave higher values, it is likely that these peaks are contaminated with other unknown fragments. If a constant amount of contamination by an unknown fragment or fragments is assumed in the peaks of mass $M + 2$, a rough estimate of the enrichment can be made as follows: Let

h = peak height of mass M for unenriched cmpd. due to single fragment
h' = peak height of mass M for enriched cmpd. due to a single fragment
h_2 = peak height of mass $M + 2$ for unenriched compound
h_2' = peak height of mass $M + 2$ for enriched compound
x = height of peak due to O^{18} fragment in h_2
x' = height of peak due to O^{18} fragment in h_2'
y = peak height due to unknown fragment (or combn. of fragments) in h_2
y' = peak height due to unknown fragment (or combn. of fragments) in h_2'

Consider a peak for which a fragment containing two oxygens can be written. Then

$$x + y = h_2$$
$$x' + y' = h_2'$$
$$y'/y = h'/h$$

Assume $x/h = 0.004$ and $x = 0.004h$

$$y = h_2 - 0.004h$$
$$y' = (h'/h)(h_2 - 0.004h)$$
$$x' = h_2' - ((h'/h)(h_2 - 0.004h))$$

Therefore, the O^{18}/O^{16} ratio is $x'/h' = h_2'/h' - h_2/h + 0.004$

This derivation is not completely satisfactory because it assumes that the mass peak heights of the fragments which contain O^{16} (unenriched) are uncontaminated by any other fragment. However, it seems likely that most of the height of the peak may be accounted for by the O^{16}-containing fragment. The results are given in Table III.

It seems likely that the enriched 3-chloropropyl acetate actually contains about 1.6 to 1.7% O^{18} which is the value to be expected from acetate prepared from water containing in excess of 1.4 atom per cent. O^{18}. The method of preparation of the enriched acetate is such that acetate should have the same enrichment in its carbonyl oxygen as the water used.

It is interesting to observe that the 93/95 ratio for 3-chloropropyl acetate is close to the natural ratio of 3 for Cl^{35}/Cl^{37}.

TABLE III

MASS RATIOS AND CALCULATED PERCENTAGE ENRICHMENT OF O^{18} IN 3-CHLOROPROPYL ACETATE

Mass ratios	O^{16} Acetate	O^{18} Acetate	Difference in ratios	Atom % O^{18}
63/61	0.030	0.043	0.013	1.7

	.007	.014	.007	1.1

3-Chloropropyl Chloroacetate.—Chloroacetic acid (118.1 g., 1.25 moles), 3-chloropropanol (94.5 g., 1.0 mole), *p*-toluenesulfonic acid (1 g.) and 150 ml. of benzene were refluxed in a 500-ml. flask equipped with a 25-cm. column packed with glass helices to which was attached a Dean and Stark water-separator with a reflux condenser. When no further separation of water occurred, the reaction was stopped, and the benzene solution was washed with 120 ml. of 10% aqueous sodium carbonate and 25 ml. of saturated sodium chloride solution. The benzene solution was dried over anhydrous magnesium sulfate and the benzene distilled. Distillation yielded 117.8 g. (69%) of 3-chloropropyl chloroacetate, b.p. 166–169° (142–147 mm.). After a further drying over magnesium sulfate, the sample was redistilled at atmospheric pressure, b.p. 222–223°, $n^{25.4}D$ 1.4595.

Anal. Calcd. for $C_5H_8O_2Cl_2$: C, 35.10; Cl, 41.17; H, 4.71. Found: C, 35.22; Cl, 41.36; H, 4.74.

3-Chloropropyl trichloroacetate was prepared by the procedure used for 3-chloropropyl chloroacetate. The 3-chloropropyl trichloroacetate distilled at 69–70° (0.9 mm.), $n^{22.5}D$ 1.4773, $n^{20}D$ 1.4784 (lit.[23] b.p. 107° (8 mm.), 97.0–97.7 (3 mm.); $n^{15}D$ 1.4830, $n^{20}D$ 1.47985).

3-Chloropropyl Trifluoroacetate.—A variation of a general method of Burgoyne and Condon was used.[24] Trifluoroacetic acid (40 g., 0.36 mole), 3-chloropropanol (25.6 g., 0.27 mole) and chloroform (50 ml.) were distilled from a 250-ml. flask fitted with an addition funnel and a 25-cm. column packed with glass helices. The distillate was placed in an addition funnel where the aqueous layer was separated from the chloroform layer. The chloroform was allowed to run back into the distilling flask. In this way 30 g. (62%) of 3-chloropropyl trifluoroacetate was obtained, b.p. 143–144°, $n^{24}D$ 1.3700, $n^{25}D$ 1.3698. The ester was insoluble in water but soluble in chloroform, carbon tetrachloride and carbon disulfide. A further distillation gave a sample, b.p. 143.5–144.2°, $n^{25}D$ 1.3694, d^{20}_4 1.349. Infrared absorption spectra showed bands at 1786, 1400, 1347, 1225 and 1146–1170 cm.$^{-1}$. A yield of 82% was obtained by using doubled amounts of starting materials.

Anal. Calcd. for $C_5H_6O_2ClF_3$: C, 31.49; H, 3.15. Found: C, 31.60; H, 3.31.

Preparation of Trimethylene Oxide from 3-Chloropropyl Esters.—The procedure used for the preparation of trimethylene oxide from 3-chloropropyl acetate was followed.[1b]

Potassium hydroxide (90.6 g.), 3-chloropropyl chloroacetate (92.2 g., 0.54 mole) and water (8 ml.) were allowed to react. Trimethylene oxide (7.6 g., 24.3%) was obtained, b.p. 46–48°, $n^{26}D$ 1.3885. A higher boiling fraction (99°) gave a positive test with ceric nitrate reagent.[25] It may have been allyl alcohol.

When 3-chloropropyl trifluoroacetate was used, the temperature of the reaction mixture rose rapidly to 200°. No trimethylene oxide was isolated. The residue gave a positive ceric nitrate test.[25]

The reaction of 3-chloropropyl trichloroacetate with potassium hydroxide gave chloroform but no trimethylene oxide. The residue gave a positive ceric nitrate test.[25]

3-Chloropropyl Trimethylsilyl Ether.—The procedure of Sprung and Nelson was followed.[26] Commercial grade trimethylchlorosilane (kindly donated by the General Electric Company) was purified by precipitation of excess hydrogen chloride with pyridine and distillation of the chlorosilane through a 25-cm. column packed with glass helices. This procedure was repeated, and the chlorosilane was stored with a small amount of pyridine.

Dry pyridine (55.0 g., 0.7 mole, Mallinckrodt reagent grade), 3-chloropropanol (57.5 g., 0.6 mole, dried over Drierite) were placed in a dry, 3-necked 500-ml. flask provided with a mechanical stirrer, thermometer and condenser. The flask was cooled to 10° in an ice-bath. Purified trimethylchlorosilane (74.5 g., 0.68 mole) was added slowly from a dropping funnel on top of the condenser while the reaction mixture was being stirred. The funnel was provided with a calcium chloride drying tube. After the addition, the stirrer was removed, and the reaction mixture was refluxed 15 minutes. Dilute hydrochloric acid was added to neutralize the excess pyridine, and the solution was extracted three times with one-half its volume of ether. The ether extracts were combined, washed twice with 0.1 *N* hydrochloric acid, twice with water and dried over anhydrous magnesium sulfate. After the ether was removed, distillation gave 56 g. (56%) of 3-chloropropyl trimethylsilyl ether, b.p. 141–146.5°, $n^{23.5}$D 1.4170. A further distillation gave a purer product, b.p. 53° (17–20 mm.), $n^{28.1}$D 1.4148, $d^{28.7}_4$ 0.931. Infrared analysis showed characteristic bands at 1253, 1176, 1105 and 846 cm.$^{-1}$.

Anal. Calcd. for $C_6H_{15}OClSi$: C, 43.17; H, 9.07; Cl, 21.27. Found: C, 43.32; H, 9.21; Cl, 21.47.

Trimethylene Oxide from 3-Chloropropyl Trimethylsilyl Ether.—The procedure used in the preparation of trimethylene oxide from 3-chloropropyl acetate was followed.[1b] The distillate from the reaction mixture containing trimethylene oxide and probably water, trimethylsilanol and hexamethyl disiloxane was dried over potassium hydroxide and distilled through a Vigreux column. The first fraction (to 61°) gave 9.5 g. of impure trimethylene oxide. This fraction was dried over sodium and distilled, after removal of the sodium, to give 7 g. (41%) of trimethylene oxide. A third fractionation gave 6 g. (35%) of the oxide which was distilled directly from sodium, b.p. 47–49°, n^{23}D 1.3910.

3-Hydroxypropyl acetate was prepared at first by the method of Bogert and Slocum from acetyl chloride and trimethylene glycol.[27] Distillation gave a fraction, b.p. 206–209°, n^{25}D 1.4191 (lit.[27] b.p. 202–203°).

Another preparation was from 95 g. (1.58 moles) of glacial acetic acid, 114 g. (1.5 moles) of trimethylene glycol (redistilled), 115 ml. of chloroform and 1 ml. of concentrated sulfuric acid which was refluxed, and the water was removed by a Dean and Stark separator. When 30 ml. of water and acetic acid had been separated, a third of the chloroform was distilled and the reaction mixture washed with a small amount of sodium bicarbonate solution. The mixture was distilled through a 25-cm. column packed with glass helices, and two fractions were collected: 24.2 g., b.p. 136–140° (95 mm.), and 72.8 g., b.p. 110–115° (25 mm.), n^{25}D 1.4175, d^{25}_4 1.026

A third preparation of 3-hydroxypropyl acetate was tried using an adaptation of the method of Meerwein and Sönke for preparing glycol monoesters.[10] Trimethylene glycol (76.1 g., 1 mole) was dissolved in 100 ml. of dioxane in a 500-ml. flask cooled in an ice-bath. Acetyl chloride (78.5 g., 1 mole) was added dropwise with stirring, and the mixture was refluxed for 2 hr. The dioxane was distilled at atmospheric pressure, and the residue was distilled under reduced pressure to give 63.8 g. (54%) of product, b.p. 105–115° (31 mm.), n^{24}D 1.4210.

3-Hydroxypropyl Chloroacetate.—Chloroacetyl chloride (103.7 g., 0.92 mole) in 20 ml. of dioxane was added to trimethylene glycol (68.5 g., 0.9 mole) in 80 ml. of dioxane in a 500-ml. flask immersed in an ice-bath. The mixture was refluxed for 3 hr., and, after removal of the dioxane and distillation through a 25-cm. column packed with glass helices, gave 46.8 g. (33.5%) of product, b.p. 95–112° (1.3–1.7 mm.), n^{23}D 1.4591.

3-Hydroxypropyl trichloroacetate was prepared by the method of Meerwein and Sönke[10] from trichloroacetyl chloride and trimethylene glycol. The trichloroacetyl chloride was prepared from trichloroacetic acid and phosphorus trichloride. The hydroxyester distilled at 98–115° (0.9–1.5 mm.), $n^{25.5}$D 1.4680.

3-Hydroxypropyl *p*-Toluenesulfonate.—Trimethylene glycol (128.2 g., 1.69 moles) was added to a stirred mixture of *p*-toluenesulfonyl chloride (160.5 g., 0.84 mole) in pyridine (133 g., 1.69 moles) in a 500-ml. flask immersed in a Dry Ice–acetone-bath. The addition was as fast as possible without causing a great rise in temperature. The reaction mixture was allowed to reach room temperature, and stirring was continued for 0.5 hr. The pyridine hydrochloride was removed by filtration, and the filtrate was poured into water to give an oil which was separated, washed with water, dilute hydrochloric acid and water again. The oil was dried over anhydrous magnesium sulfate. Distillation of the ester (74.2 g., 32%) at 1 mm. resulted in decomposition. Crystals of trimethylene glycol di-*p*-toluenesulfonate separated from the oil after standing, m.p. 92–93° (lit.[28] m.p. 93–94°).

Attempted Preparation of Trimethylene Oxide from Monoesters of Trimethylene Glycol.—No trimethylene oxide was obtained from 3-hydroxypropyl *p*-toluenesulfonate or 3-hydroxypropyl acetate on treatment with potassium hydroxide in the usual way[1b] or from 3-hydroxypropyl acetate, 3-hydroxypropyl chloroacetate, 3-hydroxypropyl trichloroacetate and 3-hydroxypropyl *p*-toluenesulfonate on treatment with sodium metal which was used in order to produce the alkoxide.

3-Chloropropyl thiolacetate was prepared by the method of Sjöberg[29] from allyl chloride and thiolacetic acid. The thiolester was obtained in 71% yield, b.p. 93–96° (20 mm.), n^{27}D 1.4910 (lit.[29] b.p. 83–84° (10 mm.), n^{20}D 1.4954).

Trimethylene Sulfide.—3-Chloropropyl thiolacetate (119 g., 0.78 mole) was added gradually to potassium hydroxide (131 g., 2.34 moles) and water (12 ml.) in the apparatus used for the preparation of trimethylene oxide.[1b] The temperature of the reaction mixture varied from 150 to 170°. The product which distilled from the reaction mixture at 77° was dried over Drierite and redistilled through a 25-cm. column packed with glass helices to give trimethylene sulfide (13.8 g., 23.8%), b.p. 94–94.5°, n^{25}D 1.5027. It was characterized as the dimethyl sulfonium iodide, m.p. 97–98°.[30] The infrared spectrum of the sample was identical with that obtained by other workers.[31] No trimethylene oxide could be isolated from the reaction.

Acknowledgments.—We wish to thank Dr. C. B. Euston, J. Sager and J. Bates and the Polychemical Department of E. I. du Pont de Nemours for the mass spectrometric analyses.

Rearrangement of Ketones in Acid Media[1]

BY HARRY D. ZOOK, WARREN E. SMITH AND JANICE L. GREENE

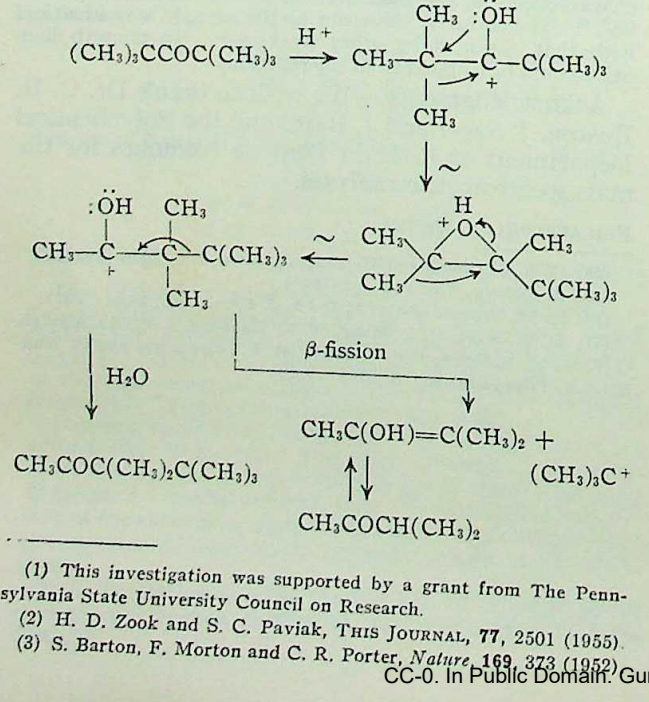
RECEIVED FEBRUARY 22, 1957

Ketones with two alkyl or two phenyl groups in the α-position rearrange to isomeric ketones in 83–97% sulfuric acid. A single product or an equilibrium mixture of a single product and the original ketone is obtained. The positions of the equilibria are qualitatively in accord with resonance and hyperconjugation theories. Methyl pentamethylethyl ketone, the initial product from the rearrangement of hexamethylacetone, undergoes β-fission to methyl isopropyl ketone. The rearrangements and cleavage have been studied kinetically.

In connection with a study of the Schmidt reaction, it was shown that ethyl *t*-butyl ketone undergoes molecular rearrangement to methyl *t*-amyl ketone in concentrated sulfuric acid.[2] The rearrangement is analogous to that reported previously for hexamethylacetone.[3] This paper describes the behavior of nine ketones in 83–97% sulfuric acid.

The rearrangement of hexamethylacetone is most interesting. When equal weights of this ketone and 97% sulfuric acid were heated for six hours at 75°, approximately half of the ketone was converted to methyl pentamethylethyl ketone. However, methyl isopropyl ketone also was identified as a product of the reaction. Similar results were obtained at 30°, where the rate of rearrangement was found to increase as the ratio of sulfuric acid to ketone was increased. Finally, eight experiments were carried out at 30.0° with 0.14 *M* solutions of hexamethylacetone in several concentrations of aqueous sulfuric acid. Aliquots were quenched in ice and extracted with carbon tetrachloride. The three ketones were determined quantitatively by infrared analysis.

The disappearance of hexamethylacetone followed a first-order rate law with a half-life varying from 40 min. in 96% sulfuric acid to 176 min. in 83.6% acid (Fig. 1). Methyl isopropyl ketone was formed at the expense of the rearranged product, methyl pentamethylethyl ketone, by a consecutive first-order reaction, the half-life of which was four to eight times greater than that for the initial rearrangement.



The over-all process of rearrangement and cleavage is most simply represented by two concerted nucleophilic substitutions involving the protonated ketone and protonated oxide followed by a β-fission of protonated methyl pentamethylethyl ketone.

Rearrangement of the *t*-butyl group rather than a methyl group in the protonated oxide would give the same product.

The rates of the two consecutive reactions do not vary in the same manner with the concentration of sulfuric acid. Therefore, the maximum concentration of methyl pentamethylethyl ketone and the relative time at which this maximum is reached are functions of the acid concentration (Fig. 2). The rates of cleavage of pure methyl pentamethylethyl ketone measured independently at several concentrations of sulfuric acid were in excellent agreement with those calculated from the rearrangement data by the equation for two consecutive first-order reactions (Table I). Only methyl pentamethylethyl ketone exhibited the cleavage reaction. In this instance, the cleaved group is stabilized by multiple hyperconjugation. The

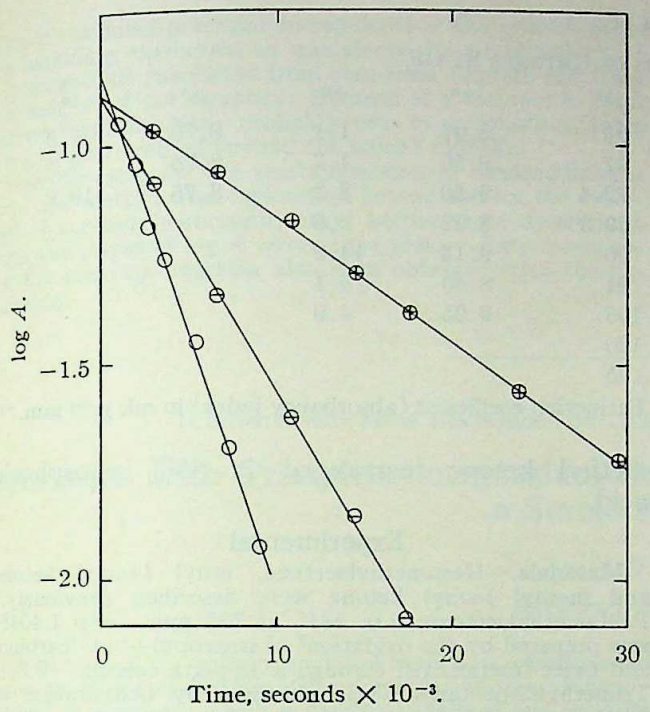

Fig. 1.—Rearrangement of hexamethylacetone; log A *vs.* time: ○, 93.7% sulfuric acid; ⊖, 87.2% sulfuric acid; ⊕, 83.6% sulfuric acid.

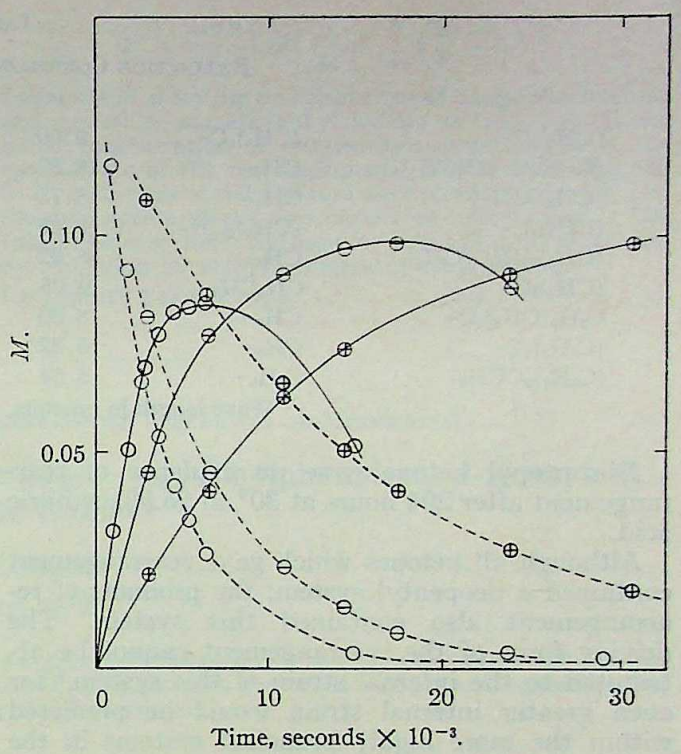

Fig. 2.—Formation and cleavage of methyl pentamethylethyl ketone. Molar concentration of ketone *vs.* time. Solid lines represent methyl pentamethylethyl ketone, broken lines show the corresponding concentrations of hexamethylacetone: ○, 95.7% sulfuric acid; ⊖, 87.2% sulfuric acid; ⊕, 83.6% sulfuric acid.

β-fission of this ketone is analogous to similar β-elimination of relatively stable groups during the dehydration of alcohols[4] and glycols[5] and accompanying the Schmidt and similar rearrangements.[2]

Effect of Structure on Equilibria.—Several rearrangements of pentamethylacetone in 92–96% sulfuric acid led to an equilibrium mixture containing 86.1 mole % 3,3,4-trimethyl-2-pentanone and 13.9 mole % pentamethylacetone corresponding to an equilibrium constant of 6.2 for the reaction

$$(CH_3)_3CCOCH(CH_3)_2 \underset{k_{-1}}{\overset{k}{\rightleftharpoons}} (CH_3)_2CHC(CH_3)_2COCH_3$$

Specific rates of approach to equilibrium were obtained from plots of log $A_0 - A_e/A - A_e$ *versus* time, where A_0, A_e and A are initial, equilibrium and instantaneous concentrations of ketone, respectively (Fig. 3). The constants obtained from the slopes of these lines are equal to the sum of the specific rates for the forward and reverse reactions. From these and the fact that $k_1/k_{-1} = 6.2$, specific rates for the forward and reverse reactions were evaluated. These values are in agreement with specific rates obtained from plots of log A *versus* time over the first 20% of the reaction.

Similarly, rearrangement of ethyl *t*-butyl ketone in 93% sulfuric acid gave a mixture of methyl *t*-amyl ketone and ethyl *t*-butyl ketone corresponding to an equilibrium constant of 5. The equilibrium then was approached by rearrangement of methyl *t*-amyl ketone. After 127 hr., a mixture containing 15.3 mole % ethyl *t*-butyl ketone and corresponding to a constant of 5.5 was obtained.

(4) F. C. Whitmore and E. E. Stahly, THIS JOURNAL, **55**, 4153 (1933); F. C. Whitmore, *Chem. Eng. News*, **26**, 671 (1948).

An equilibrium constant for the conversion of hexamethylacetone to methyl pentamethylethyl ketone could not be determined because of the fission of the latter compound. However, the equilibrium is extremely far to the right. No hexamethylacetone could be detected during the cleavage reactions of pure methyl pentamethylethyl ketone.

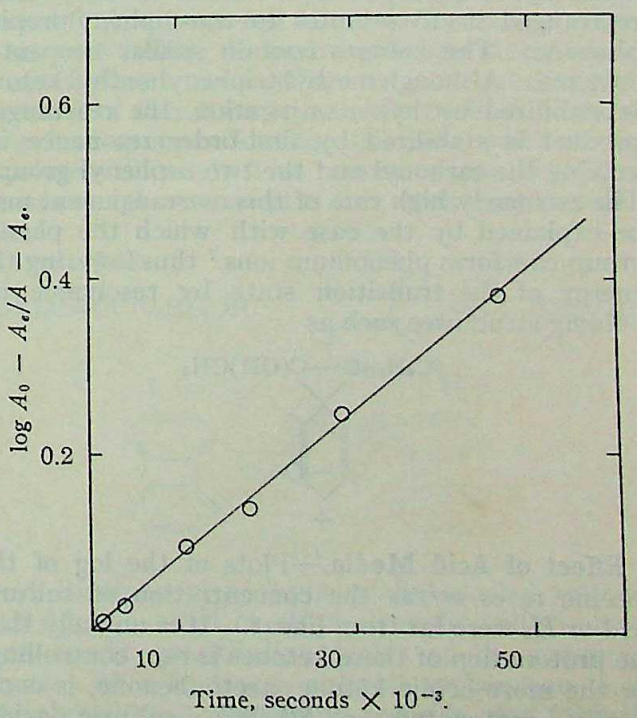

Fig. 3.—Rate of approach of pentamethylacetone to equilibrium; log $A_0 - A_e/A - A_e$ *vs.* time

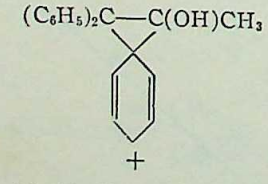
Diisopropyl ketone gave no evidence of rearrangement after 294 hours at 30° in 95.5% sulfuric acid.

Although all ketones which gave rearrangement contained a neopentyl system, the products of rearrangement also contained this system. The driving force of the rearrangement cannot be attributed to the internal strain of this system,[6] for even greater internal strain would be predicted within the more highly branched systems in the products. The series in which the hydrogen atoms of pinacolone are progressively substituted by methyl groups is of interest. Protonated hexamethylacetone is not stabilized by resonance, whereas three contributing hyperconjugation structures are involved in the protonated rearranged product. Pentamethylacetone and methyl *t*-butyl ketone have one and two α-hydrogen atoms, respectively, which results in a corresponding decrease in the extent of the rearrangement equilibria.

Methyl triphenylmethyl ketone is completely rearranged in 15 minutes to α,α-diphenylpropiophenone. The ketones contain similar neopentyl systems. Although methyl triphenylmethyl ketone is stabilized by hyperconjugation, the rearranged product is stabilized by first-order resonance involving the carbonyl and the two α-phenyl groups. The extremely high rate of this rearrangement may be explained by the ease with which the phenyl group can form phenonium ions,[7] thus lowering the energy of the transition state by resonance involving structures such as



Effect of Acid Media.—Plots of the log of the specific rates *versus* the concentration of sulfuric acid or H_0 were far from linear. It is unlikely that the protonation of these ketones is rate controlling, for the more acidic ketone, acetophenone, is completely protonated in 80–96% sulfuric acid.[8] Neither hexamethylacetone nor methyl triphenylmethyl ketone rearranged in 85% phosphoric acid.

Experimental

Materials.—Hexamethylacetone, ethyl *t*-butyl ketone and methyl *t*-amyl ketone were described previously.[2] Pentamethylacetone, b.p. 131° at 725 mm., $n^{25}D$ 1.4046, was prepared by the oxidation[9] of isopropyl-*t*-butylcarbinol and twice fractionated through a 12-plate column. 3,3,4-Trimethyl-2-pentanone was obtained by dehydration of 2,3,4-trimethyl-2,3-pentanediol.[10] The material used in this study, b.p. 149° at 735 mm., $n^{24.8}D$ 1.4209–1.4210, was obtained by refractionation of a sample prepared in this Laboratory by C. R. Enyeart. Sulfuric acid solutions were prepared by diluting Baker Analyzed Reagent with distilled water. Concentrations were determined by dilution and titration with standard base. Carbon tetrachloride was fractionated through a 35-plate column to remove carbon disulfide.

Methyl Pentamethylethyl Ketone (3,3,4,4-Tetramethyl-2-pentanone).—To 1 l. of 88% sulfuric acid at 27° was added 20.5 g., 25 ml., of hexamethylacetone. The mixture was shaken, allowed to stand 4 hr. at 30° and poured onto 5 l. of crushed ice. The ketone was extracted into three 50-ml. portions of carbon tetrachloride and steam distilled along with the solvent to remove traces of sulfuric acid. Fractional distillation through a 12-plate column gave 13.1 g. (64%) of methyl pentamethylethyl ketone, b.p. 164–167°, m.p. 54–60°, containing 15% of hexamethylacetone (infrared). Two additional refractionations were required to give material boiling at 165° at 728 mm., m.p. 61–63°, free of hexamethylacetone. Purification probably would have been easier had the reaction been allowed to continue for 8 hr. Then the main impurity would have been the lower-boiling methyl isopropyl ketone.

Kinetic Studies.—A standard procedure was used for most of the experiments. Sulfuric acid (200.0 ml.) was measured at 30.0° and cooled to 27° in a 250-ml. volumetric flask. After addition of 5.00 ml. of ketone, the mixture was shaken and held at 30.0 ± 0.05° in a constant-temperature bath. Eight 25.0-ml. aliquots were removed at suitable intervals, quenched in 125 ml. of crushed ice and extracted with carbon tetrachloride in 10-ml., 10-ml. and 5-ml. portions. The first 20 ml. of extract was washed with 10 ml. of distilled water and the last 5 ml. used to wash the water layer. The extract was made up to 25.0 ml. and dried with 1 g. of Drierite. A 1:1 dilution of this solution in a 0.52-mm. cell was suitable for infrared analysis. A Perkin-Elmer model 21 spectrophotometer was employed. Analyses were made by determination of a base line with solvent in two matched cells, then by substitution of the solution for the solvent in one cell. Absorbance was measured at frequencies characteristic of each ketone present, and concentrations were determined by solution of simultaneous equations. Extinction coefficients were obtained from the slopes of absorbance curves determined from four or five concentrations of each pure ketone (Table II). Known mixtures of ketones were analyzed to a precision of ±5%.

This is the same precision encountered in the over-all process including extraction as was shown by a comparison of concentrations calculated from zero-time aliquots and from the weights of the samples. Because of a decrease in total ketone concentration, probably due to sulfonation, rates were not determined beyond the second half-life.

Specific rates for the rearrangements of hexamethylacetone and methyl triphenylmethyl ketone and for the cleavage of methyl pentamethylethyl ketone were determined from the slopes of log *A versus* time plots. Rate constants for the cleavage reaction also were obtained from the expression

$$k' = \frac{-2.3}{t} \log \left[\frac{A}{A_0} - \frac{B}{A_0}\left(\frac{k'}{k} - 1\right) \right]$$

where A and B are the concentrations of hexamethylacetone and methyl pentamethylethyl ketone at time t, A_0 is the initial concentration of hexamethylacetone and k is the specific rate of the rearrangement. Values were assigned to k', both sides of the equation were plotted against k' and the intersection of the two curves was determined. The values of k' were fairly constant for points near the maximum concentration of methyl pentamethylethyl ketone.

Syntheses with Triarylvinylmagnesium Bromides. α,γ-Bisdiphenylene-β-phenylallyl, a Stable Free Radical

BY C. F. KOELSCH

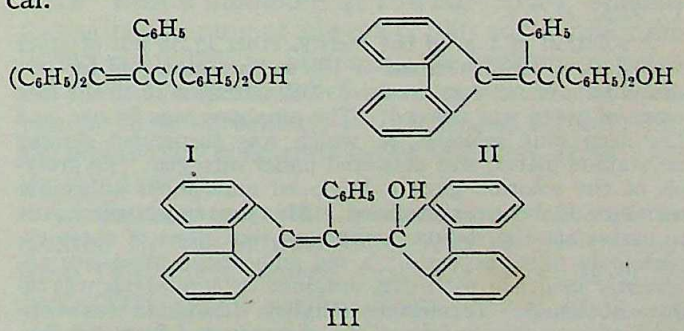
RECEIVED[1] APRIL 10, 1957

Unlike α,α,β,γ,γ-pentaphenylallyl alcohol, α,γ-bisdiphenylene-β-phenylallyl alcohol can be converted into a chloride because its geometry hinders it from cyclization to an indene. The chloride has been converted into the corresponding free radical, a substance which is highly dissociated and remarkably stable to oxygen.

Ziegler's[2] tetraphenylallyl radical, $(C_6H_5)_2C{=}CH{-}C(C_6H_5)_2$, and its substituted derivatives are particularly remarkable in that although they contain only two aryl groups on the methane carbon atom, molecular weight determinations show them to be largely monomolecular. Their deep colors in solution or in the solid state, and their sensitivity toward oxygen also attest their high degree of dissociation. This degree of dissociation, so much exceeding that of triphenylmethyl, was explained by Ziegler on the ground that as 1,1-diphenylethylene is more unsaturated than benzene, diphenylvinyl has a larger "valence requirement" than phenyl.

The completely phenylated allyl radical, pentaphenylallyl, as yet unknown, is of interest because of the intermediate position of the constituent triphenylvinyl group between tetraphenylethylene, whose double bond does not add bromine, and 1,1-diphenylethylene, which adds bromine readily.

A previous paper[3] described the difficulties which were encountered when an attempt was made to synthesize the pentaphenylallyl radical and suggested a means for avoiding these. When pentaphenylallyl alcohol (I) is treated with any acidic reagent, a necessary step in its conversion into a radical, it loses water to form 1,1,2,3-tetraphenylindene. α,α,β-Triphenyl-γ-diphenyleneallyl alcohol (II) is unable to lose water directly, but acidic reagents cause it to undergo an allylic rearrangement followed by the formation of 1-diphenylene-2,3-diphenylindene. α,γ-Bisdiphenylene-β-phenylallyl alcohol (III) is hindered in indene formation, since no matter whether the hydroxyl group is on carbon 1 or 3 the same steric effect tends to prevent the approach of this atom to an *ortho* position of a diphenylene group. Linkage of these positions is therefore difficult.[4] The present paper describes the successful conversion of this alcohol into a radical.



α,γ-Bisdiphenylene-β-phenylallyl alcohol treated with dilute methyl or ethyl alcoholic sulfuric acid gave nearly quantitative yields of the expected ethers. With hydrogen chloride in benzene, α,γ-bisdiphenylene-β-phenylallyl chloride was formed.

The ethers were of no value in the preparation of the radical. When they were treated with sodium amalgam in ether, they yielded deep blue solutions, believed to contain the expected sodio deriva-

(1) The experimental work in the present paper was done in the Converse Memorial Laboratory of Harvard University in 1931–1932, when the author was a National Research Council fellow. A paper describing the work was submitted to THIS JOURNAL June 9, 1932, but it was not accepted for publication. The referee held that the properties of the chief compound, α,γ-bisdiphenylene-β-phenylallyl, could not be those of a radical.

Recent quantum mechanical calculations by M. M. Kreevoy (to be published in *J. Chem. Phys.*), however, now indicate that a radical of the structure named would be unusually resonance-stabilized, and that the properties reported for the substance in question would be not at all inconsistent with the structure claimed. A study of the thermodynamics of addition of sodium to the substance [N. B. Keevil, THIS JOURNAL **59**, 2104 (1937)] hinted that the compound might be unusually stable as a radical. And finally, recent studies by J. E. Wertz and J. L. Vivo, using electron spin resonance methods (briefly reported in OSR Technical Note 55-203, May 1955, p. 133, and to be published in detail in *J. Chem. Phys.*) indicate that the substance is highly dissociated, has an unusually narrow line-width, and is very stable. A sample kept in air 23 years is unchanged in appearance and shows a high free-radical content.

Because the structure originally suggested appears to be confirmed, and because many requests for samples and preparational details are being received, it appears desirable to publish the work now. In the interest of historical accuracy, the only important changes in the original paper are the additions of footnotes 5, 6 and 8.

tive. But this sodio derivative did not react with tetramethylethylene dibromide. Its ether solution was not decolorized until a considerable amount of alcohol was added. When 40% sodium amalgam was used to cleave the ethers, the blue solutions first formed became red on continued shaking and then contained trisodium compound, whose hydrolysis gave α,γ-bisdiphenylene-β-phenylpropane.[5]

α,γ-Bisdiphenylene-β-phenylallyl chloride reacted with mercury to form the radical, α,γ-bisdiphenylene-β-phenylallyl. The molecular weight of this radical in boiling benzene indicated that it was largely dimolecular (α = 5.6%), and this was also evidenced by its great resistance to atmospheric oxidation.[6] The radical could be recovered in part unchanged after oxygen has been passed through its solution in boiling benzene for six hours. Bromine cleaved the radical slowly, but the reaction was complicated by partial formation of unworkable substitution products. It is difficult, however, to reconcile the behavior of the substance toward sodium with a low degree of dissociation; it is cleaved immediately by even 1% amalgam. Also the deep color of the substance, green in the solid state and red in solution, appears to be much too intense to be caused only by the fulvene groups present in a dimer.

In order to be able to ascribe the anomalous behavior of α,γ-bisdiphenylene-β-phenylallyl to the presence of the diphenylene groups or to the fifth (β) aryl group, it is planned to investigate tetraarylallyl radicals containing two diphenylene groups.[7]

Experimental

α,γ-Bisdiphenylene-β-phenylallyl Methyl Ether.—A solution of 6 g. of α,γ-bisdiphenylene-β-phenylallyl alcohol[4] in 360 ml. of hot methanol was cooled rapidly and mixed with 5 ml. of concd. sulfuric acid in 20 ml. of methanol. After ten hours, the product was removed by filtration and washed with methanol containing ammonia. Recrystallization from benzene–ligroin gave 5.7 g. of pale yellow prisms, m.p. 184–186°.

Anal. Calcd. for $C_{34}H_{24}O$: C, 91.1; H, 5.3. Found: C, 91.1; H, 5.5.

The ethyl ether had m.p. 187–190°.

Anal. Calcd. for $C_{35}H_{26}O$: C, 90.8; H, 5.6. Found: C, 90.5; H, 5.7.

A solution of 1 g. of the methyl ether in 35 ml. of ether was shaken with an excess of 1% sodium amalgam for several hours, or with an excess of 40% amalgam until the first tinge of green was noticed. The amalgam was frozen, and the deep blue solution, in which was suspended shining crystalline plates, was decanted under nitrogen. Hydrolysis of the solution gave a brick-red amorphous substance which could not be crystallized. Many attempts were made to carbonate the sodium compound, but none of these experiments were successful; a red amorphous substance apparently identical with that obtained by hydrolysis was always obtained. Tetramethylethylene dibromide was without action on the monosodium compound. Phenyl isocyanate reacted, as did benzyl chloride, but no crystalline products could be obtained.

When the methyl ether was shaken in ether with an excess of 40% sodium amalgam for about one hour the color changed from blue to green and finally to deep red-brown. Kept for several days this solution deposited dichromate-colored prisms of presumably a trisodium compound. Carbon dioxide, phenyl isocyanate and benzyl chloride gave no crystalline products. Tetramethylethylene dibromide reacted, giving deep blue solution of the monosodium compound, hydrolyzed to the red amorphous substance. Hydrolysis of the trisodium compound gave *α,γ-bisdiphenylene-β-phenylpropane* (0.6 g. from 1 g. of the methyl ether), colorless needles from acetic acid, m.p. 236–237°. The hydrocarbon was not changed when treated with an excess of sodium in boiling amyl alcohol.

Anal. Calcd. for $C_{33}H_{24}$: C, 94.3; H, 5.7. Found: C, 94.5; H, 5.7.

α,γ-Bisdiphenylene-β-phenylallyl Chloride.—A solution of 16 g. of α,γ-bisdiphenylene-β-phenylallyl alcohol in the minimum amount of hot dry benzene was cooled to 15°, a few grams of powdered calcium chloride was added, and a current of dry hydrogen chloride was led in for one hour. The mixture was filtered and distilled to a small volume under reduced pressure at a temperature not higher than 30°. The addition of ligroin caused a rapid separation of the chloride, pure enough for use directly. Recrystallization from benzene–ligroin gave bright yellow prisms that darkened at 125° and melted with blackening and gas evolution at 145–155°.

Anal. Calcd. for $C_{33}H_{21}Cl$: C, 87.7; H, 4.6; Cl, 7.8. Found: C, 88.1; H, 4.6; Cl, 7.8.

When boiled with methyl or ethyl alcohol, the chloride gave the corresponding ethers in quantitative yield. When treated with sodium in boiling ethanol, it yielded a deep blue solution, not decolorized by excess sodium; diluted with water, this solution lost its color ahd deposited a red amorphous substance. A benzene solution of the chloride gave a deep violet color with aluminum chloride.

α,γ-Bisdiphenylene-β-phenylallyl.—A suspension of 12 g. of α,γ-bisdiphenylene-β-phenylallyl chloride in 200 ml. of dry ether was shaken with 50 g. of mercury for 12 hours. The solid was then removed, washed with ether, and extracted repeatedly with hot benzene. Cooling the combined extracts gave 4.5 g. of the radical, and from the combined ether and benzene mother liquors there was obtained an additional 1.3 g. At first these operations were carried out under nitrogen, but the inert atmosphere was later found to be unnecessary.

From benzene the radical crystallized in beautiful diamond-shaped plates, green by reflected light and red-brown by transmitted light, m.p. 222–224°. These crystals contain one molecule of benzene which is given off completely only when the compound is heated at 100° for two hours under reduced pressure.

Anal. Calcd. for $C_{33}H_{21} + C_6H_6$: C, 94.6; H, 5.4; C_6H_6, 15.8. Found (sample dried at 25° under reduced pressure): C, 94.3; H, 5.5; C_6H_6 (loss at 100°), 16.5. Calcd. for $C_{33}H_{21}$: C, 94.9; H, 5.1. Found (sample dried at 100° under reduced pressure): C, 94.5; H, 5.0.

From acetic acid the radical crystallized in brown needles, m.p. 188–191°, that contained no solvent.[8]

Anal. Calcd. for $C_{33}H_{21}$: C, 94.9; H, 5.1. Found: C, 94.8; H, 5.1.

Molecular Weight (ebullioscopic).—Benzene, 19.9; $C_{33}H_{21} + C_6H_5$, 0.2782, 0.4139, 0.6277, 0.6962; Δt, 0.038, 0.056, 0.093, 0.103: M, 818, 827, 756, 757; mean, 790. Calcd. for $C_{66}H_{42}$: M, 834; α = 5.6%.

Reactions of the Radical.—The red-brown solution of the radical in acetone became deep blue when a piece of solid potassium hydroxide was added; this color was discharged by water.

A 1% ether solution of the radical became blue immediately on shaking with 1% sodium amalgam. With 40% amalgam, the solution became blue and finally red-brown, and then on hydrolysis gave α,γ-bisdiphenylene-β-phenylpropane in nearly quantitative yield. The same hydrocar-

(5) A hydrocarbon tentatively given this structure was synthesized in a different way by L. A. Pinck and G. E. Hilbert (THIS JOURNAL, 68, 2014 (1946)]. Repetition of their synthesis gave the product described by them and found to be identical with the substance described here (mixed m.p. and infrared spectrum), confirming the structure assigned.

(6) In view of the recent more accurate data from E. S. R. measurements (footnote 1) it is now felt that the original molecular weight determinations were in error. Resistance to oxygen is ascribed to unusual resonance stabilization of the radical.

(7) Early experiments in this direction were unsuccessful, but it now appears feasible to try again using a synthetic method discovered recently by S. Wawzonek and E. Dufek (THIS JOURNAL, 78, 3530 (1956)).

(8) The appearance of this solvent-free material was unchanged after 23 years, but unlike the solvated radical, E.S.R. measurements by Professor Wertz showed that the old sample had lost its free radical

bon was obtained by reduction of the radical with sodium and boiling amyl alcohol.

An excess of a carbon tetrachloride solution of chlorine decolorized the radical after 30 minutes; hydrogen chloride was evolved and no crystalline product could be isolated. When the radical (0.5 g.) in 20 ml. of carbon tetrachloride was mixed with 0.2 g. of bromine and allowed to stand for 12 hours, the color became noticeably lighter. Distillation of the solvent at room temperature left a brown gum which was partly dissolved by 35 ml. of boiling alcohol. Cooling this solution gave 0.15 g. of α,γ-bisdiphenylene-β-phenylallyl ethyl ether.

A solution of 0.4 g. of the radical in 25 ml. of benzene was boiled for 6 hours while a stream of oxygen was passed through. The solution was then distilled to a small volume and cooled, giving 0.1 g. of unchanged radical. No other crystalline substance could be isolated.

A hot solution of 0.5 g. of the radical in 25 ml. of acetic acid was treated with 1 g. of chromic acid in a little water. After the vigorous reaction was over the solution was boiled for five minutes. There was obtained 0.1 g. of benzoic acid and 0.3 g. of steam distilled fluorenone.

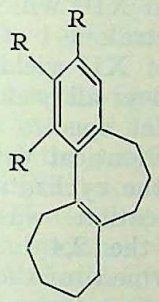
The Cyclodehydration of 2-(γ-Phenylpropyl)-cycloheptanone[1,2]

BY C. DAVID GUTSCHE, N. N. SAHA[3] AND HERBERT E. JOHNSON

RECEIVED DECEMBER 26, 1956

The cyclodehydration of 2-(γ-phenylpropyl)-cycloheptanone has been found to give, instead of the expected olefin Ia, a mixture containing 1-cyclohexyltetralin, 2-cyclohexyltetralin, 1-cyclohexylnaphthalene, 2-cyclohexylnaphthalene and other unidentified products. These materials were characterized by isolation from the cyclization mixture followed by comparison with authentic samples, the syntheses for which are described.

The work described in this communication had its inception in an attempt to synthesize octahydrodemethoxydeoxydeacetamidocolchicine (Ib)[4] by cyclization of 2-[(γ-3′,4′ 5′-trimethoxyphenyl)-propyl]-cycloheptanone (IVb). The reaction, however, did not take the desired course. In the hope of elucidating the actual events, the same reaction with the un-methoxylated analog IVa was investigated in considerable detail.



Ia, R = H
Ib, R = OCH_3

The ketones IVa and IVb were prepared in 60 and 68% over-all yield, respectively, from the corresponding γ-arylbutylamines IIa and IIb by cathylation to IIIa and IIIb followed by nitrosation and treatment with cyclohexanone under the usual ring-enlargement conditions.[5] In view of the known efficacy of polyphosphoric acid as a cyclizing agent for systems containing methoxyl groups,[6] this was the reagent of choice in the case of IVb and, for comparative purposes, in the case of IVa also. In both instances, somewhat more strenuous conditions than are usually employed were necessary to effect complete disappearance of the ketone, and it is this fact which may be responsible for the wayward course of the cyclization. Ketone IVb required contact with polyphosphoric acid at 125° for 30 minutes; ketone IVa required contact with polyphosphoric acid at 100° for 24 hr. or 200° for 2.5 hr. In each case a volatile fraction (30–45%) was obtained which boiled in the range expected for the cyclodehydration product. It is these materials, principally that derived from IVa, which is the subject of this discussion.

The cyclization product from IVb consisted of an oil possessing an analysis in approximate agreement with a $C_{19}H_{26}O_3$ formula (although a methoxyl determination indicated some demethylation). The ultraviolet spectrum, however, showed strong absorption bands at 235 mμ 41,500) and 278 mμ (5000) with a minimum at 254 mμ (3580), whereas Ib has a maximum at 254 mμ (7760) and a minimum at 243 mμ (6030).[4] Similarly, the cyclization product from IVa consisted of an oil possessing an analysis in close agreement with a $C_{16}H_{20}$ formula but an ultraviolet spectrum quite different from that expected for Ia.[7]

Cyclization into the benzene nucleus was indicated by the infrared spectrum of the product from IVa which showed a pattern of bands in the 1650–2000 $cm.^{-1}$ region characteristic of 1,2-disubstituted benzenes.[8] The virtual absence of an olefinic linkage in the product was indicated by the

(1) This work was supported, in part, by: (a) a grant-in-aid from the American Cancer Society upon recommendation of the Committee on Growth of the National Research Council, and (b) a grant-in-aid from the National Science Foundation.

(2) A preliminary account of this work was presented at the 126th Meeting of the American Chemical Society, New York, N. Y., 1954, Abstracts, p. 33-O.

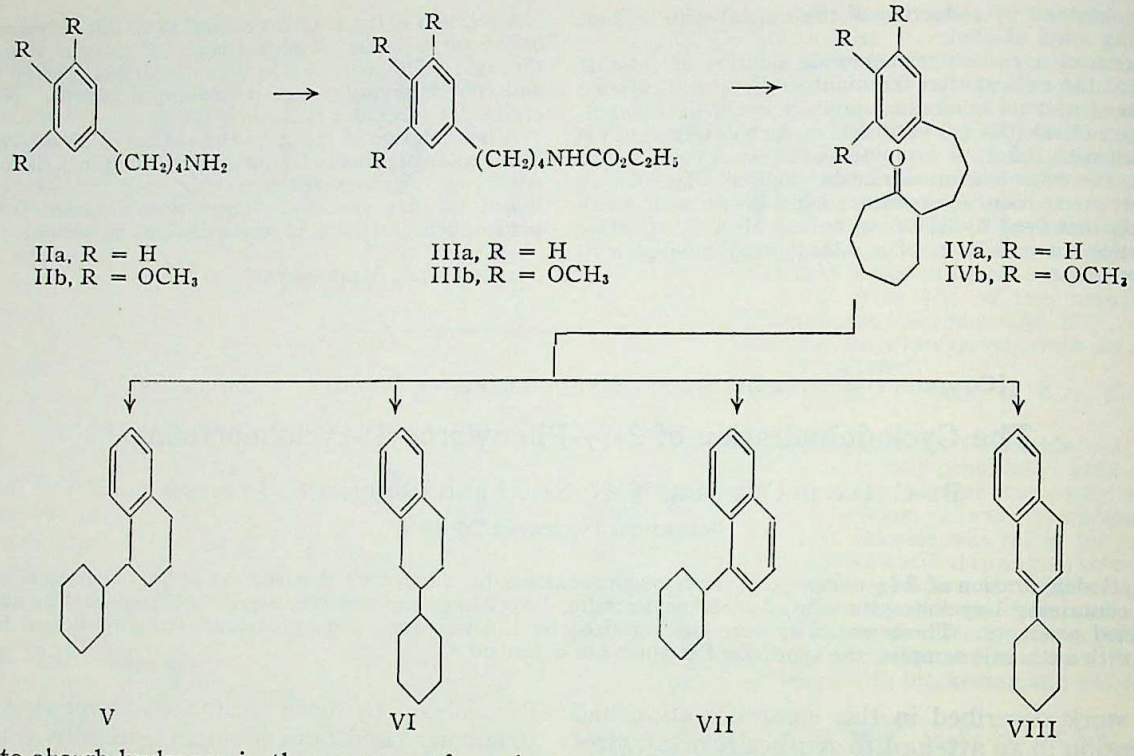
Digitized by Arya Samaj Foundation Chennai and eGangotri



failure to absorb hydrogen in the presence of a palladium catalyst and by the failure to react with potassium permanganate, nitrosyl chloride, ozone or perbenzoic acid.[9] At first, these facts were difficult to reconcile with a $C_{16}H_{20}$ formula. It was eventually ascertained, however that the cyclization product is not a single entity but a mixture of at least five compounds including 1-cyclohexyltetralin (V), 2-cyclohexyltetralin (VI), 1-cyclohexylnaphthalene (VII) and 2-cyclohexylnaphthalene (VIII).[10] The evidence for this conclusion is detailed in the following section.

Identification of 1-Cyclohexyltetralin (V).—When the cyclization product from IVa was fractionated, either by distillation through a spinning band column or by chromatography on alumina, a lower-boiling, less strongly adsorbed material was obtained which had an analysis in close agreement with a $C_{16}H_{22}$ formula. The infrared spectrum of this compound was characteristic of a 1,2-disubstituted benzene derivative,[8] and the ultraviolet spectrum showed only the bands characteristic of the phenyl nucleus. When dehydrogenated with 10% palladium-on-charcoal, 1-phenylnaphthalene was produced, suggesting that the $C_{16}H_{22}$ compound is 1-cyclohexyltetralin. However, since migration of phenyl groups between the 1- and 2-positions of naphthalene is known to occur[11] and since even more drastic events are known to take place under conditions of dehydrogenation,[12] a more secure identification was sought through comparison with the product from an unequivocal synthesis of 1-cyclohexyltetralin. Hexahydrobenzophenone (IX) was subjected to a Reformatsky reaction with ethyl α-bromoacetate, and the resulting hydroxy ester was dehydrated, hydrolyzed and reduced to the acid X. An Arndt–Eistert sequence applied to X yielded XI[13] which was then cyclized to 4-cyclohexyltetralone-1 (XII). Removal of the keto group of XII yielded 1-cyclohexyltetralin (V) in 41% over-all yield from IX. The infrared and ultraviolet spectra of the authentic sample of V were identical with those of the sample obtained from the cyclization product of IVa. Further identification was obtained through a comparison of the 2,4-dinitrophenylhydrazones (two isomers formed) of the acetyl derivative of authentic V and that derived from IVa.

Identification of 2-Cyclohexyltetralin (VI).—When the cyclization product from IVa was fractionated by chromatography on alumina, a material was obtained in exceedingly small amount which had an infrared spectrum different from that of 1-cyclohexyltetralin and almost identical with that of 2-cyclohexyltetralin (VI). An authentic sample of VI was prepared from cyclohexylsuccinic anhydride by condensation with benzene followed by reduction to XIX and XVI, cyclization to 2-cyclohexyltetralone-1 (XIX) and 3-cyclohexyltetralone-1 (XVII) and reduction to 2-cyclohexyltetralin (VI). The structural assignment of XIX and XVI is based on the premise that mono-alkyl-substituted succinic anhydrides usually react with benzene to yield the α-alkyl-β-benzoylpropionic

(9) Ozone and perbenzoic acid, however, were not completely without action. Ozonolysis produced a very small amount of carbonyl-containing material, and perbenzoic acid oxidation showed a 25% consumption of oxidant in 24 hr. and another 25% in 14 days.

(10) In addition to these four compounds, an unidentified solid was isolated in small quantity. It had an analysis compatible with a $C_{16}H_{16}$ formula and an ultraviolet spectrum very similar to that of a naphthalene but shifted somewhat to the visible. Dehydrogenation yielded a hydrocarbon with a $C_{16}H_{12}$ or a $C_{16}H_{10}$ formula.

(11) F. Mayer and R. Schiffner. *Ber.*, **67**, 67 (1934).

(12) P. A. Plattner in "Newer Methods of Preparative Organic Chemistry," Interscience Publishers, Inc., New York, N. Y., 1948, pp. 36–51.

(13) An alternate synthesis of XI from IX was attempted *via* the Stobbe condensation. Difficulties were encountered, however, (*cf.* Experimental section) and the route was abandoned. Also attempted was the condensation of cyclohexylmagnesium bromide and α-tetralone as reported by J. W. Cook and C. A. Lawrence, *J. Chem. Soc.*, 1434 (1936). 1-Cyclohexyl-3,4-dihydronaphthalene was formed in low yield (Cook and Lawrence do not report a yield) and was contaminated with difficultly separable starting ketone.

acid in larger amount.[14] Thus, the higher-melting product from XIII and benzene, obtained in 73% yield, is assigned structure XV; the lower-melting product, obtained in 13% yield, is assigned structure XIV. 2-Cyclohexyltetralin, like the 1-isomer, forms two 2,4-dinitrophenylhydrazones of the acetyl derivative.

Identification of 1-Cyclohexylnaphthalene (VII).—From one of the middle fractions obtained from the distillation of the product from IVa 1-cyclohexylnaphthalene (VII) could be isolated *via* the picrate. Authentic VII was prepared by controlled dehydrogenation of 1-cyclohexyltetralin.

Identification of 2-Cyclohexylnaphthalene (VIII). When the cyclization product from IVa was fractionated, either by distillation through a spinning band column or by chromatography on alumina, a higher-boiling, more strongly adsorbed material was obtained which had an analysis in close agreement with a $C_{16}H_{18}$ formula. The ultraviolet spectrum of this fraction was identical with that of authentic VIII, it formed a trinitrobenzene complex which gave no depression in m.p. when admixed with the trinitrobenzene complex of authentic VIII, and it could be dehydrogenated to 2-phenylnaphthalene. Authentic VIII was prepared by reduction of 2-cyclohexenylnaphthalene, obtained from 2-naphthylmagnesium bromide and cyclohexanone.[15]

No accurate quantitative data as to the relative amounts of V, VI, VII and VIII present in the mixture were obtained. However, on the basis of the ultraviolet spectrum of the crude material, the yields of dehydrogenation products and the yields from chromatographic separation, it appears that the mixture contains *ca.* 65% of V, 25% of VIII and 10% of VI, VII and unidentified products.[16]

Discussion of Results

The rearrangement of alicyclic rings under the influence of various catalysts is a well-known and extensively-studied phenomenon. For instance, Pines, *et al.*,[17] have found that cycloheptanol reacts with benzene under the influence of aluminum chloride or sulfuric acid to give a mixture containing appreciable amounts of methylphenylcyclohexanes. In the course of the present work an intramolecular counterpart to this reaction was discovered when it was found that the alcohol XX yields 1-cyclohexyltetralin (V) under the influence of Friedel–Crafts catalysts.[18] This conversion

(16) These figures apply only to the volatile portion of the product (30–45%). The non-volatile portion has not been investigated.

(17) H. Pines, A. Edeleanu and V. N. Ipatieff, THIS JOURNAL, **67**, 2193 (1945).

(18) The product from XX contains other materials in addition to V, possibly the spiran A which, on the basis of other published data (*cf.* R. O. Roblin, D. Davidson and M. T. Bogert, *ibid.*, **57**, 151 (1935); R. A. Barnes, *ibid.*, **76**, 3004 (1953)) would be expected to be the major product. On the basis of the infrared and ultraviolet spectra of the product and on the basis of its dehydrogenation products, 2-cyclohexyltetralin does not appear to be present.

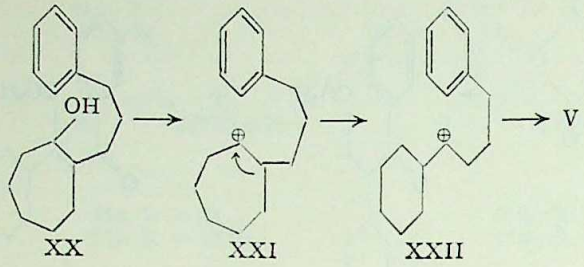
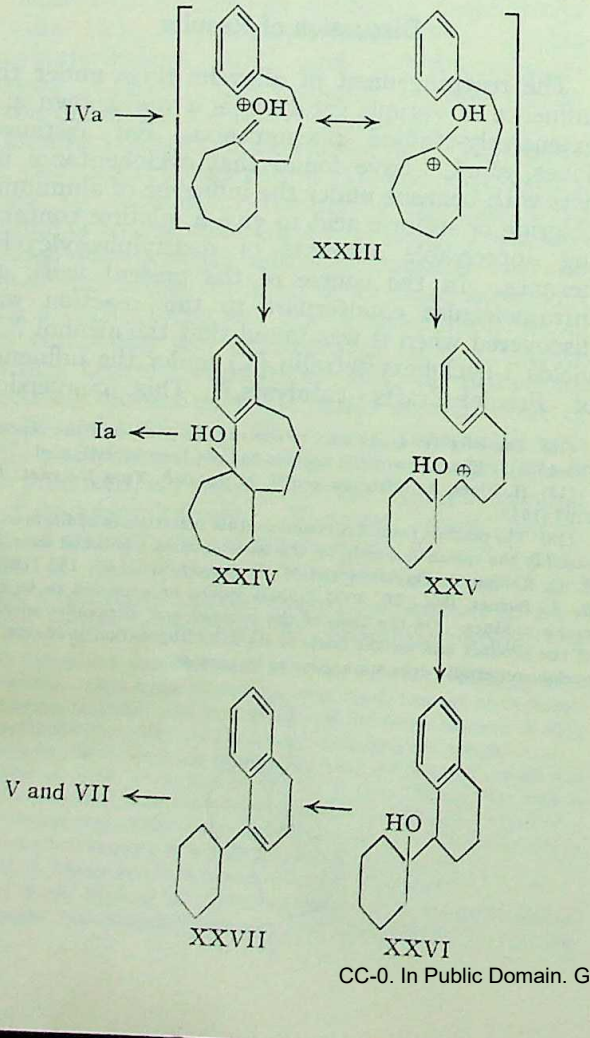
can be rationalized as



A similar rationalization can be invoked to explain the formation of 1-cyclohexyltetralin and 1-cyclohexylnaphthalene from IVa. Addition of a proton to IVa would give the cation XXIII which, although more stable and less reactive than an oxonium ion derived from an alcohol (*e.g.*, the intermediate between XX and XXI), has several possibilities for further reaction. Direct cyclization would yield the alcohol XXIV and from it the olefin Ia. The formation of a seven-membered ring, however, is a process with a higher energy and/or a lower entropy of activation than the formation of a six-membered ring, and molecular rearrangements giving rise to the latter possibility may become important in appropriately constructed molecules. For instance, ring contraction of XXIII to XXV would give an intermediate which could cyclize to the hydroxytetralin (XXVI). Loss of water and bond migration could then yield 1-cyclohexyl-3,4-dihydronaphthalene (XXVII) which, through disproportionation, would lead to 1-cyclohexyltetralin (V) and 1-cyclohexylnaphthalene (VII). Failure to find equivalent amounts of V and VII might indicate a more obscure mechanism, but in any event there is ample precedent for hydrogen transfer reactions under comparable conditions, particularly from the work of Pines, Ipatieff and co-workers.[19,20] A rationalization for the formation of 2-cyclohexyltetralin and 2-cyclohexylnaphthalene is less obvious, and speculation on this point has not been particularly productive.



Although cyclodehydration reactions have been extensively studied in certain series,[21] there are only a few examples of reactions analogous to the one under discussion, and all but one of these involve cyclodehydration to form six-membered rings.[22] The one exception is the attempt by Nunn and Rapson[23] to effect the cyclization of 2-[γ-(*p*-methoxyphenyl)-propyl]-cyclopentanone with phosphorus pentoxide in refluxing xylene. The cyclization required 50 hr., and the product, obtained in 32% yield, consisted of an oil with the correct analysis for $C_{15}H_{18}O$ but with properties different from those expected. It is probable that their product has a structure resulting from molecular rearrangements. Similarly, it is supposed that the material resulting from the cyclization of IVb contains products of molecular rearrangement, probably cyclohexyltrimethoxytetralins and cyclohexyltrimethoxynaphthalenes.

Experimental[24-26]

2-Arylcycloalkanones (IV). γ-(3,4,5-Trimethoxyphenyl)-butyronitrile.—Following a previously described procedure[27] a mixture of 53.0 g. (0.217 mole) of 1-chloro-3-(3′,4′,5′-trimethoxyphenyl)-propane (b.p. 135–144° (0.5 mm.); $n^{25}D$ 1.5305), 31.8 g. (0.49 mole) of potassium cyanide, 1.5 g. of potassium iodide, 210 ml. of 95% ethanol and 80 ml. of water was refluxed for 14 hr. The reaction mixture was then concentrated to half of its original volume, poured into 400 ml. of water and worked up in the usual fashion to yield 45.0 g. (88%) of a colorless liquid with b.p. 150–160° (mainly 156°) at 0.4 mm., $n^{25}D$ 1.5263. A middle cut was taken for analysis.

Anal. Calcd. for $C_{13}H_{17}NO_3$: C, 66.36; H, 7.28. Found: C, 66.75; H. 7.31.

(19) C. Mentzer and Dat Xuong, *Bull. soc. chim. France*, 885 (1947), found that anisole and cyclohexanone react in the presence of aluminum chloride to give a mixture of *p*-methoxyphenylcyclohexene and *p*-methoxyphenylcyclohexane, the latter apparently predominating. R. F. Evans and J. C. Smith, *J. Chem. Soc.*, 798 (1954), have described a reaction in which a compound of the dihydronaphthalene type undergoes disproportionation in the presence of polyphosphoric acid.

δ-(3,4,5-Trimethoxyphenyl)-butylamine (IIb).—A solution of 45.0 g. of γ-(3,4,5-trimethoxyphenyl)-butyronitrile in 250 ml. of ethanol and 60 ml. of 28% ammonium hydroxide was treated with 3 half-teaspoonsful of Raney nickel and hydrogenated at 2.5 atmospheres in a Parr-type apparatus. After 5 hr. the uptake of hydrogen ceased, and the reaction mixture was worked up to yield 38.5 g. (84%) of a colorless liquid with b.p. 137–139° (0.3 mm.), $n^{25}D$ 1.5292. A lithium aluminum hydride reduction of the nitrile resulted in only a 51% yield of the amine.

Anal. Calcd. for $C_{13}H_{21}NO_3$: C, 65.24; H, 8.85. Found: C, 65.65; H, 8.79.

The picrate of IIc was obtained as yellow-green needles after several recrystallizations from hot water; m.p. 172–173°.

Anal. Calcd. for $C_{19}H_{24}N_4O_{10}$: C, 48.72; H, 5.16. Found: C, 48.76; H, 5.11.

Ethyl N-[δ-(3,4,5-Trimethoxyphenyl)-butyl]-carbamate (IIIb).—Using previously described procedures,[28] 51.6 g. of the amine IIb was converted with ethyl chlorocarbonate at 0–5° to 67.0 g. (100%) of a viscous, colorless liquid with $n^{25}D$ 1.5150.

Anal. Calcd. for $C_{16}H_{25}NO_5$: C, 61.61; H, 8.09. Found: C, 61.73; H, 8.28.

2-[γ-(3′,4′,5′-Trimethoxyphenyl)-propyl]-cycloheptanone (IVb).—Ethyl N-nitroso-N-[δ-(3,4,5-trimethoxyphenyl)-butyl]-carbamate was obtained in 98% yield by nitrosation of IIIb at 15–20° for 6 hr. using standard procedures.[29] In a 500-ml. three-necked flask fitted with a dropping funnel and a stirrer was placed 30 g. (0.306 mole) of cyclohexanone, 80 ml. of absolute methanol and 5 g. of finely powdered potassium carbonate. The flask was placed in a water-bath maintained at 25°, and to the stirred mixture was added 67.0 g. (0.212 mole) of the nitroso compound over a period of 45 minutes. The yellowish mixture was allowed to stand at room temperature for 4 hr. and was then filtered. The filtrate was evaporated by heating under reduced pressure, and the residue was distilled to give 41.6 g. (62%) of a yellow liquid with b.p. 190–220° (0.5–1.5 mm.). Redistillation gave 36.0 g. (54%) of almost colorless product, b.p. 172–175° (0.2 mm.), $n^{25}D$ 1.5286.

Anal. Calcd. for $C_{19}H_{28}O_4$: C, 71.22; H, 8.81. Found: C, 71.05; H, 8.59.

The 2,4-dinitrophenylhydrazone of IVb was obtained as dull red needles from petroleum ether (b.p. 63–69°), m.p. 140–141°.

Anal. Calcd. for $C_{25}H_{32}N_4O_7$: C, 59.99; H, 6.44. Found: C, 60.13; H, 6.45.

Ethyl N-(δ-Phenylbutyl)-carbamate (IIIa).—Using previously described procedures, 49.0 g. of δ-phenylbutylamine (IIIa) (prepared by catalytic reduction of γ-phenylbutyronitrile) was converted to 66.3 g. (91%) of IIIa, obtained as a colorless liquid, b.p. 120–122° (0.2 mm.), n_D^{25} 1.5060.

Anal. Calcd. for $C_{13}H_{19}NO_2$: C, 70.55; H, 8.65. Found: C, 70.34; H, 8.81.

2-(γ-Phenylpropyl)-cycloheptanone (IVa).—Ethyl N-nitroso-N-(δ-phenylbutyl)-carbamate was obtained in 100% yield by nitrosation of IIIa at 18–25° for 5.5 hr. using standard procedures. A 73.0-g. sample of the nitroso compound was treated with 40 g. of cyclohexanone, 100 ml. of methanol and 10 g. of potassium carbonate as described above to yield 50.6 g. (74.5%) of a colorless liquid with b.p. 124–125°(0.3 mm.), $n^{25}D$ 1.5212.

Anal. Calcd. for $C_{16}H_{22}O$: C, 83.43, H, 9.63; N, 0.00. Found: C, 83.64; H, 9.63; N, 0.00.

The 2,4-dinitrophenylhydrazone of IVa was obtained as bright orange needles from ethanol; m.p. 120–121°.

Anal. Calcd. for $C_{22}H_{26}N_4O_4$: C, 64.37; H, 6.39. Found: C, 64.65; H, 6.18.

Redistillation of the forerun obtained in the preparation of IVa gave a colorless liquid with b.p. 55°(0.3 mm.), $n^{25}D$ 1.4917. This material appears to be **ethyl δ-phenylbutyl ether.**

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.85; H, 10.18. Found: C, 80.92; H, 9.82.

Polyphosphoric Acid Cyclizations. Cyclization of 2-[γ-(3′,4′,5′-Trimethoxyphenyl)-propyl]-cycloheptanone (IVb).—The polyphosphoric acid was prepared by dissolving, with heating, 40 g. of phosphorus pentoxide in 25 ml. of 85% phosphoric acid.[6] A 2.00-g. sample of IVb was treated with 30 ml. of polyphosphoric acid and was heated, with swirling, for 30 minutes at 120–130°. The brownish-red mixture was poured onto chopped ice and allowed to stand overnight. The organic material was then extracted into ether, the ether solution was dried and the ether was evaporated to leave a yellow residue. The residue was taken up in petroleum ether (b.p. 63–69°) and passed through a column of alumina. The fraction removed with petroleum ether–benzene (1:10) was distilled to give 0.56 g. (30%) of an oil, b.p. 160–163° (0.1 mm.), $n^{25}D$ 1.5713; λ_{max}^{EtOH} mμ (ε): 235 (37,700), 278 (5350); λ_{min}^{EtOH} (ε): 254 mμ (3280); $\tilde{\gamma}_{max}^{liquid}$ in cm.$^{-1}$: 707, 738, 760, 782, 838, 878, 922, 943, 969, 1003, 1042, 1065, 1097, 1121, 1146, 1158, 1190, 1227, 1248, 1280, 1324, 1350, 1390, 1421, 1445, 1490, 1602, 2630, 2810, 2880, 3460(weak) and 4300.

Anal. Calcd. for $C_{19}H_{26}O_3$: C, 75.46; H, 8.67; CH_3O, 30.7. Found: C, 76.75; H, 8.85; CH_3O, 25.3.

Cyclization of 2-(γ-Phenylpropyl)-cycloheptanone (IVa).—A mixture of 75 g. of IVa and 900 ml. of polyphosphoric acid was heated with stirring for 2.5 hr. at 200°. The product was distilled in a Claisen flask and yielded 1.8 g. of naphthalene[30] as a forerun and 31 g. (45%) of material with b.p. 109–126° (0.4 mm.); λ_{max}^{EtOH} mμ (ε): 218 (13,800), 224 (30,000), 268 (1820), 274 (1900). A second distillation through a Claisen flask of a 4-g. sample of this material gave 2.6 g. of a colorless oil, b.p. 96–98° (0.2 mm.), $n^{25}D$ 1.5548.

Anal. Calcd. for $C_{16}H_{20}$: C, 90.50; H, 9.50. Found: C, 90.61; H, 9.82.

The remaining 27 g. of material was distilled through a Piros–Glover spinning band column, and 25 fractions were collected at arbitrary intervals. These could be roughly classified into four groups: (a) fractions 5–10 containing 7.5 g. with b.p. 104–108° (0.7 mm.), $n^{25}D$ 1.5490–1.5510; (b) fractions 17–20 containing 4.2 g. with b.p. 115–117° (0.8 mm.), $n^{25}D$ 1.5600–1.5810; (c) fractions 23–24 containing 2.9 g. with b.p. 124–126° (0.8 mm.), $n^{25}D$ 1.5970–1.5980; (d) fraction 25 containing 2.3 g. with b.p. 127–128° (0.3 mm.), $n^{25}D$ 1.6215. Further information on these fractions is given in succeeding sections of the Experimental section.

From another comparable experiment, a 3.91-g. sample of once-distilled material was subjected to chromatographic separation on a column 2 cm. × 30 cm. containing 173 g. of alumina (Fisher adsorption grade). The column was eluted with petroleum ether (b.p. 63–69°), and 45 fractions of 15 ml. each were collected. These could be classified into three groups: (a) fractions 8–18 containing 2.80 g., $n^{25}D$ 1.5490; (b) fraction 20 containing 0.03 g.; (c) fractions 27–45 containing 0.37 g., $n^{25}D$ 1.5980.

Cyclization also could be effected by heating for longer periods at 100°. A reaction carried out at 100° for 2.5 hr. showed *ca.* 80% of unreacted IVa; after 10 hr., *ca.* 30% of unreacted IVa remained; after 24 hr., *ca.* 5% of unreacted IVa remained. The infrared spectrum of the material obtained from the 24-hr. run at 100° was identical in every respect with that of the material obtained from a 2.5 hr. run at 200°, and it is presumed that the products are very similar in nature. The identification of V, VI, VII and VIII as described below involved material obtained from the 200° runs. In a number of instances, however, similar experiments with similar results were performed on material from 100° runs

1-Cyclohexyltetralin (V). (A) Synthesis from Hexahydrobenzophenone *via* Reformatsky and Arndt–Eistert Sequence.—Ethyl β-hydroxy-β-phenyl-β-cyclohexylpropionate was prepared by the reaction of 28 g. (0.148 mole) of hexahydrobenzophenone[31] with a total of 37 g. (0.22 mole) of ethyl α-bromoacetate and 14.6 g. (0.22 gram atom) of zinc according to previously described methods.[32] The product consisted of 38 g. (93%) of solid material, m.p. 55–56.5°,

(30) The genesis of naphthalene is uncertain, but it is believed to arise through cyclization of ethyl δ-phenylbutyl ether, a probable contaminant of IVa, to tetralin followed by dehydrogenation.

from which an analytical sample was obtained as colorless needles by recrystallization from ethanol; m.p. 57–57.5°.

Anal. Calcd. for $C_{17}H_{24}O_3$: C, 73.88; H, 8.75. Found: C, 73.22; H, 8.56.

The hydroxy ester was dehydrated by the thionyl chloride–pyridine method[32] to yield a mobile, yellow oil with b.p. 155–158° (0.9 mm.). Reduction with hydrogen at two atmospheres of pressure in the presence of 10% palladium-on-charcoal catalyst followed by saponification by refluxing for 7 hr. with 30% aqueous potassium hydroxide produced **β-phenyl-β-cyclohexylpropionic acid** (X) in 80% over-all yield from the hydroxy ester, m.p. 96–98°. An analytical sample was obtained as fine needles by two recrystallizations from aqueous ethanol; m.p. 99–100°.

Anal. Calcd. for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68. Found: C, 77.20; H, 8.55.

γ-Phenyl-γ-cyclohexylbutyric acid (XI) was obtained from X by application of the Arndt–Eistert sequence. A 10.0-g. sample of X was converted to the acid chloride with an excess of purified[33] thionyl chloride. The crude acid chloride was then treated at 0° over a period of 25 minutes with 300 ml. of ether containing diazomethane from 31 g. of nitrosomethylurea. After the reaction mixture had stood at 0° for an additional hour, the volatile materials were removed under vacuum, and the residue was dissolved in methanol and decomposed by the method of Newman and Beal,[34] 95% of the theoretical amount of nitrogen being evolved. The resulting methyl ester was saponified by 2.5 hr. of refluxing with 50 ml. of 45% aqueous potassium hydroxide and 50 ml. of ethanol and yielded 9.3 g. (88%) of a solid with m.p. 56–78°. Two recrystallizations from petroleum ether (b.p. 63–69°) gave 7.5 g. (71%) of colorless, short, thick needles, m.p. 101–102°.

Anal. Calcd. for $C_{16}H_{22}O_2$: C, 78.01; H, 9.00. Found: C, 78.05; H, 8.98.

4-Cyclohexyl-3,4-dihydronaphthalenone (XII) was obtained in 85% yield by cyclization of XI with anhydrous hydrogen fluoride; b.p. 128–130° (0.06 mm.). For analysis, a portion of this material was redistilled and a center cut taken; $n^{25}D$ 1.5640, $\tilde{\nu}_{max}^{liquid}$ 1684 cm.$^{-1}$ (benzoyl).

Anal. Calcd. for $C_{16}H_{20}O$: C, 84.16; H, 8.83. Found: C, 83.60; H, 8.79.

A 2,4-dinitrophenylhydrazone of XII was obtained as fine, deep red needles after two recrystallizations from ethyl acetate; m.p. 234–234.5° dec.

Anal. Calcd. for $C_{22}H_{24}N_4O_4$: C, 64.69; H, 5.92. Found: C, 64.80; H, 5.77.

An 8.64-g. sample of XII was dissolved in 170 ml. of ethyl acetate, treated with 3 g. of 10% palladium-on-charcoal and 12 drops of 70% perchloric acid[35] and subjected to hydrogenation at two atmospheres pressure. After 30 minutes the theoretical amount of hydrogen for complete reduction of the carbonyl group had been absorbed. The product, **1-cyclohexyltetralin** (V), consisted of 7.4 g. (91%) of a colorless oil with b.p. 101–102° (0.1 mm.). A middle fraction taken for analysis had n_D^{25} 1.5464; λ_{max}^{EtOH} mμ (ε); 212.5(8305), 266.5 (488), 274 (479); $\tilde{\nu}_{max}^{liquid}$ in cm.$^{-1}$ *736, 753, 761, 802,* 841, 851, 867, *891, 942,* 967, 1035, 1118, 1130, 1156, 1215, *1240, 1265, 1280, 1325, 1347, 1451, 1492,* 1585, *1608,* 1690, *2860, 2920, 3035.*[36]

Anal. Calcd. for $C_{16}H_{22}$: C, 89.65; H, 10.35. Found: C, 89.94; H, 10.19.

(B) Attempted Synthesis from Hexahydrobenzophenone *via* Stobbe Method.—An 18.8-g. (0.1 mole) sample of hexahydrobenzophenone was condensed with 73 g. (0.5 mole) of dimethyl succinate in the presence of 400 ml. of *t*-butyl alcohol containing 16.8 g. (0.43 g. atom) of dissolved potassium according to the method described for the Stobbe condensation with benzophenone.[37] The crude product consisted of 31 g. (102%) of a solid with m.p. 104–111°. After a number of recrystallizations of a portion of this material from petroleum ether (b.p. 63–69°)–benzene, a sample of feathery needles was obtained, m.p. 120–121°, which is presumed to be **β-carbomethoxy-γ-phenyl-γ-cyclohexylvinylacetic acid** or a bond isomer thereof.

Anal. Calcd. for $C_{18}H_{22}O_4$: C, 71.50; H, 7.33. Found: C, 71.18; H, 7.29.

Attempted decarboxylation of the half-ester by refluxing with acetic acid–48% hydrobromic acid–water[38] gave a mixture from which no pure compound could be isolated. However, when the crude material was subjected to treatment with phosphorus and hydrogen iodide, a solid could be separated which has an analysis and a spectrum in accord with **γ-phenyl-γ-cyclohexylparaconic acid.** After recrystallization from aqueous methanol, this material was obtained as prismatic needles, m.p. 182–182.5°; $\tilde{\nu}_{max}^{CHCl_3}$ in cm.$^{-1}$ 1718 (carboxyl), 1766 (γ-lactone).

Anal. Calcd. for $C_{17}H_{20}O_4$: C, 70.81; H, 6.99. Found: C, 70.91; H, 6.98.

Saponification of the Stobbe half-ester gave **β-carboxy-γ-phenyl-γ-cyclohexylvinylacetic acid,** m.p. 152–153°, in 94% yield. An analytical sample was prepared by further recrystallization from petroleum ether (b.p. 63–69°)–ethyl acetate and was obtained in the form of small pellets, m.p. 153–154°.

Anal. Calcd. for $C_{17}H_{20}O_4$: C, 70.81; H, 6.99. Found: C, 70.81; H, 7.28.

Attempted decarboxylation of the dibasic acid by heating for 1 hr. at 160–180° over potassium bisulfate yielded 73% of a compound which, on the basis of the analysis and infrared spectrum, is presumed to be **α-(β-phenyl-β-cyclohexyl)-methylenesuccinic anhydride,** m.p. 123–126°. Further purification by recrystallization from methanol yielded diamond-shaped plates, m.p. 130–130.5°, $\tilde{\nu}_{max}^{CHCl}$ 1780 and 1840 cm.$^{-1}$ (anhydride).

Anal. Calcd. for $C_{17}H_{18}O_3$: C, 75.53; H, 6.71. Found: C, 75.58; H, 7.30.

(C) Isolation from Cyclization Product of IVa.—Fraction 8 from the fractional distillation of the cyclization product from IVa (*cf.* above), b.p. 108° (0.7 mm.), $n^{25}D$ 1.5495, possessed an infrared spectrum identical in every detail with that given above for authentic 1-cyclohexyltetralin except for an additional weak band at 696 cm.$^{-1}$. This band, which is strong in the earlier fractions of the distillation, is probably due to slight contamination from these materials. Similarly, fraction 13 from the chromatographic separation of the cyclization product from IVa (*cf.* above) possessed an infrared spectrum identical with that of authentic 1-cyclohexyltetralin.

Anal. Calcd. for $C_{16}H_{22}$: C, 89.65; H, 10.35. Found: Fraction 8 from distillation: C, 89.94; H, 10.19. Fraction 13 from chromatography: C, 89.55; H, 10.05.

(D) Synthesis from 2-(γ-Phenylpropyl)-cycloheptanol (XXI).—The reduction of the ketone IVa to the alcohol XXI was accomplished in 89% yield with lithium aluminum hydride in ether solution. The **2-(γ-phenylpropyl)-cycloheptanol** was obtained as a colorless oil, b.p. 132–134° (0.3 mm.), $n^{25}D$ 1.5272.

Anal. Calcd. for $C_{16}H_{24}O$: C, 82.70; H, 10.41. Found: C, 83.14; H, 10.61.

A solution of 2.71 g. (0.012 mole) of XXI in 20 ml. of carbon disulfide was cooled to 10° and treated with 2.00 g. (0.015 mole) of anhydrous aluminum chloride. The reaction mixture was allowed to warm to room temperature whereupon hydrogen chloride was evolved. After the evolution of gas had ceased, the mixture was gently boiled for a few minutes and then poured onto ice and sulfuric acid. The product, isolated in the usual manner, consisted of 1.91 g. (76%) of a colorless liquid, b.p. 109–110° (0.4 mm.), $n^{25}D$ 1.5460; λ_{max}^{EtOH} mμ (ε): 210 (8700), 266 (850), 274 (725); $\tilde{\nu}_{max}^{liquid}$ in cm.$^{-1}$: *696, 737, 753, 762, 802,* 842, 851, 867, *891, 942, 971, 989,* 1020–1040 (broad), 1118, 1127, 1158, 1218, *1238, 1266, 1280, 1324, 1347, 1450, 1491,* 1581, *1605,* 1690, 1702, 1800, 1910, 1940, 2650, *2840, 2900, 3010* and *3020.*[36]

Anal. Calcd. for $C_{16}H_{22}$: C, 89.65; H, 10.35. Found: C, 89.44; H, 10.39.

That the product resulting from the cyclization of XXI contains 1-cyclohexyltetralin is indicated by the infrared

spectrum and, more conclusively, by the formation of solid derivatives identical with those from authentic V (*cf.* below). Other compounds must also be present, however, as suggested by certain bands (*e.g.*, 696, 971 and 989 cm.$^{-1}$) in the infrared spectrum which are not present in the spectrum of pure V.

(E) **Acetyl Derivatives of 1-Cyclohexyltetralin.**—Acetylation of a sample of authentic 1-cyclohexyltetralin with acetyl chloride and aluminum chloride in carbon disulfide yielded 100% of a pale yellow oil. This was treated with 2,4-dinitrophenylhydrazine to yield a solid which could be separated, by fractional crystallization from ethanol–ethyl acetate, into two compounds: (a) yellow, micro-crystalline material with m.p. 239–240°; *Anal.* Calcd. for $C_{24}H_{28}N_4O_4$: C, 66.03; H, 6.47. Found: C, 66.04; H, 6.16. (b) An orange-red micro-crystalline material with m.p. 177–178°. *Anal.* Calcd. for $C_{24}H_{28}N_4O_4$: C, 66.03; H, 6.47. Found: C, 65.99; H, 6.29.

In similar fashion, fraction 8 from distillation and fraction 13 from chromatography (from the cyclization product of IVa) were acetylated and converted to a 2,4-dinitrophenylhydrazone mixture from which in each case two compounds, identical with those described above, were isolated.

Also, the product resulting from the cyclization of 2-(γ-phenylpropyl)-cycloheptanol (XXI) yielded the same two 2,4-dinitrophenylhydrazone derivatives, although in somewhat lower yield, when subjected to this treatment.

2-Cyclohexyltetralin. (A) Synthesis from Cyclohexylsuccinic Anhydride.—β-Carbethoxy-β-cyclohexenylpropionic acid was prepared from cyclohexanone and diethyl succinate according to the method of Johnson, *et al.*[39] The half-ester was hydrogenated in the presence of 10% palladium-on-charcoal catalyst, saponified to cyclohexylsuccinic acid and converted, with acetic anhydride, to cyclohexylsuccinic anhydride, m.p. 35–36°. To a stirred solution of 8.84 g. (0.048 mole) of the anhydride in 35 ml. of dry, thiophene-free benzene cooled to 5–10°, 13.08 g. (0.098 mole) of anhydrous aluminum chloride was added slowly. The reaction mixture was allowed to stand for 16 hr. at room temperature, then heated for 2 hr. at 60–70° and finally worked up in the usual fashion to yield 12 g. (95%) of crude product, m.p. 110–120°. Two recrystallizations from benzene–hexane yielded 9.20 g. (73%) of colorless, fine needles, m.p. 125–126°, presumed to be **α-cyclohexyl-β-benzoylpropionic acid (XV)**.

Anal. Calcd. for $C_{16}H_{20}O_3$: C, 73.82; H, 7.74. Found: C, 74.26; H, 7.81.

Concentration of the mother liquors from the recrystallizations followed by two further recrystallizations from benzene–hexane yielded 1.61 g. (13%) of colorless needles, m.p. 99–100°, presumed to be **β-cyclohexyl-β-benzoylpropionic acid (XIV)**.

Anal. Calcd. for $C_{16}H_{20}O_3$: C, 73.82; H, 7.74. Found: C, 73.92; H, 7.67.

A 5.0-g. sample of the higher-melting keto acid was reduced by the Huang-Minlon modification of the Wolff–Kishner method[40] to give 3.2 g. (68%) of **α-cyclohexyl-γ-phenylbutyric acid (XIX)**, with b.p. 174–175° (0.15 mm.), m.p. 59–60°.

Anal. Calcd. for $C_{16}H_{22}O_2$: C, 78.01; H, 9.00. Found: C, 77.88; H, 9.01.

2-Cyclohexyl-3,4-dihydronaphthalenone (XVIII) was obtained when a 4.5-g. sample of XIX was treated with 150 ml. of anhydrous hydrogen fluoride, allowed to stand for 6 hr. and worked up in the usual fashion to yield 3.44 g. (83%) of pale yellow liquid with b.p. 140° (0.13 mm.), $n^{25}D$ 1.5547, $\bar{\nu}_{max}^{liquid}$ 1685 cm.$^{-1}$ (benzoyl).

Anal. Calcd. for $C_{16}H_{20}O$: C, 84.16; H, 8.83. Found: C, 84.10; H, 8.84.

The 2,4-dinitrophenylhydrazone of XVIII was obtained, after two recrystallizations from ethanol–ethyl acetate, as orange-red needles, m.p. 231–231.5°.

Anal. Calcd. for $C_{22}H_{24}N_4O_4$: C, 64.69; H, 5.92. Found: C, 64.71; H, 5.96.

The 2,4-dinitrophenylhydrazone of 3-cyclohexyl-3,4-dihydronaphthalenone (XVII) was obtained by reducing the lower-melting keto acid XIV to β-cyclohexyl-γ-phenylbutyric acid (XVI) followed by cyclization to the ketone XVII and derivatization with 2,4-dinitrophenylhydrazine. The pure material was obtained as bright orange, very small needles after two recrystallizations from ethanol–ethyl acetate; m.p. 235–236° dec.

Anal. Calcd. for $C_{22}H_{24}N_4O_4$: C, 64.69; H, 5.92. Found: C, 65.06; H, 6.16.

2-Cyclohexyltetralin (VI) was obtained in 80% yield by hydrogenolysis of XVIII in the presence of 10% palladium-on-charcoal in an ethyl acetate solution containing perchloric acid. It consisted of a colorless, mobile liquid with b.p. 132–134° (0.6 mm.), $n^{25}D$ 1.5413; λ_{max}^{EtOH} mμ (ε): 210 (8280), 266.5 (613), 273.5 (710); $\bar{\nu}_{max}^{liquid}$ in cm.$^{-1}$: *739*, 810, 840, 886, 910, *942*, 968, 1034, 1096, 1185, 1249, *1346*, 1370, *1432*, *1448*, *1494*, *1583*, 1678, *2850* and *2912*.[36]

Anal. Calcd. for $C_{16}H_{22}$: C, 89.65; H, 10.35. Found: C, 89.39; H, 10.13.

(B) Isolation from Cyclization Product from IVa.—Fraction 20 from the chromatographic separation of the cyclization product from IVa (*cf.* above) showed an infrared spectrum almost identical with that of authentic 2-cyclohexyltetralin. The infrared spectrum of 1-cyclohexyltetralin contains more bands than that of 2-cyclohexyltetralin and includes all of those present in the former compound. Only two of these show any noticeable shift (736 and 891 cm.$^{-1}$ in 1-cyclohexyltetralin, 739 and 886 cm.$^{-1}$ in 2-cyclohexyltetralin). Concurrent spectral determinations charted on the same graph, however, show quite clearly the difference between V and VI and support the identity of fraction 20 with VI.

(C) Acetyl Derivatives of 2-Cyclohexyltetralin.—Acetylation of a sample of authentic 2-cyclohexyltetralin with acetyl chloride and aluminum chloride in carbon disulfide yielded a liquid which was then treated with 2,4-dinitrophenylhydrazine. The resulting solid was recrystallized from ethanol–ethyl acetate and yielded two compounds: (a) dark yellow, microcrystalline material with m.p. 247–248°. *Anal.* Calcd. for $C_{24}H_{28}N_4O_4$: C, 66.03; H, 6.47. Found: C, 66.03; H, 6.18. (b) yellow, micro-crystalline material with m.p. 187–188°.

Anal. Calcd. for $C_{24}H_{28}N_4O_4$: C, 66.03; H, 6.47. Found: C, 66.02; H, 6.53. Mixed m.p.'s of these derivatives with the corresponding ones from 1-cyclohexyltetralin showed marked depressions. Insufficient VI was available from fraction 20 of the chromatographic separation to allow identification through the acetyl derivative.

1-Cyclohexylnaphthalene (VII). (A) Synthesis from 1-Cyclohexyltetralin.—A 1.0-g. sample of 1-cyclohexyltetralin was heated for 5 hr. at 235–258° with 0.7 g. of 5% palladium-on-charcoal. The crude product was chromatographed on 40 g. of alumina using petroleum ether (b.p. 63–69°) as the elutrient, and 0.25 g. of VII was obtained, $n^{25}D$ 1.6005; λ_{max}^{EtOH} mμ (ε): 225 (80,050), 273 (6170), 283 (7285), 294 (5120), 313.5 (387) [reported[41] λ_{max} mμ (ε): 225 (31,500), 274 (4000), 283 (4800), 294 (3300), 314 (320)]; $\bar{\nu}_{max}^{liquid}$ in cm.$^{-1}$: 699, *729*, 741, *775*, *788*, *795*, *842*, *856*, *887*, *898*, 947 965, *989*, 1015, *1028*, *1090*, 1130, 1142, *1168*, *1232*, *1263*, 1300, 1325, *1350*, *1400*, *1453*, *1516*, *1606*, *2867*, *2930* and *3080*.[36]

Anal. Calcd. for $C_{16}H_{18}$: C, 91.37; H, 8.63. Found: C, 91.34; H, 8.68.

A picrate of VII with m.p. 126–127° (reported[42] 122–123.5°) and a trinitrobenzene complex with m.p. 118–119° (reported[42] 116.5–117.5°) could be prepared.

(B) Isolation from Cyclization Product of IVa.—Inspection of the infrared spectra of distillation fractions 18–22 indicated that 1-cyclohexylnaphthalene was present (based particularly on the bands at 775, 795, 887, 947, 1263 and 1400 cm.$^{-1}$ which are prominent in VII but weak or absent in VIII) although contaminated with other materials. When a 2.25-g. sample comparable to fraction 18 of the distillation, b.p. 115–117° (0.7 mm.), $n^{25}D$ 1.5870, was treated with an alcoholic solution of picric acid, 1.47 g. of an orange picrate, m.p. 112–115°, precipitated. Several recrystallizations of this material from methanol saturated with picric acid yielded 0.37 g. of orange needles, m.p. 124–125°, which

Digitized by Arya Samaj Foundation Chennai and eGangotri

showed no depression in m.p. when admixed with the picrate of authentic VII. The picrate was decomposed by dissolving in benzene and passing through a column of alumina. The resulting product was an oil (λ_{max}^{EtOH} mμ (ε): 225 (78,000), 273 (5800), 283 (6800) 294 (4550), 313.5 (398)) which was converted to a trinitrobenzene complex, m.p. 118–119°, which showed no depression in m.p. when admixed with the same derivative of authentic VII.

2-Cyclohexylnaphthalene (VIII). (A) Synthesis from 2-Naphthylmagnesium Bromide.—A stirred mixture of 6.79 g. (0.033 mole) of 2-bromonaphthalene, 1.59 g. (0.066 g. atom) of magnesium and 50 ml. of dry ether was treated over a period of 30 minutes with a solution of 3.58 g. (0.033 mole) of ethyl bromide in 15 ml. of ether. After an additional 3 hr. of stirring, the reaction mixture was cooled and treated with a solution of 6.44 g. (0.066 mole) of cyclohexanone in 25 ml. of ether. After refluxing the reaction mixture for 3.5 hr. and allowing it to stand at room temperature overnight, the product was isolated in the usual fashion. The crude material was slowly distilled from 3 g. of fused potassium bisulfate in a Claisen flask to yield 4.0 g. (59%) of 2-cyclohexenylnaphthalene, b.p. 135° (0.06 mm.), m.p. 55–57°. One recrystallization from methanol yielded colorless needles, m.p. 60–60.5° (reported[44] 61–62°). Reduction of the olefin with hydrogen in the presence of 10% palladium-on-charcoal yielded 89% of 2-cyclohexylnaphthalene as a colorless, mobile liquid, b.p. 150–152° (0.65 mm.), $n^{25}D$ 1.5955; λ_{max}^{EtOH} mμ (ε): 225 (114,000), 268 (4700), 275 (5050), 285 (3400), 304 (475), 310 (280) 319 (430); $\tilde{\nu}_{max}^{liquid}$ in cm.$^{-1}$: *745*, 768, 786, *815*, *852*, *883*, 920, *954*, *1018*, *1127*, 1142, 1155, 1203, *1270*, *1352*, 1380, *1451*, *1510*, *1610*, *1640*, *2867*, *2934*, and *3067*.[36]

Anal. Calcd. for $C_{16}H_{18}$: C, 91.37; H, 8.63. Found: C, 91.48; H, 8.87.

A trinitrobenzene complex of VIII was obtained as feathery, yellow needles after several recrystallizations from methanol; m.p. 122–123°.

Anal. Calcd. for $C_{22}H_{21}N_3O_6$: C, 62.40; H, 5.00. Found: C, 62.55; H, 4.86.

A picrate with m.p. 98–103° which could not be further purified could be prepared from VIII.

(B) Isolation from Cyclization Product of IVa.—Fraction 24 from the distillation (*cf.* above) and fractions 27–45 from the chromatographic separation (*cf.* above) had infrared spectra very close to that of authentic 2-cyclohexylnaphthalene.

Anal. Calcd. for $C_{16}H_{18}$: C, 91.37; H, 8.63. Found: Fraction 24 from distillation: C, 91.28; H, 8.90. Fraction 27–45 from chromatography: C, 91.31; H, 8.44.

When a 0.35-g. sample of distillation fraction 24 was treated with an alcoholic solution of trinitrobenzene, 0.26 g. of bright yellow needles, m.p. 116–120°, precipitated. Several recrystallizations from methanol produced feathery yellow needles, m.p. 122–123°, which showed no depression in m.p. when admixed with the trinitrobenzene complex of authentic VIII.

Unidentified Product.—A 1.70-g. sample of fraction 25 from the distillation of the cyclization product of IVa, b.p. 127–128° (0.3 mm.), was treated with an alcoholic solution of trinitrobenzene. The precipitate, consisting of 1.61 g. of bright orange needles with m.p. 100–114°, was recrystallized from methanol to give 1.0 g. of dull orange needles, m.p. 115–119°. This material was dissolved in petroleum ether (b.p. 63–69°), passed through a column of alumina and 0.46 g. of an oil collected, $n^{32}D$ 1.6255. Upon standing, the oil partially solidified and was thereupon pressed on a porous plate to yield 0.21 g. of material with m.p. 78–84°. Recrystallization from methanol yielded glistening plates, m.p. 91–92°; λ_{max}^{EtOH} (ε): 230 (55,000), 235 (79,000), 285 (6300), 295 (6600), 314 (3800), 328 (3800).

Anal. Calcd. for $C_{16}H_{16}$: C, 92.26; H, 7.74. Found: C, 92.01; H, 7.66.

Dehydrogenation Experiments. (A) Dehydrogenation of 1-Cyclohexyltetralin (V).—The low temperature dehydrogenation of V to give cyclohexylnaphthalene is described above. A more strenuous dehydrogenation was carried out by mixing 1.0 g. of V with 0.3 g. of 10% palladium-on-charcoal catalyst and heating at 235–310° for 10.5 hr. The product consisted of 0.6 g. of a colorless liquid with a slight bluish fluorescence, b.p. 140–143° (0.4 mm.), $n^{25}D$ 1.6598; λ_{max}^{EtOH} mμ (ε): 225 (55,600), 240 (6530), 282.5 (8230), 287.5 (9515), 341.5 (186) [reported[43] λ_{max}^{EtOH} mμ (ε): 226 (62,000), 282 (11,000), 288 (11,000)].

(B) Dehydrogenation of 2-Cyclohexyltetralin (VI).—A mixture of 0.5 g. of 2-cyclohexyltetralin and 0.2 g. of 10% palladium-on-charcoal was heated for 3 hr. at 260–330°. The product consisted of 0.3 g. of solid, m.p. 95–99°, from which pure 2-phenylnaphthalene could be obtained after two recrystallizations from ethanol; m.p. 102–103° (reported[43] 102–103°); λ_{max}^{EtOH} mμ (ε): 212 (36,000), 250 (63,000), 285 (11,000) [reported[43] λ_{max}^{EtOH} mμ (ε): 251 (63,000), 269 (12,500), 288 12,500)].

(C) Dehydrogenation of Cyclization Product of IVa.—A 2.67-g. sample of cyclization product, b.p. 109–126° (0.4 mm.), was treated with 1.0 g. of 5% palladium-on-charcoal catalyst and heated for 2.5 hr. at 390°. The product consisted of 2.00 g. of a red oil from which 1.30 g. of 1-cyclohexylnaphthalene and 0.50 g. of 2-phenylnaphthalene could be separated by chromatography on alumina.

(D) Dehydrogenation of Chromatographic Fractions from Cyclization Product of IVa.—A 0.5-g. sample of chromatographic fractions 8–18 (*cf.* above) dehydrogenated in the presence of 0.35 g. of 5% palladium-on-charcoal at 245–300° for 22 hr. yielded a mixture of 1-cyclohexylnaphthalene and 1-phenylnaphthalene and 4% of 2-phenylnaphthalene, separated by chromatography on alumina. Although the 2-phenylnaphthalene may have arisen by rearrangement during the dehydrogenation, it is thought more probable that it was formed from the small amount of 2-cyclohexyltetralin probably present in chromatographic fractions 8–18. A 0.2-g. sample of chromatographic fractions 27–45 (*cf.* above) dehydrogenated in the presence of 0.1 g. of 10% palladium-on-charcoal at 300–350° for 3.5 hr. yielded 60% of 2-phenylnaphthalene.

(E) Dehydrogenation of Distillation Fractions from Cyclization Product of IVa.—A 0.83-g. sample of distillation fraction 9, b.p. 107–108° (0.7 mm.) (*cf.* above), was dehydrogenated in the presence of 0.2 g. of 5% palladium-on-charcoal at 290° for 2.5 hr. and yielded 2-cyclohexylnaphthalene, isolated as the picrate in 27% yield. A 0.96-g. sample of distillation fraction 24, b.p. 125–126° (0.8 mm.), (*cf.* above) was dehydrogenated in the presence of 0.2 g. of 5% palladium-on-charcoal at 360° for 3 hr. and yielded 90% of 2-phenylnaphthalene.

(F) Dehydrogenation of Cyclization Product of XXI.—A 0.44-g. sample of the cyclization product of XXI was treated with 0.20 g. of 5% palladium-on-charcoal and heated for 3 hr. at 390°. The product consisted of 0.38 g. of a greenish-yellow oil with λ_{max}^{EtOH} mμ (ε): 225 (55,000), 285 (8100) and λ_{min}^{EtOH} 250 mμ. This is very similar to the ultraviolet spectrum of 1-phenylnaphthalene and different from that of 2-phenylnaphthalene which has a maximum at 250 mμ (63,000).

(G) Dehydrogenation of Unidentified Product.—A 40-mg. sample of the unidentified product obtained from the cyclization of IVa (*cf.* above) was treated with 20 mg. of 10% palladium-on-charcoal and heated for 3 hr. at 260–300°. The solid product was recrystallized from ethanol to give colorless plates: m.p. 107–108°; λ_{max}^{EtOH} mμ (ε): 212 (26,000), 224 (16,000), 250 (47,000), 257 (58,000), 280 (10,400), 291 (10,500), 303 (13,700), 321 (890), 336 (1600).

Anal. Calcd. for $C_{16}H_{12}$: C, 94.08, H, 5.92. For $C_{16}H_{10}$: C, 95.02, H, 4.98. Found: C, 94.74; H, 6.24.

A trinitrobenzene complex of the dehydrogenation product was obtained after recrystallization from ethanol, as yellow feathery needles, m.p. 168–169°.

Anal. Calcd. for $C_{22}H_{15}N_3O_6$: C, 63.31; H, 3.62. For $C_{22}H_{13}N_3O_6$: C, 63.61; H, 3.15. Found: C, 63.81; H, 3.48.

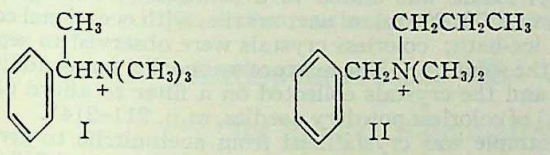
A Novel Ring Enlargement Involving the *ortho* Substitution Rearrangement by Means of Sodium Amide in Liquid Ammonia[1]

BY DANIEL LEDNICER AND CHARLES R. HAUSER

RECEIVED MARCH 28, 1957

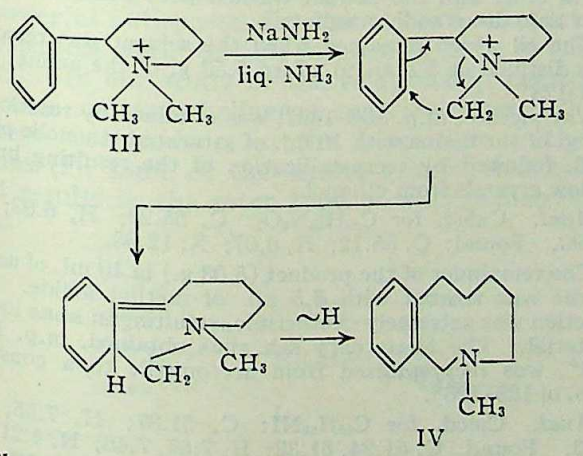
The *ortho* substitution rearrangement was realized with the 1,1-dimethyl-2-phenylpiperidinium ion, the piperidine ring of which underwent ring enlargement to form a new nine-membered nitrogen-containing ring system. The structure of the product was established by independent synthesis. The success of the rearrangement appears to be dependent on a favorable conformation of the molecule, in which a methyl group is near to the *o*-position of the aromatic ring, since similar open-chain quaternary ammonium ions exhibit considerable β-elimination.

The *ortho* substitution rearrangement by means of sodium amide in liquid ammonia has been especially characteristic of benzyl-type quaternary ammonium ions having no β-hydrogen such as the benzyltrimethylammonium ion.[2] The rearrangement has been realized, however, in fairly good yields with quaternary ions I and II which do have β-hydrogens.[3] For example, the former ion underwent the rearrangement to 2-ethylbenzyldimethylamine in 42% yield. This reaction was accompanied by β-elimination to give styrene in 14% yield as well as some dimerization and trimerization.



I II

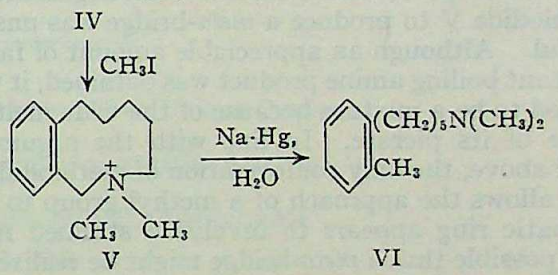
Since the quaternary ion III has some of the structural features of both I and II, it might be expected to undergo the rearrangement to some extent involving the novel ring enlargement shown below. Actually this reaction was realized in 83% yield to form tertiary amine IV, which has a new nine-membered nitrogen-containing ring system. No appreciable β-elimination was observed.



III IV

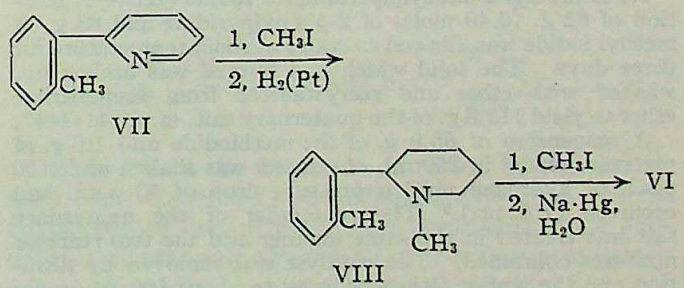
The starting quaternary ion III (as iodide) was prepared by the hydrogenation of the methiodide of 2-phenylpyridine followed by treatment with methyl iodide. This is a modification of the route described in the literature[4] in which 2-phenylpyridinium chloride was hydrogenated, the product then methylated and finally quaternized.

The reaction of III with sodium amide in liquid ammonia was carried out in the usual manner. The colorless amine product boiled over a narrow range. On exhaustive oxidation with permanganate, *o*-phthalic acid was obtained in 55% yield, showing that the rearrangement had indeed involved substitution into an *o*-position of the aromatic ring. That ring enlargement had occurred to form amine IV was established by an Emde reduction of the methiodide of the product V which gave amine VI in 80% yield.



V VI

The structure of the latter amine VI was confirmed by an independent synthesis from 2-*o*-tolylpyridine (VII),[5] the structure of which seems well established.



VII VIII

Each of four steps of this independent synthesis appears unequivocal. Thus, the hydrogenation of the methiodide should not be expected to cause structural changes, while the Emde reduction is known to cleave only benzyl-type quaternary salts. The over-all yield from VII to VI was 54%.

It was shown, incidentally, that the product from the *ortho* substitution rearrangement of quaternary ion III was not tertiary amine VIII[6] which is isomeric with tertiary amine IV. Thus, the methiodides of these two amines not only melted seventeen degrees apart, but a considerable depression of the melting points was observed on mixing the two

(5) We are indebted to Dr. C. K. Bradsher and Mr. Kenneth B. Moser for a generous sample of this compound which was prepared from *o*-tolyllithium and pyridine, by the method for the preparation of 2-phenylpyridine; J. C. W. Evans and C. F. H. Allen, "Organic Syntheses," Coll. Vol. II, John Wiley and Sons, Inc., New York, N. Y., 1943, p. 517.

(6) This product might have arisen by the migration of a methyl group from nitrogen to the ring by a mechanism that has earlier been discarded; see ref. 2.

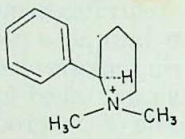
derivatives. Moreover, the two amines showed different infrared absorption bands in the 10–15 μ region.

The fact that quaternary ion III underwent the *ortho* substitution rearrangement unaccompanied by an appreciable amount of β-elimination may be due in part to the closeness of the methyl groups to the aromatic ring as indicated in IX. All conformations of the molecule have at least one of the methyl groups in a favorable position for the attack of its carbanion on the ring. On the other hand, the quaternary ions I and II have conformations which appear to place the methyl groups in less favorable positions for rearrangement; hence, even though they have fewer β-hydrogens than quaternary ion III, they exhibit relatively more β-elimination.



IX

An attempt to effect further rearrangement of methiodide V to produce a *meta*-bridge was unsuccessful. Although an appreciable amount of fairly constant boiling amine product was obtained, it was judged to be a mixture because of the wide melting range of its picrate. In line with the argument cited above, the only conformation of methiodide V that allows the approach of a methyl group to the aromatic ring appears to involve a strained ring. It is possible that a *meta*-bridge might be realized if a larger nitrogen-containing ring were employed. Studies along these lines are now being carried out.

Experimental[7]

1,1-Dimethyl-2-phenylpiperidinium Iodide (III).—A solution of 62 g. (0.40 mole) of 2-phenylpyridine and 88 g. of methyl iodide was allowed to stand at room temperature for three days. The solid which had formed was broken up, washed with ether and recrystallized from acetonitrile–ether to yield 113.8 g. of the quaternary salt, m.p. 141–144°.

A suspension of 56.9 g. of the methiodide and 1.0 g. of platinum oxide[8] in 250 ml. of ethanol was shaken under 50 p.s.i. of hydrogen until a pressure drop of 40 p.s.i. had occurred (1.5 hr.).[9] The remainder of the quaternary salt was treated in the same manner and the two reaction mixtures combined. The catalyst was removed by filtration and the amber filtrate reduced to about 100 ml. under vacuum. The residual oil was taken up in water and the solution saturated with sodium bicarbonate. The alkaline suspension was then extracted with ether and the organic layer dried over sodium sulfate. The yellow oil which remained behind when the solvent was removed *in vacuo* was distilled to afford 41.8 g. of 1-methyl-2-phenylpiperidine, b.p. 103–109° at 9 mm.

The solid which came out when a solution of the tertiary amine in 100 ml. of acetonitrile was treated with methyl iodide (65 g.) followed by ether was recrystallized from acetonitrile–ether to yield 74.1 g. (68% from 2-phenylpyridine) of III, m.p. 178–179.5°, lit.[4] 180°.

Rearrangement of III to IV.—Over a period of 10 minutes 74.1 g. (0.234 mole) of the solid methiodide III was added to 0.46 mole of sodium amide (from 10.6 g. of sodium metal) in 900 ml. of liquid ammonia. The light orange-tan suspension was stirred for an additional hour and then neutralized with 23 g. of solid ammonium chloride. The residue which remained after the ammonia had evaporated was washed thoroughly with about 1 l. of ether; these extracts were washed with water and dried over anhydrous sodium sulfate. The light yellow oil which remained after the ether was removed afforded 38.5 g. (83%) of IV, b.p. 104–106° at 4 mm.

The analytical sample, n^{24}D 1.5380, distilled at 95.5° at 3 mm.

Anal. Calcd. for $C_{13}H_{19}N$: C, 82.48; H, 10.12; N, 7.40. Found: C, 82.67; H, 9.92; N, 7.33.

The picrate of IV was formed from 0.5 g. of the amine and 10 ml. of saturated ethanolic picric acid and recrystallized to a constant m.p. of 169–170°.

Anal. Calcd. for $C_{19}H_{22}N_4O_7$: C, 54.54; H, 5.31; N, 13.38. Found: C, 54.61; H, 5.20; N, 13.35.

Exhaustive Oxidation of IV.—The tertiary amine IV (2.5 g., 0.013 mole) was added to a solution of 0.5 g. of potassium hydroxide and 6.25 g. of potassium permanganate in 100 ml. of water. The suspension was brought to reflux and, over a period of 48 hr., an additional 18.75 g. of permanganate was added in portions. The cooled suspension was filtered and reduced in volume to 30 ml. This solution was cooled in ice, saturated with hydrogen chloride and extracted with 120 ml. of ether. The solid which remained (1.2 g., 55%) on removing the ether was recrystallized from water. The m.p. of this acid, 216° dec., was not depressed by admixture with *o*-phthalic acid. The infrared spectrum of the oxidation product was superposable on that of an authentic sample of the dibasic acid.

Reaction of Amine IV with Methyl Iodide.—Forty ml. of methyl iodide was added to a solution of 38.5 g. (0.205 mole) of IV in 200 ml. of acetonitrile, with occasional cooling in an ice-bath; colorless crystals were observed to separate from the solution. The mixture was cooled for an additional hour and the crystals collected on a filter to afford 65.0 g. (96%) of colorless powdery needles, m.p. 211–214°.

A sample was crystallized from acetonitrile to give the analytical sample as heavy colorless prisms, m.p. 223–225°.

Anal. Calcd. for $C_{14}H_{22}NI$: C, 50.76; H, 6.70; N, 4.23. Found: C, 50.68; H, 6.58; N, 4.31.

Emde Reduction of the Methiodide V to VI.—Over a period of 50 minutes 276 g. of 5% sodium amalgam was added to a hot stirred solution of 10.5 g. (0.034 mole) of the quaternary salt in 200 ml. of water. The mixture was then heated (with stirring) on a steam-bath for 24 hr. The oily layer which separated when the reaction cooled was taken up in ether and the extract washed with water and dried over anhydrous sodium sulfate.

The oil which remained when the solvent was removed was distilled at 5 mm. to afford 5.53 g. of the amine, b.p. 126–128°.

The picrate, m.p. 108–109°, was obtained by reaction of 0.5 g. of the amine with 10 ml. of saturated ethanolic picric acid, followed by recrystallization of the resulting bright yellow crystals from ethanol.

Anal. Calcd. for $C_{20}H_{26}N_4O_7$: C, 55.29; H, 6.03; N, 12.90. Found: C, 55.12; H, 6.07; N, 12.93.

The remainder of the product (5.03 g.) in 10 ml. of acetonitrile was treated with 6.5 ml. of methyl iodide. The reaction was extremely exothermic, resulting in some loss of material. The quaternary salt thus obtained, m.p. 124–126°, was recrystallized from acetonitrile to a constant m.p. of 125–126°.

Anal. Calcd. for $C_{15}H_{26}NI$: C, 51.87; H, 7.55; N, 4.03. Found: C, 51.24, 51.33; H, 7.57, 7.46; N, 4.21.

Independent Synthesis of the Tertiary Amine VI. 1-Methyl-2-*o*-tolylpyridinium Iodide.—Thirty grams (0.21 mole) of methyl iodide was added to 20 g. (0.12 mole) of 2-*o*-tolylpyridine in an ice-cooled flask. The orange solid thus obtained was dissolved in chloroform and treated with activated charcoal. Yellow to orange crystals came out on the addition of ether. The yield of methiodide, m.p. 182–187°, was 34.7 g. (94%). This material was used in the next step without further purification.

A sample, m.p. 199–200°, was obtained by repeated recrystallization from acetonitrile–ether.

Anal. Calcd. for $C_{13}H_{14}NI$: C, 50.18; H, 4.53; N, 4.55. Found: C, 50.14; H, 4.56; N, 4.55.

1-Methyl-2-*o*-tolylpiperidine (VIII).—A suspension of 34.2 g. (0.109 mole) of the above methiodide and 0.5 g. of

(7) Boiling points are uncorrected; melting points are recorded as obtained on a Fisher–Johns melting point block. The microanalyses are by Galbraith Laboratories, Knoxville, Tenn.

(8) American Platinum Works, Newark, N. J.

(9) In a preliminary run it was noted that if the reaction is not stopped when one equivalent of hydrogen has been taken up, considerable overreduction probably in the form of ring cleavage occurs.

Digitized by Arya Samaj Foundation Chennai and eGangotri

platinum oxide in 200 ml. of ethanol was shaken under 60 p.s.i. of hydrogen. The pressure drop was less than 1 p.s.i.; 3.5 hours after an additional 0.5 g. of catalyst had been added, the theoretical amount (23 p.s.i.) of hydrogen had been taken up. The reaction was worked up in the same manner as described for the reduction of 1-methyl-2-phenylpyridinium iodide. Distillation of the residual oil afforded 15.6 g. (75%) of yellow liquid, b.p. 103–105° at 4.5 mm. This was redistilled through a short Vigreux column to yield 14.8 g. of yellowish oil, $n^{24}D$ 1.5280, b.p. 98–99° at 3.5 mm.

Anal. Calcd. for $C_{13}H_{19}N$: C, 82.48; H, 10.12; N, 7.40. Found: C, 82.30; H, 9.93; N, 7.29.

1,1-Dimethyl-2-*o*-tolylpiperidinium iodide was obtained as colorless fine crystals, m.p. 190–195°, from the reaction of 10.0 g. (0.053 mole) of the tertiary amine in 25 ml. of acetonitrile with 15 ml. of methyl iodide. The yield was 17.4 g. (99%).

A sample of this quaternary salt was recrystallized from acetonitrile–ether to a constant melting point of 206–208°. The mixed melting point of this with the methiodide V (223–225°) was 179–185°.

Anal. Calcd. for $C_{14}H_{22}NI$: C, 50.78; H, 6.70; N, 4.23. Found: C, 50.65; H, 6.72; N, 4.24.

1-Dimethylamino-5-*o*-tolylpentane (VI).—To a well-stirred hot solution of 16.4 g. (0.050 mole) of the above methiodide in 300 ml. of water there was added over 1 hr. 400 g. of 5% sodium amalgam. After an additional 26 hr. heating on steam, the reaction mixture was worked up as in the Emde reduction described above to afford 7.80 g. (77%) of the tertiary amine, b.p. 122–125° at 4.8 mm.

The picrate, m.p. 108–109°, and the methiodide, m.p. 125–126°, were prepared in the same manner as described above. A mixed m.p. of each of these derivatives with those of the amine obtained by reduction of V failed to show any depression.

Attempted Rearrangement of V.—The methiodide (20 g., 0.0605 mole) was added to 0.122 mole of sodium amide (from 2.8 g. of sodium metal) in 200 ml. of liquid ammonia. After 40 minutes stirring, the reaction was neutralized with 12 g. of solid ammonium chloride. The oil which was obtained when the reaction mixture was worked up in the usual manner was distilled through a short Vigreux column. At 2 mm., 2.72 g. of colorless liquid, b.p. 96–100°, was obtained; this was followed by 1.0 g., b.p. 100–110°; the residue (5.07 g.) had not yet come over when the bath temperature was 250°. The first fraction formed a picrate of m.p. 110–165°, which could not be recrystallized readily.

Substantially the same result was obtained with a reaction time of 5 hr. In this case, however, some ether-insoluble, rubber gum was obtained as well.

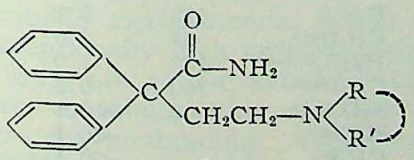
Antispasmodics. X. α,α-Diphenyl-γ-amino Amides[1]

BY ROBERT BRUCE MOFFETT AND BROOKE D. ASPERGREN

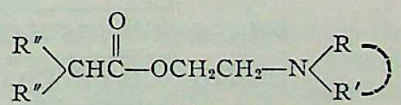
RECEIVED MARCH 25, 1957

A number of α,α-diphenyl-γ-amino amides, their salts and intermediate nitriles have been prepared and tested for anticholinergic activity. In several cases the same tertiary amino groups that previously gave highly active anticholinergics in the ester series also gave very active compounds when introduced into the γ-position of these amides. The effects of substitution or replacement of one of the phenyl groups and of branching the alkyl chain were also explored.

The reports of Bockmühl and Ehrhart[2] in which certain α,α-diphenylamino amides were shown to be powerful antispasmodic agents have stimulated considerable work[3] on this interesting type of compound. In our study of the relationship between structure and anticholinergic activity it seemed of interest to introduce, in the γ-position of these amides (I), some of the amino groups that gave good results in the ester type of anticholinergics[4] (II).



I



II

Table I lists the compounds tested in this study with their toxicities and antispasmodic and gastric antisecretory activities. For comparison the activities of atropine, Pamine,[5] and a few previously reported amides have also been included.

It would hardly be expected that any correlation would exist between the anticholinergic activity and the type of amino groups in molecules so fundamentally different, and indeed no *close* correlation was found. For example, esters containing dimethylamino and piperidyl groupings have not been very effective, whereas at least one amide with each of these groupings has been outstanding enough to market.[6] On the other hand, some pyrrolidine-containing amides are no better than the corresponding pyrrolidine-containing esters. However, the methyl-substituted pyrrolidine-containing esters III, IV and V had atropine indexes (in Thiry-vella dogs) of 2, 1 and 1, and antisecretory ED_{50}'s of 0.4, 0.5 and 0.1, respectively, while the

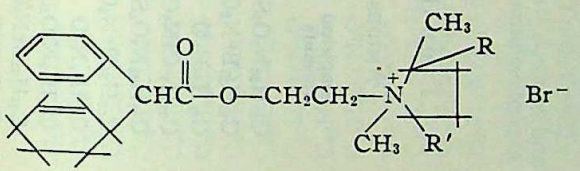
[a] The compounds were administered to mice intraperitoneally. The values are approximations with an accuracy of about +100% to −50%. [b] The antispasmodic activity was determined in Thiry-Vella dogs [O. H. Plant, *J. Pharmacol. Exp. Therap.*, 16, 311 (1921)]. The results are expressed as the ratio of the activity to that of atropine sulfate (Atropine Index). [c] The gastric antisecretory activity was determined in pyrolic ligration rats [F. E. Visscher, P. H. Seay, A. P. Tazelaar, Jr., W. Veldkamp and M. J. VanderBrook, *J. Pharmacol. Exp. Therap.*, 110, 188 (1954)]. It is expressed as the effective dose necessary to reduce the gastric secretion by approximately 50%. [d] The corresponding free base, methiodide, and ethosulfate have been reported previously.[3c] [e] This compound was reported by us before the Division of Medicinal Chemistry, A.C.S., at Los Angeles, California, March, 1953. [f] The corresponding free base and methyl *p*-toluenesulfonate quaternary salt have been reported.[3c] [g] Preparation by a different method reported by D. J. Dupré, J. Elks, B. A. Hems, K. N. Speyer and R. M. Evans, *J. Chem. Soc.*, 506 (1949). [h] Preparation reported in paper IX of this series, THIS JOURNAL, 79, 3186 (1957).

corresponding amides had atropine indexes of 3.5, 4 and 3 and ED_{50}'s of 0.08, 0.003 and 0.1. Another grouping occurring in active compounds in both series was the diisopropylamino group. An



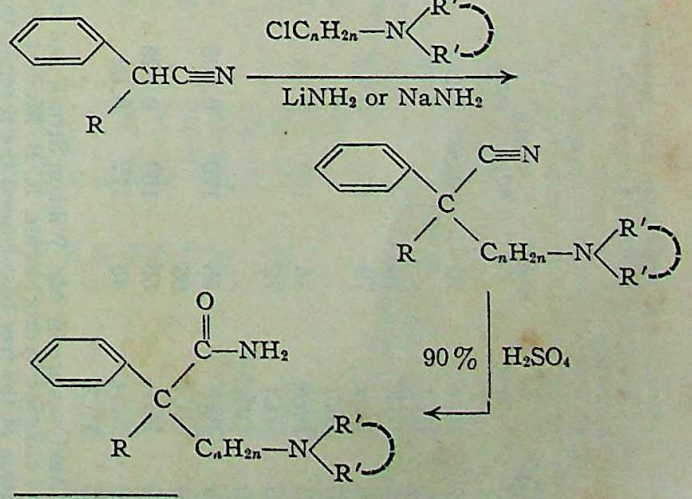
III, R and R′ = H
IV, R = CH_3, R′ = H
V, R = H, R′ = CH_3

ester containing this group, 2-(diisopropylamino)-ethyl-9-xanthine carboxylate methobromide is on the market[7] and the corresponding amide (No. 15 (CH_3Br), Table I) has been extensively studied by Dr. Paul Janssen and associates.[3d] One compound, α,α-diphenyl-γ-(2,2,4-trimethyl-1-pyrrolidyl)-butyramide methobromide (Table I, no. 9) showed exceptionally high antispasmodic activity but only moderate gastric antisecretory activity. The esters containing this trimethylpyrrolidyl group[4] were not outstanding. Therefore, whereas broadly speaking, a surprising number of groups previously found in active esters are also present in our most active amides, considerable variation is apparent between parallel members of the two classes. In addition, it is clear that ED_{50}'s do not go hand-in-hand with atropine indexes.

The amide series (Table I) has been extended by the preparation of a few compounds in which one of the phenyl groups is replaced by an isopropyl group. These were found to be less active than the corresponding diphenyl amides. Substitution of a chlorine atom in the *meta* or *para* positions of one of the phenyl rings tended to decrease the anticholinergic activity. Compounds with the amino group on the δ-carbon atom had very little activity. α,α-Diphenyl-γ-amino amides with a methyl group on the γ-carbon atom are well known.[3a,b,c] Aminopentamide[8] (Table I, no. 16) is of this type. In one case in which two methyl groups were substituted on the γ-carbon atom, the product (Table I, no. 18, MeBr) was considerably more active than the corresponding compound with no methyls on the γ-carbon.

In general, the quaternary salts (methobromides) were more active both as antispasmodics and as antisecretories than the corresponding tertiary amine salts. Aminopentamide[9] is an exception, being more active than its methiodide.[3a] The amine oxides of a few of these amino amides were prepared. They were considerably less toxic than the parent amines but also less active.

A number of the intermediate nitriles were also tested but were found to be much less active as anticholinergics than the corresponding amides.



(7) Probanthine, G. D. Searle and Company.

(8) Centrine, Bristol Laboratories, Inc.

[a] Analyses are by Mr. William Struck and staff of our Analytical Chemistry Laboratory. [b] Crystallized from isopropyl alcohol. [c] Prepared from 2-(2,2-dimethyl-1-pyrrolidyl)-ethyl chloride hydrochloride, R. B. Moffett, J. L. White, B. D. Aspergren and F. E. Visscher, THIS JOURNAL, **77**, 1565 (1955). The addition of hydrochloric acid to the toluene solution of the free base caused the precipitation of the hydrochloride. It was collected, dried and recrystallized from a mixture of ethanol and methyl ethyl ketone. [d] This was prepared from 2-(2,5-dimethyl-1-pyrrolidyl)-ethyl chloride hydrochloride, W. B. Reid, J. B. Wright, H. G. Kolloff and J. H. Hunter, THIS JOURNAL, **70**, 3100 (1948). [e] Yield based on the reaction of diphenylacetonitrile without isolation of the free base. A sample was recrystallized from ethyl acetate. [f] This methobromide was prepared from the known base[2] by Mr. John L. White in these laboratories. It was recrystallized from methanol plus methyl ethyl ketone. [g] This was prepared from 2-(2,6-dimethyl-1-piperidyl)-ethyl chloride hydrochloride, J. W. Cusic and R. A. Robinson, *J. Org. Chem.*, **16**, 1921 (1951). (See Table I, footnote *g*.) [h] The addition of hydrochloric acid to the toluene solution of the crude free base caused the precipitation of the hydrochloride. It was collected, dried and recrystallized from methyl ethyl ketone. [i] Prepared from α-phenyl-β-methylbutyronitrile (Table III, footnote *k*) by the general procedure described in the Experimental part except sodium amide was used in place of lithium amide. [j] Recrystallized from ethanol plus ethyl acetate.

[a] Melting points are uncorrected. [b] See Table II, footnote *a*. [c] The free base and several quaternary salts of this amide have been reported by Janssen, *et al.*[3d] [d] Some samples of this compound which crystallized from the reaction mixture (tetrahydrofuran) had a melting point of 177.5–178.5°. These had the correct analysis (Found: Br, 19.23) and the same infrared spectrum in chloroform solution although different in a mull. The two forms must therefore be dimorphic. See Table I, footnote *e*. [e] The free base could not be obtained crystalline. The hydrochloride was prepared from the crude free base. The yield for the methobromide is based on the pure hydrochloride from which it was prepared. [f] The free base is reported by Cheney, *et al.*[3o] [g] Water determination by the Karl Fischer method indicated approximately one molecule of water of crystallization. [h] The intermediate nitrile was distilled, b.p. 174° (0.03 mm.), but was not obtained in analytical purity. The yield is the over-all yield from diphenylacetonitrile. [i] Prepared from the corresponding nitrile, D. J. Dupre, J. Elks, B. A. Hems, K. N. Speyer and R. M. Evans, *J. Chem. Soc.*, 500 (1949). [j] The intermediate α-(*p*-chlorophenyl)-α-phenyl-γ-(2,2-dimethyl-1-pyrrolidyl)-butyronitrile was prepared from α-(*p*-chlorophenyl)-α-phenylacetonitrile [M. E. Speeter, L. C. Cheney and S. B. Binkley, THIS JOURNAL, 72, 1659 (1950)] in 55% yield, b.p. 170° (0.1 mm.), but not obtained in analytical purity. [k] The intermediate α-phenyl-α-isopropyl-γ-(2,2-dimethyl-1-pyrrolidyl)-butyronitrile was prepared from α-phenyl-β-methylbutryonitrile (D. A. Shirley, "Preparation of Organic Intermediates," John Wiley and Sons, Inc., New York, N. Y., 1951, p. 252) in 44% yield by the general procedure described in the Experimental Part, except sodium amide was used in place of lithium amide. The yield was 44%, b.p. 120° (0.015 mm.). It was not obtained in analytical purity but was hydrolyzed to the amide and converted to the hydrochloride.

Digitized by Arya Samaj Foundation Chennai and eGangotri

Except as noted in the experimental part or in the tables, the amides were prepared by alkylating the appropriate disubstituted nitrile with the requisite amino alkyl halide and hydrolyzing with 90% sulfuric acid. An example is given in the Experimental part.

Acknowledgments.—The authors are indebted to Dr. F. E. Visscher, Dr. P. H. Seay, Mr. Wm. Veldkamp, Mr. O. F. Swoap and associates of our Department of Pharmacology for the pharmacological data. The authors also wish to express their appreciation to Dr. R. V. Heinzelman of our Department of Chemistry for guidance in this work.

Experimental

Unless otherwise indicated all the nitriles, amides and their salts were prepared essentially as described in the following examples.

α,α-Diphenyl-γ-(2-methyl-1-pyrrolidyl)-butyronitrile.—To a suspension of 13.8 g. (0.6 mole) of lithium amide in 900 ml. of dry toluene, was added slowly with stirring 96.62 g. (0.5 mole) of diphenylacetonitrile. The mixture was heated and stirred under reflux for four hours. A solution of 2-(2-methyl-1-pyrrolidyl)-ethyl chloride was prepared by adding an excess of 40% aqueous sodium hydroxide to 92.1 g. (0.5 mole) of the corresponding hydrochloride[9] and extracting with 500 ml. of toluene in several portions. The toluene solution was dried over potassium carbonate and slowly added to the hot suspension of the lithium derivative of diphenylacetonitrile. After heating under reflux with stirring for 18 hours the mixture was cooled and 300 ml. of water was cautiously added. The toluene layer was extracted with dilute hydrochloric acid, and this aqueous acid solution was washed with ether and made basic with 20% sodium hydroxide solution. The free base was extracted with several portions of benzene which were washed with water and dried over sodium sulfate. After removal of the solvent the product was distilled under reduced pressure giving 107 g. (70.3%) of nearly colorless oil; b.p. 173–175° (0.2 mm.).

Hydrochloride.—A sample of the above nitrile in ethyl acetate was acidified with ethanolic hydrogen chloride. The product was recrystallized from isopropyl alcohol giving white crystals, m.p. 189–192°.

α,α-Diphenyl-γ-(2-methyl-1-pyrrolidyl)-butyramide.—A mixture of 126 ml. of concentrated sulfuric acid, 12.6 ml. of water and 67 g. (0.22 mole) of the above nitrile free base[10] was heated with stirring on a steam-bath for four hours. The mixture was cooled, poured onto ice and made strongly basic with ammonium hydroxide. The product separated as a gum which crystallized on standing. It was collected, dried and recrystallized from 400 ml. of isopropyl alcohol giving 52.2 g. (74%) of white crystals, m.p. 142–144°.

Hydrochloride.—A sample of the above amide in ethyl acetate was acidified with ethanolic hydrogen chloride. The resulting gum was recrystallized from methyl ethyl ketone; m.p. 207–209°.

Acid Sulfate.—A sample of the above amide free base in methanol was treated with one molar equivalent of concentrated sulfuric acid. The acid sulfate was precipitated by the addition of absolute ether and was recrystallized from ethanol; m.p. 185–187°.

Methobromide.—A large excess of cold methyl bromide was added to a cold solution of 20 g. (0.062 mole) of the above amide free base in 100 ml. of benzene.[11] The flask (round) was tightly stoppered, and allowed to stand at room temperature for three days. The product was collected giving 25.5 g. (98.5%) of crystals, m.p. 230–233°. This was recrystallized from a mixture of methyl and isopropyl alcohols giving 22.8 g. of white crystals, m.p. 231–233°.

α,α-Diphenyl-γ-(1-piperidyl)-butyramide N-Oxide.—To a suspension of 19.7 g. (0.061 mole) of α,α-diphenyl-γ-(1-piperidyl)-butyramide[2] in about 1 l. of methanol was added 35 ml. of 30% hydrogen peroxide. The mixture was shaken for three days during which time the solid dissolved. The excess hydrogen peroxide was decomposed by adding an aqueous slurry of platinum-on-charcoal and shaking for five hours. The solution was filtered and distilled below 50° under reduced pressure. The residue was dissolved in boiling ethyl acetate and on cooling an oil separated which soon crystallized. The crystalline solid was collected and air dried; weight 22 g., m.p. 70–75°. This appears to be a hydrate containing about 1.5 molecules of water.

Anal. Calcd. for $C_{21}H_{26}N_2O_2 \cdot 1\frac{1}{2}H_2O$: C, 69.0; H, 8.00; N, 7.67; H_2O, 7.40. Found: C, 68.94, 69.95; H, 8.18, 7.82; N, 7.61; H_2O, 8.88 by Karl Fischer method.[12]

A sample of this hydrate was mixed with 75 ml. of boiling acetone. Most of it dissolved and then immediately began to precipitate as a white crystalline solid. After boiling a few minutes and cooling the anhydrous material was obtained, m.p. 167.5–168.5°.

α,α-Diphenyl-γ-(dimethylamino)-valeramide N-Oxide Hydrate.—This was prepared by a procedure similar to the above from 14.8 g. (0.05 mole) of the corresponding free base[3c] and 10 ml. of 30% hydrogen peroxide in 190 ml. of methanol. The product was crystallized from 80% aqueous isopropyl alcohol and appears to contain approximately one molecule of water as a hydrate.

Hydrobromide.—To a solution of 11.2 g. (0.04 mole) of the above free base in 50 ml. of methanol was added 4 ml. (0.041 mole) of 48% hydrobromic acid. The solution was distilled nearly to dryness below 40° under reduced pressure. The resulting sirup was dissolved in 25 ml. of methyl ethyl ketone and diluted to turbidity at the b.p. with ethyl acetate. After cooling in the refrigerator the crystals were collected and dried for a short time in a vacuum desiccator. Too much drying causes the material to turn red; yield 10.94 g. (82.5%). It appears to contain a small amount (about 1/4 molecule) of water of crystallization.

2-(2,2,4-Trimethyl-1-pyrrolidyl)-ethyl Chloride Hydrochloride.—Hydrogen chloride gas was passed into a solution of 42 g. (0.267 mole) of 2-(2,2,4-trimethyl-1-pyrrolidyl)-ethanol[13] in 200 ml. of benzene, with stirring and cooling by an ice-bath, until it tested strongly acid. While still cooled by the ice-bath, 24.5 g. (0.4 mole) of thionyl chloride was added dropwise with stirring. The solution was then gently heated under reflux for two hours during which sulfur dioxide and hydrogen chloride were evolved. About 50 ml. of solvent was removed by distillation and the mixture was cooled. The crystalline product was collected and washed with absolute ether; yield 55.3 g. (98%), m.p. 162–165°. Recrystallization from isopropyl alcohol raised the melting point to 164–166°.

Anal. Calcd. for $C_9H_{19}Cl_2N$: C, 50.95; H, 9.03; Cl, 33.42; N, 6.60. Found: C, 51.29; H, 9.19; Cl, 33.22; N, 6.96.

2-Methyl-2-(1-pyrrolidyl)-propyl Chloride Hydrochloride.—This was prepared by a procedure similar to the above from 104 g. (0.728 mole) of 2-methyl-2-(1-pyrrolidyl)-propanol,[14] 65 ml. of thionyl chloride and 500 ml. of benzene. The product was recrystallized from a mixture of ethanol and ethyl acetate; yield 138 g. (96%), m.p. 145–147°.

Anal. Calcd. for $C_8H_{17}Cl_2N$: C, 48.49; H, 8.65; N, 7.07; Cl, 35.79. Found: C, 48.79; H, 8.74; N, 6.78; Cl, 35.58.

3-(1-Pyrrolidyl)-propyl Chloride Hydrochloride.—This was prepared by a similar procedure from 200 g. (1.55 moles) of 3-(1-pyrrolidyl)-propanol,[15] 135 ml. of thionyl chloride and 1 l. of benzene. The product was recrystallized from a mixture of isopropyl alcohol and ethyl acetate; yield 250 g. (88%), m.p. 140–142°.

Anal. Calcd. for $C_7H_{15}Cl_2N$: C, 45.66; H, 8.21; Cl, 38.52; N, 7.61. Found: C, 46.13; H, 8.40; Cl, 38.87; N, 7.78.

(10) Hydrochlorides or other salts may be used equally well for this hydrolysis.

(11) In general methyl ethyl ketone was found to be a superior solvent for the preparation of quaternary salts.

(12) The Karl Fischer water determination tends to give high results with amine oxide hydrates probably due to reaction of the N-oxide with the reagent.

m-Chlorophenylphenylacetonitrile.—This was prepared essentially as described for diphenylacetonitrile[16] from 203.2 g. (2.0 moles) of *m*-chlorophenylacetonitrile, 110.3 ml. (2.2 moles) of bromine, 936 ml. of benzene and 267 g. (2.0 moles) of aluminum chloride. The product was distilled under reduced pressure, b.p. 145–148° (0.25 mm.), giving an oil which crystallized from 300 ml. of isopropyl alcohol, m.p. 50–52°; yield 230.3 g. (50.6%).

Anal. Calcd. for $C_{14}H_{10}ClN$: C, 73.85; H, 4.43; N, 6.15; Cl, 15.57. Found: C, 73.95; H, 4.25; N, 6.09; Cl, 15.59.

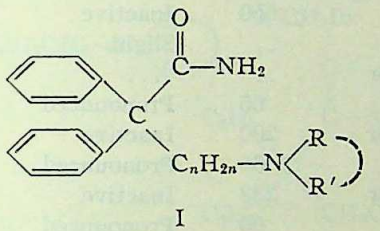
Antispasmodics. XI. α,α-Diphenyl-γ-amino-N-monosubstituted Amides[1]

BY ROBERT BRUCE MOFFETT, BROOKE D. ASPERGREN AND M. E. SPEETER

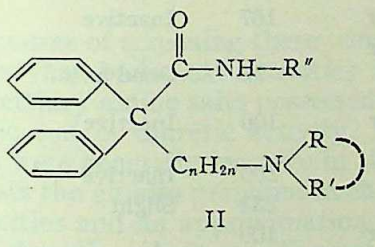
RECEIVED MARCH 25, 1957

Although α,α-diphenyl-γ-tertiaryamino amides (I) are well known as anticholinergics, no similar amides monosubstituted on the amide nitrogen (II) have been previously reported. A series of these have now been made but unexpectedly they have little if any anticholinergic properties. However, these tertiary amino amides were found to be powerful oxytocics and/or diuretics.

Amides of the general type I, unsubstituted on the amide nitrogen, are well known as anticholinergics.[2] In our study of the relationship of structure



I

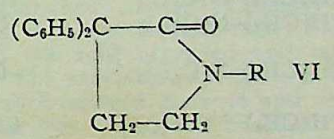


II

to anticholinergic activity it seemed desirable to prepare some amides substituted on the amide nitrogen. A search of the literature revealed that while many unsubstituted amides and a few disubstituted amides[3–5] of this type are known, none of the N-monosubstituted amides (II) have been reported.

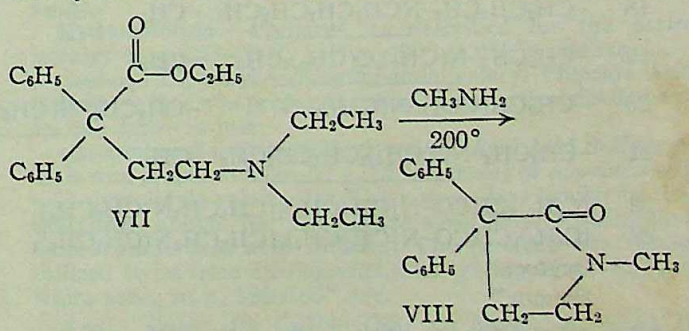
The simplest method for preparing these substituted amides would involve hydrolysis of the well known nitriles III, to the acids IV. These would then be converted to the acid chlorides V, and treated with the requisite primary amine.

This (method A) gave good results when $-C_nH_{2n}-$ was $-CH_2CH(CH_3)-$ or $-CH_2CH_2CH_2-$ but when $-C_nH_{2n}-$ was $-CH_2CH_2-$ or $-CH(CH_3)CH_2-$ the cyclization reaction to give 3,3-diphenylpyrrolidones (VI)[6,7] took precedence and little if any of the desired amides were obtained.



VI

Likewise when the ethyl ester VII was heated with methylamine under sufficiently vigorous conditions to cause reaction, the only product isolated was a pyrrolidone (VIII). It is interesting that in this case the substituent on the nitrogen was methyl rather than ethyl.



VII VIII

An attempt to alkylate a diphenyl-N-monosubstituted acetamide with an amino alkyl chloride gave only N-alkylation even when a hindered amide (isopropyl) was used.

The amides (II, $-C_nH_{2n}-$ = $-CH_2CH_2-$ or $-CH(CH_3)CH_2-$) could, however, be obtained readily (with one exception) by alkylating the correspond-

ing unsubstituted amides with sodium amide and an alkyl halide (method B). Methyl bromide was used in this work. The one exception noted was the case where R and R′ were methyls. In this case the attack was on the amino nitrogen and the quaternary salt was the principal product.

These amides in the form of their hydrochlorides and also their methobromides were tested as anti-

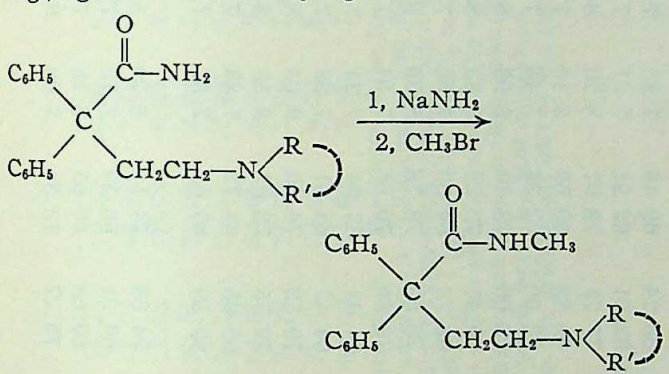
spasmodics in Thiry-Vella dogs and as gastric antisecretories in pyloric ligation rats. Surprisingly neither the tertiary amine nor quaternary salts showed any appreciable anticholinergic activity, being generally less than one-tenth as active as atropine sulfate as antispasmodic and inactive at 1 mg./kg. as antisecretory agents.



In the course of screening these compounds for a wide variety of biological activities it was found that the tertiary amine salts possessed a high order of oxytocic and/or diuretic activity. The quaternary salts were generally inactive in these respects. Table I lists the amides prepared in this study with their toxicities and an approximation of their oxytocic and diuretic activities. Several of these are considered to have sufficiently desirable properties to warrant clinical investigation.

Acknowledgments.—The authors are indebted to Dr. P. H. Seay, Mr. Wm. Veldkamp, Mr. O. F. Swoap, Mr. B. E. Graham and associates of our Department of Pharmacology for the pharmacological data. The authors also wish to express their appreciation to Dr. R. V. Heinzelman of our Department of Chemistry for guidance in this work.

Experimental

Method A (compounds no. 6–18 and 20 in Table II were made by this method).

α,α-Diphenyl-γ-dimethylamino-N-methylvaleramide.—To a cooled suspension of 207 g. (0.5 mole) of α,α-diphenyl-γ-dimethylaminovaleryl chloride acid sulfate[6] in 600 ml. of benzene was added slowly 78 g. of methylamine in 300 ml. of benzene with stirring. The mixture was allowed to warm to room temperature with stirring for 4 hours. It was then heated under reflux on a steam-bath for one-half hour. After cooling, the benzene solution was well washed with water and extracted with dilute hydrochloric acid. The acidic aqueous solution was made basic with sodium hydroxide and the free base was collected on a filter and dried. The product was recrystallized from isopropyl alcohol giving 138.5 g. (89.2%) of white crystals, m.p. 168–169°.

Hydrochloride.—To a warm solution of 62.1 g. (0.2 mole) of the above free base in 700 ml. of ethyl acetate was added a slight excess of ethanolic hydrogen chloride. On cooling, the hydrochloride crystallized giving 64.5 g. (93%) of white crystals, m.p. 217–219°.

Methobromide.—To a cold solution of 10 g. (0.032 mole) of the above free base in 100 ml. of benzene was added a large excess of cold methyl bromide. The flask was stoppered and allowed to stand at room temperature for 4 days. The product was collected on a filter, dried, m.p. 190–192°.

α,α-Diphenyl-γ-dimethylamino-N-methylvaleramide N′-Oxide.—A mixture of 31.0 g. (0.1 mole) of the above free base, 350 ml. of methanol and 25 ml. of 30% hydrogen peroxide was stirred rapidly at room temperature for 22 hours by which time all the solid had dissolved. After standing for 3 days the excess hydrogen peroxide was decomposed by adding a small amount of an aqueous slurry of platinum-on-charcoal and stirring for 5 hours. The solution was filtered through Supercel and distilled practically to dryness under reduced pressure below 50°. The crystalline residue was recrystallized from ethyl acetate giving white crystals, m.p. 141–144° after sintering at about 120°. This appeared to be a solvate which lost weight on drying at 50° (20 mm.) for 20 hours; yield 29.4 g. (90%); m.p. 147–148.5°.

***dextro*-α,α-Diphenyl-γ-dimethylaminovaleric Acid Acid Sulfate.**—A mixture of 138 g. (0.5 mole) of *dextro*-α,α,γ-dimethylaminovaleronitrile,[8] 175 ml. of concentrated sulfuric acid and 107 ml. of water was heated under reflux at 150° for 5 hours. After cooling it was poured onto ice and the white solid was collected on a filter. This was dissolved in 290 ml. of boiling absolute ethanol and diluted with an equal amount of ether. The product was collected and dried giving 322 g. (94%) of the acid sulfate salt; m.p. 195–198°; $[\alpha]^{22}D$ +74° (1.0% in methanol).

Free Basic Acid.—A sample of the above salt was dissolved in dilute sodium hydroxide and made just acid with acetic acid. The product was collected and dried; m.p. 219–221° dec.; $[\alpha]^{22}D$ +115° (1.0% in methanol).

Anal. Calcd. for $C_{19}H_{23}NO_2$: C, 76.73; H, 7.79; N, 4.71. Found: C, 76.74; H, 7.70; N, 4.76.

***dextro*-α,α-Diphenyl-γ-dimethylaminovaleryl Chloride Acid Sulfate.**—A mixture of 105 g. (0.265 mole) of the above *dextro* acid sulfate salt, 120 ml. of thionyl chloride and 150 ml. of benzene was heated under reflux with stirring for 45 minutes. All the acid dissolved and later the product crystallized. The excess thionyl chloride was removed by distillation under reduced pressure and an additional 100 ml. of benzene was added and distilled. The crystalline product was collected, washed with benzene and absolute ether and dried in a vacuum desiccator; yield 104 g. (95%).

***levo*-α,α-Diphenyl-γ-dimethylaminovaleric Acid Acid Sulfate.**—This was prepared as described above for the *dextro* isomer; yield 81%; m.p. 195–198°, $[\alpha]^{22}D$ −76° (1.0% in methanol).

Free Basic Acid.—Prepared as described for the *dextro* isomer; m.p. 219–221° dec., $[\alpha]^{22}D$ −111° (1.0% in methanol).

Hydrochloride.—Prepared as described for the *dextro* isomer; m.p. 228–230°, $[\alpha]^{22}D$ −90° (1.0% in methanol).

***levo*-α,α-Diphenyl-γ-dimethylaminovaleryl Chloride Acid Sulfate.**—This was prepared in 96% yield as described above for the *dextro* isomer.

α,α-Diphenyl-γ-(1-pyrrolidyl)-valeric Acid Acid Sulfate.—This was prepared from 50 g. (0.146 mole) of α,α-diphenyl-γ-(1-pyrrolidyl)-valeronitrile[2] by a procedure similar to that described above for the *dextro*-α,α-diphenyl-γ-dimethylaminovaleric acid acid sulfate. The product was recrystallized twice from alcohol plus ether giving 50 g. (82%) of white solid, m.p. 180–185° dec.

Anal. Calcd. for $C_{21}H_{27}NO_6S$: C, 59.83; H, 6.45; N, 3.33; S, 7.61. Found: C, 60.16; H, 6.71; N, 3.50; S, 7.52.

β-Pyrrolidylethylamine.[9]—To 853 g. (12 moles) of dry pyrrolidine, in a 5-l. flask, was added slowly 499 g. (2.44 moles) of β-bromoethylamine hydrobromide with vigorous stirring and cooling by an ice-bath. The addition was carried out at such a rate that the temperature did not rise

(8) A. Pohland, F. J. Marshall and T. P. Carney, THIS JOURNAL, **71**, 460 (1949).

(9) This compound has been previously reported, J. J. van Alphen, *Rec. trav. chim.*, **58**, 1105 (1939), and R. H. Reitsema and J. H. Hunter, THIS JOURNAL, **70**, 4009 (1948), but the present method appears to be more convenient.

[a] Unless otherwise indicated the yields of the salts are calculated from the corresponding free bases. The yields of the bases are calculated from the acid chlorides (method A, used for numbers 6 to 18 inclusive and for number 20) or the amides (method B, used for numbers 1 to 5 inclusive and for number 21). [b] Analyses and rotations are by Mr. William Struck and staff of our Analytical Chemistry Laboratory. [c] This yield is based on the corresponding unsubstituted amide. The free base was not isolated in pure form. [d] This yield is based on the corresponding purified hydrochloride. [e] $[\alpha]^{22}D$ +100° (1% in MeOH). [f] $[\alpha]^{22}D$ +66° (1.5% in MeOH). [g] $[\alpha]^{22}D$ +28° (1.5% in MeOH). [h] $[\alpha]^{22}D$ −98° (0.7% in MeOH). [i] $[\alpha]^{22}D$ −64° (0.7% in MeOH). [j] $[\alpha]^{22}D$ −29° (1.0% in MeOH). [k] This yield is based on the corresponding acid chloride acid sulfate salt. The free base was not isolated in pure form. [l] This was prepared from the acid sulfate of α,α-diphenyl-δ-diethylaminovaleric acid (D. J. Dupre, J. Elks, B. A. Hems, K. N. Speyer and R. M. Evans, *J. Chem. Soc.*, 500 (1949)) *via* the acid chloride, and free basic amide, neither of which were obtained crystalline. The procedure was similar to that described in the experimental section for the corresponding pyrrolidyl compounds. [m] This was prepared from the acid sulfate salt of the corresponding basic acid (Experimental section) *via* the acid chloride which, however, was not isolated.

above 10°. Most of the excess pyrrolidine was then distilled through an efficient column and recovered. To the residue was added with stirring 240 g. (6 moles) of sodium hydroxide in 240 ml. of water. The oil was decanted and dried over solid potassium hydroxide. The sodium bromide and potassium hydroxide residues were extracted with absolute ether which was added to the oil and dried over potassium carbonate. After filtration the solution was carefully distilled though an efficient column. The product distilled at 164–167° giving 220 g. (80%) of colorless liquid; $n^{25}D$ 1.4672.

α,α-Diphenyl-γ-dimethylamino-N-[2-(1-pyrrolidyl)-ethyl]-valeramide Dihydrochloride.—A solution of 70 g. (0.61 mole) of β-pyrrolidylethylamine in 250 ml. of benzene was cooled in an ice-bath and 82.8 g. (0.2 mole) of α,α-diphenyl-γ-dimethylaminovaleryl chloride acid sulfate[6] was added in small portions with stirring during one-half hour. After stirring for 2 hours at room temperature and 15 minutes under reflux the mixture was cooled and filtered. The filtrate was washed well with water and extracted with dilute hydrochloric acid. The aqueous acid solution was washed with ether and made basic with sodium hydroxide. The free base was extracted with benzene which was washed with water and the solvent was distilled.

The residual free base was dissolved in ethyl acetate and a slight excess of ethanolic hydrogen chloride was added. After cooling the product was collected giving 57.4 g. (62%) of white crystals, with the properties given in Table II.

Method B (compounds no. 1–5 and 21 in Table II were prepared by this method from amides previously described[2]).

α α-Diphenyl-γ-diethylamino-N-methylbutyramide Hydrochloride.—A mixture of 63.5 g. (0.205 mole) of α,α-diphenyl-γ-diethylaminobutyramide,[4] 8 g. (0.205 mole) of sodium amide and 500 ml. of dry toluene was heated under reflux for 2.5 hours. After cooling, a solution of 19.5 g. (0.205 mole) of methyl bromide in 100 ml. of dry toluene was added slowly. After stirring for 1 hour more water was added. The organic layer was extracted with dilute hydrochloric acid and this acid solution was again made basic with dilute sodium hydroxide. The free base was extracted with benzene and the solvent was distilled leaving 40 g. of yellow oil. This was dissolved in 400 ml. of methyl ethyl ketone and a slight excess of ethanolic hydrogen chloride was added. The hydrochloride separated as a white solid; m.p. 175–185°. This product contained a small amount of the hydrochloride of the starting material which was removed by repeated crystallizations from isopropyl or ethyl alcohol. The over-all yield was 23%. The infrared spectrum[10] indicated that this was monosubstituted amide essentially free from unsubstituted or disubstituted amides.

Reaction of Ethyl α,α-Diphenyl-γ-diethylaminobutyrate with Methylamine.—A solution of 25 g. (0.074 mole) of ethyl α,α-diphenyl-γ-diethylaminobutyrate[11] and 47.5 g. (1.53 moles) of methylamine in 75 ml. of ethylene glycol gave no reaction at room temperature or at 100°, but reacted when heated in an autoclave at 200° for 15 hours. On standing, crystals separated which were collected, washed with water and dried; m.p. 140–145°. After two recrystallizations from benzene–cyclohexane, it gave a product, m.p. 144–146°. This was found by mixed melting point and comparison of the infrared spectrum[10] with that of an authentic sample to be 1-methyl-3-diphenylpyrrolidone-2.[12]

α,α-Diphenyl-N-isopropylacetamide.—A mixture of 72.6 ml. (1.0 mole) of thionyl chloride, 106.1 g. (0.5 mole) of diphenylacetic acid and 100 ml. of benzene was heated under reflux for 45 minutes. The benzene and excess thionyl chloride were distilled under reduced pressure and 75 g. (1.26 moles) of isopropylamine in 200 ml. of dry benzene was added slowly with cooling. After stirring for 2 hours, the mixture was heated to the boiling point, filtered and cooled. The crystalline amide was collected and recrystallized from benzene giving 89 g. (70%) of white solid, m.p. 158–159°.

Anal. Calcd. for $C_{17}H_{19}NO$: C, 80.59; H, 7.56; N, 5.53. Found: C, 80.89; H, 7.48; N, 5.81.

α,α-Diphenyl-N-isopropyl-N-(2-diethylaminoethyl)-acetamide Hydrochloride.—To a suspension of 12.5 g. (0.32 mole) of sodium amide in 700 ml. of dry toluene was added

(10) The infrared spectra are by Dr. James L. Johnson and associates of our Department of Physics.

Digitized by Arya Samaj Foundation Chennai and eGangotri

78.49 g. (0.31 mole) of α,α-diphenyl-N-isopropylacetamide and the mixture was heated under reflux with stirring for 3 hours. A solution of 44.7 g. (0.33 mole) of β-diethylaminoethyl chloride in 100 ml. of dry toluene was added slowly with stirring at reflux temperature and the heating was continued for 20 hours. The toluene solution was washed with water, and extracted with dilute hydrochloric acid. The aqueous solution was washed with toluene and made basic with sodium hydroxide. The free base was extracted with benzene which was washed with water, dried over sodium sulfate and the solvent distilled. A yellow oil remained which could not be crystallized.

The free base was dissolved in methyl ethyl ketone, acidified with a slight excess of ethanolic hydrogen chloride and evaporated. A gum was obtained which crystallized from dioxane giving white crystals, with the properties given in Table II.

Methobromide.—An aqueous solution of 10 g. of this hydrochloride was made basic with sodium hydroxide and extracted with benzene. A portion of the benzene was distilled to remove water and cooled. Then 30 g. of cold methyl bromide was added, the flask was stoppered, clamped and allowed to stand at room temperature for 3 days. Concentration of the solution caused an oil to separate which solidified on trituration with ether. It was recrystallized from ethyl acetate and a little ethanol giving crystals, m.p. 76–78°. Recrystallization of this material gave a different modification, m.p. 161–163°.

[CONTRIBUTION FROM THE RESEARCH LABORATORIES OF THE UPJOHN COMPANY]

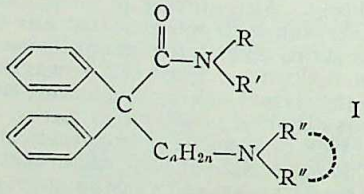
Antispasmodics. XII. α,α-Diphenyl-tertiaryamino-N,N-disubstituted Amides[1]

BY ROBERT BRUCE MOFFETT AND BROOKE D. ASPERGREN

RECEIVED MARCH 25, 1957

A series of α,α-diphenyl-γ-tertiaryamino-N,N-disubstituted amides (I, R and R′ = alkyl) have been prepared. In general they have been found to have little if any anticholinergic properties, but, like the monosubstituted amide series, the acid addition salts are oxytocics and/or diuretics.

Amides of the general type I (R and R′ = H), unsubstituted on the amide nitrogen, are well known as anticholinergics.[2]

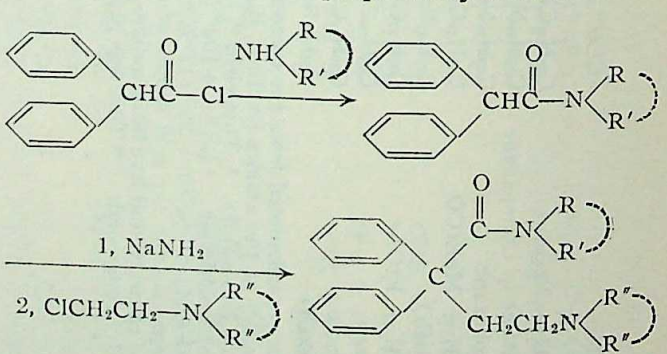


I

The preceding paper of this series[3] reported monosubstituted amides (I, R = H, R′ = alkyl). These were found to have little, if any, anticholinergic properties, but were powerful oxytocics and/or diuretics. It was therefore of interest to determine what type of activity would be shown by the disubstituted amides (I, R and R′ = alkyl). A very few of these disubstituted amides have been reported in the literature.[4–6] The first of these were reported in articles[4,5] dealing with antispasmodics but no pharmacology was given. Recently certain ones were reported to have high analgetic activity.[6]

A considerable number of these disubstituted amides have now been made and are listed in Table I. Like the monosubstituted amides[3] neither the hydrochlorides nor the methobromides had much antispasmodic activity in the Thiry-Vella dogs or gastric antisecretory activity in pyloric ligation rats but the hydrochlorides were generally oxytocics and/or diuretics.

In cases where $-C_nH_{2n}-$ (I) was $-CH_2CH(CH_3)-$ or $-CH_2CH_2CH_2-$ the dimethylamides (no. 15–18 in the table) were prepared from the corresponding acid chloride by a procedure essentially like procedure A described in the preceding paper[3] using dimethylamine in place of monomethylamine. When C_nH_{2n} = $-CH_2CH_2-$ or with large or hindered secondary amines pyrrolidones[7,8] were the chief products. Where $-C_nH_{2n}-$ was $-CH_2CH_2-$ the disubstituted amides were prepared by the method



This method is illustrated by an example in the Experimental part and the physical properties of the amides are listed in Table II (no. 1–14).

Acknowledgments.—The authors are indebted to Dr. P. H. Seay, Mr. Wm. Veldkamp, Mr. O. F. Swoap, Mr. B. E. Graham and associates of our Department of Pharmacology for the pharmacological data. The authors also wish to express their appreciation to Dr. R. V. Heinzelman of our Department of Chemistry for guidance in this work.

Experimental

α,α-Diphenyl-γ-(2,2-dimethyl-1-pyrrolidyl)-N,N-dimethylbutyramide.—A mixture of 54 g. (0.226 mole) of diphenyl-

[a] Administered to mice intraperitoneally. The values are approximations with an accuracy of about +100% to −50%. [b] Tested by intravenous administration in cats by a modification of the method of M. L. Clary, A. Cameron and B. N. Cramer, *Proc. Soc. Exp. Biol. Med.*, **77**, 778 (1951). [c] Administered orally to rats. [d] Previously reported.[5] This base was dissolved in dilute acid for testing. [e] Isolated as a solvate containing one molecule of acetone. [f] Preparation previously reported, R. B. Moffett, THIS JOURNAL, **79**, 4457 (1957).

[a] Unless otherwise noted the yields of the free bases are based on the diphenyl dialkylacetamide. The yields of the salts are based on the pure free bases. [b] Analyses and rotations are by Mr. William Struck and staff of our Analytical Chemistry Laboratory. Infrared spectra are by Dr. James L. Johnson and associates of our Department of Physics. [c] This yield is based on diphenyl-N,N-dimethylacetamide. The free basic amide was not isolated in pure form. [d] Yield based on pure hydrochloride. [e] The infrared spectrum[b] as well as the analysis indicates that this is a hydrate. [f] Prepared from the corresponding free base which has been previously reported.[5] [g] This salt has been reported by Bockmühl and Ehrhart[4] with m.p. 182–183°, but no analytical figures were given. It was prepared from diphenyl-N,N-diethylamide [N. Maxim, *Compt. rend.*, 182, 1393 (1926); *Ann. chim.*, 9, 55 (1928)]. [h] This compound was isolated as a hydrate, m.p. 129–132°. *Anal.* Calcd. for $C_{27}H_{41}BrN_2O \cdot H_2O$: N, 5.52; Br, 15.75. Found: N, 5.44; Br, 15.65. A sample was dried giving the properties listed in the table. The hydrate was used for pharmacological study. [i] The free base was not isolated. The hydrochloride crystallized from an aqueous acid solution on the addition of ether. [j] This yield is based on diphenylacetyl-1-piperidine.[5,9] The free basic amide was not isolated in pure form. [k] In spite of repeated attempts by two laboratories a satisfactory carbon analysis could not be obtained. The results ranged from 56.66 to 58.09. Good analyses for the other elements were obtained without difficulty. [l] Yield based on the α,α-diphenyl-γ or δ-*t*-aminovaleroyl chloride acid sulfate. The intermediate free basic amide was not isolated in pure form. [m] $[\alpha]^{23}D$ +59° (1% in CH_3OH). [n] $[\alpha]^{23}D$ +7° (1% in CH_3OH). [o] $[\alpha]^{23}D$ −63° (0.6% in CH_3OH). [p] $[\alpha]D$ −6° (1% in CH_3OH). [q] Isolated as a hydrate as shown by infrared[b] spectrum but after drying analyzed as anhydrous material.

N,N-dimethylacetamide,[5,9] 9.7 g. (0.25 mole) of sodium amide and 500 ml. of dry toluene was heated under reflux with stirring for 3 hours. To 44.8 g. (0.226 mole) of 2-(2,2-dimethyl-1-pyrrolidyl)-ethyl chloride hydrochloride[10] was added a slight excess of aqueous sodium hydroxide and the mixture was extracted with 300 ml. of toluene in several portions. The toluene solution was dried over potassium carbonate and slowly added to the above suspension of the sodium derivative. The mixture was heated under reflux with stirring for 2 hours, cooled, washed with water and extracted with dilute hydrochloric acid. The aqueous acid solution was made basic with dilute sodium hydroxide and the product was extracted with benzene. After removal of the solvent an oil was obtained which crystallized from pentane and was recrystallized from hexane giving white crystals having the properties given in Table II (no. 5, base).

Hydrochloride.—This was prepared by treating a sample of the free base in ethyl acetate with a slight excess of ethanolic hydrogen chloride. It was recrystallized from ethyl acetate, m.p. 206–207° (no. 5, HCl).

Methobromide.—To a cold solution of 10 g. (0.0322 mole) of the free base in 100 ml. of methyl ethyl ketone was added a large excess of cold methyl bromide. The flask was stoppered, clamped and allowed to stand at room temperature for 2 days. The crystals which separated had the properties given in Table II (no. 5, CH_3Br).

N-Oxide Hydrobromide.—A solution of 14.6 g. (0.04 mole) of the above free base and 10 ml. of 30% hydrogen peroxide in 150 ml. of methanol was allowed to stand at room temperature for 2 days. The excess hydrogen peroxide was decomposed by adding a small amount of a slurry of platinum-on-charcoal and shaking for 2 hours. The solution was filtered and distilled to dryness under reduced pressure below 30°. The resulting gummy free base failed to crystallize. It was dissolved in acetone and made acidic with a slight excess of 48% hydrobromic acid, and diluted with ether. On standing, the gummy hydrobromide partly crystallized. This was rubbed with ethyl acetate giving a solid product. This was recrystallized from isopropyl alcohol giving light tan crystals having the properties given in Table II (no. 5 → O·HBr).

α,α-Diphenylacetyl-1-pyrrolidine.—A mixture of 106.1 g. (0.5 mole) of diphenylacetic acid, 73 ml. of thionyl chloride and 100 ml. of benzene was heated under reflux with stirring for 1 hour. The solvent and excess thionyl chloride were removed by distillation under reduced pressure and the crude acid chloride was diluted with 300 ml. of benzene. To this was added slowly with stirring a solution of 85.4 g. (1.2 moles) of dry pyrrolidine in 200 ml. of benzene. After standing at room temperature overnight or heating under reflux for 1 hour, the solution was washed with water. The benzene solution was concentrated by distillation, treated with decolorizing charcoal, and cooled. It crystallized giving 111 g. (84%) of white crystals, m.p. 163–165°.

Anal. Calcd. for $C_{18}H_{19}NO$: C, 81.47; H, 7.22; N, 5.28. Found: C, 81.66; H, 8.01; N, 5.38.

Diphenyl-N,N-diisopropylacetamide.—By a similar procedure this was prepared from diisopropylamine. It was recrystallized from *n*-pentane giving a 60% yield of amide, m.p. 53–55°.

Anal. Calcd. for $C_{20}H_{25}NO$: C, 81.31; H, 8.53; N, 4.74. Found: C, 81.26; H, 8.59; N, 4.88.

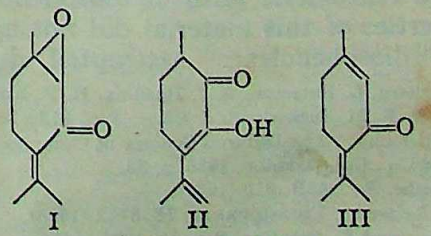
The Synthesis of Racemic Piperitenone Oxide and Diosphenolene

BY ROBERT H. REITSEMA[1]

RECEIVED OCTOBER 12, 1956

The enolic diketone, diosphenolene, separated from the oil of *Mentha rotundifolia* has been synthesized by three methods. Piperitenone has been converted to a monoepoxide and this with acid gave diosphenolene. Pulegone was a useful starting material for two other methods. The syntheses provide further evidence that the structure of diosphenolene is 3,8(9)-*p*-menthadiene-2-one as previously proposed.

Mentha rotundifolia is one of the more interesting mint species and its oil contains constituents which are quite different from most other mint oils. It has been shown that the major constituent is piperitenone oxide (1,2-epoxy-4(8)-*p*-menthene-3-one) (I).[2] Associated with this keto oxide in the oil and readily obtained from it in the laboratory is a new enolic ketone called diosphenolene for which the structure of 3-hydroxy-3,8(9)-*p*-menthadiene-2-one (II) was proposed.[2]



I II III

The evidence for the location of the double bond

in piperitenone oxide at the 4–8 position giving an isopropylidene group was from chemical and spectroscopic evidence. The structure given for diosphenolene required the shift of the double bond to the 8–9 position. This was postulated particularly on the basis of the ultraviolet absorption maximum at about 306 mμ as could be calculated for the system C=CC=C(OH)C=O. Additional evidence for the view that this tautomeric form is predominant is given by the infrared spectrum. Diosphenolene shows a strong absorption at 884 cm.$^{-1}$ in agreement with the assignment of this region to the isopropenyl group.[3] Absence of significant absorption at 825 cm.$^{-1}$ makes the isopropylidene structure unlikely. The absorption at 1604 cm.$^{-1}$ is in agreement with the conjugated C=C group.[4]

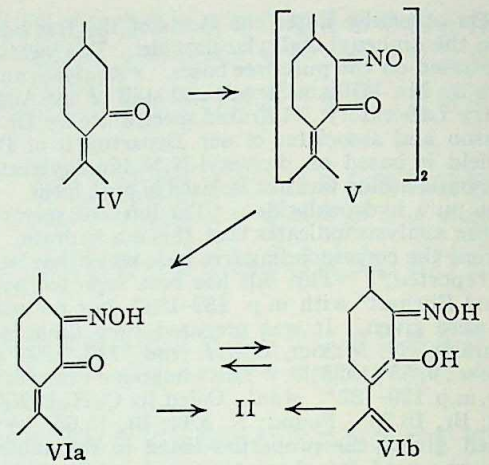
Piperitenone was treated with alkaline hydrogen peroxide by the general method of Treibs[5] to give a monoepoxide. Elementary analysis indicated the presence of a small amount of piperitenone in the product. The semicarbazone, prepared in aqueous suspension as for the active piperitenone oxide from *M. rotundifolia*, was identical to the *M. rotundifolia* ketone in respect to elementary analysis, ultraviolet absorption spectrum and in behavior in acid and base. The minor differences between the infrared spectra of the two appeared to be due to the necessary use of solid spectra.

The monoepoxide or its semicarbazone derivative could be converted to diosphenolene (II) readily by treatment with dilute acid. The product was identical in all respects to that obtained from piperitenone oxide obtained from *M. rotundifolia*. The reaction is analogous to the formation of diosphenol from piperitone oxide.[6]

Other syntheses of diosphenolene started with pulegone which is more readily available than piperitenone. Conversion of pulegone into diosphenolene by two independent paths was possible.

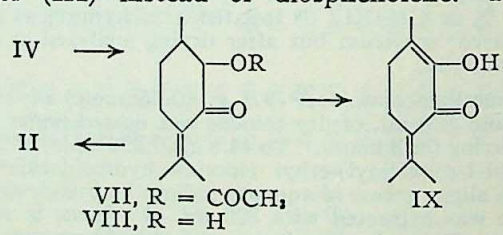
The formation of bis-nitrosopulegone (V) by treatment of pulegone with amyl nitrite and hydrochloric acid was reported by Bayer and Prentice.[7] This had been converted to an isonitrosopulegone with ammonia. Heating the isonitroso derivative VI with dilute acid had given a low yield of nitrogen containing material which was not characterized. It has now been found that the isonitroso derivative can be converted to diosphenolene by acid treatment as already used for syntheses of diosphenolene reported above. The product was identical to diosphenolene from other methods of synthesis.

A possible synthetic route to diosphenolene from pulegone was by selenium dioxide treatment as reported by Cauquil.[8] The product was reported to be a diketone to which the structure of 4(8)-*p*-menthene-2,3-dione was given. This was a possible tautomeric form of diosphenolene, but the properties of this material did not agree with those of diosphenolene. Attempted duplication



of the work gave a product in poor yield which was quite distinct from diosphenolene and in view of the other successful syntheses was not further studied.

The most useful synthesis of diosphenolene was a modification of the method used for the preparation of diosphenol from menthone.[9] Treatment of pulegone (IV) with mercuric acetate gave the desired 2-acetoxypulegone (VII). Hydrolysis and oxidation steps as with acetoxymenthone gave diosphenol (IX) instead of diosphenolene. It was



found that acetoxypulegone was saponified readily and in the presence of excess alkali rearrangement of the bonds gave diosphenol. The formation of diosphenol occurred in the presence of 8% potassium hydroxide under reflux very quickly, and somewhat more slowly with 4% potassium hydroxide at 52°. It was possible to avoid this reaction by use of 1% alkali at lower temperatures. The resulting 2-hydroxypulegone (VIII) was then oxidized in good yield to diosphenolene under milder conditions than used for hydroxymenthone. The product from this synthesis also was identical to authentic diosphenolene.

Thus, the synthesis used, involving the conversion of ketone derivatives of piperitenone and pulegone to diosphenolene, provides further evidence for the proposed structures.

Acknowledgment.—The technical assistance of Mr. Verners J. Varnis and encouragement of this work by the A. M. Todd Company is gratefully acknowledged.

(n^{20}D 1.5296; reported[12] 1.5294) in 20 ml. of isopropyl alcohol cooled to −9° there was added dropwise with stirring, at equal rates through two dropping funnels, 4 ml. of 30% aqueous hydrogen peroxide and 4.0 ml. of 10% potassium hydroxide. The temperature was maintained below −2° during the addition and the mixture was stirred at this temperature for an additional five hours. After standing overnight in a refrigerator, the slightly yellow solution was diluted with 70 ml. of water containing sodium chloride. The mixture was extracted with three 10-ml. portions of ether, the ether layers were combined, dried over magnesium sulfate and distilled. After removal of ether, two main fractions, distilling at 12 mm. pressure were obtained: (a) b.p. 149–154°, 2.5 g., n^{20}D 1.5056; and (b) b.p. 154–160°, 1.54 g., n^{20}D 1.4948. These were recombined and 3.24 g. was redistilled through a 10 cm. helices packed column at 2 mm. pressure giving: (1) b.p. 84–87°, 0.28 g., n^{20}D 1.5065, λ_{max}^{EtOH} 260 mμ (ε 6,950); (2) b.p. 87°, 1.28 g., n^{20}D 1.5043, λ_{max}^{alc} 260 mμ (ε 6,040); and (3) b.p. 87–88°, 0.42 g., n^{20}D 1.5048.

The elementary analysis of the fractions showed the presence of some unreacted piperitenone mixed with the major product, piperitenone oxide. Chromatography also showed the presence of a low concentration of piperitenone with the main constituent not distinguishable from naturally occurring piperitenone oxide. The infrared spectrum of the product fractions showed the presence of all peaks found in the piperitenone oxide separated from *M. rotundifolia*. Eight additional minor absorption points correlated with the major absorptions of piperitenone. Separation of the epoxide from the starting material contaminant by distillation was difficult because of the limited amount of starting material and the similarity in boiling points. Regeneration from derivatives was not possible due to sensitivity of the oxide to acids and bases.

The semicarbazone was prepared from the reaction product by vigorously stirring a suspension of 0.4 g. with 0.45 g. of sodium acetate and 0.6 g. of semicarbazide hydrochloride in 6.6 ml. of water for 4.5 hours at room temperature. The liquid was decanted from the waxy solid after cooling. The solid was washed with warm methanol and recrystallized from methanol giving 0.15 g. of a white granular product, m.p. 168–169°, λ_{max}^{EtOH} 274.5 mμ (ε 10,950). The melting point varied slightly under different conditions of recrystallization, drying and melting point determination and 170–171° was observed at times.

Anal. Calcd. for $C_{11}H_{17}O_2N_3$: C, 59.17; H, 7.68; N, 18.82. Found: C, 59.17; H, 7.67; N, 18.88.

The semicarbazone of *d*-piperitenone oxide from *M. rotundifolia* melted at 177.5–178° and had the same ultraviolet absorption as the synthetic material with λ_{max} 10,700 at 274.5 mμ.[2] As a result of the very low solubility of the semicarbazones in suitable solvents, the liquid phase infrared spectra were not obtained. The spectra of the solids run pelletized with KBr were slightly different in minor respects. It is known that differences in crystal structure can lead to some differences in infrared spectra.[13] Whether this slight variation is the result of different crystal structures of the racemic and active materials, of different forms of the semicarbazones being isolated, or, less likely, of diastereoisomerism was not determined. All other properties of the two series were identical.

3-Hydroxy-3,8(9)-*p*-menthadiene-2-one (Diosphenolene).—The synthetic piperitenone oxide (fraction 2 above) (0.5 g.) was added to 50 ml. of hot 10% sulfuric acid. Steam was passed into the mixture and 20 ml. of first fraction distillate and 35 ml. of second fraction distillate were collected. Both fractions gave very strong ferric chloride tests. Filtration of the first fraction after cooling gave white needles which were recrystallized from aqueous ethanol giving diosphenolene, m.p. 74–75°, λ_{max}^{alc} 306.5 mμ (ε 8,900), which showed no depression of melting point when mixed with material prepared by similar treatment of *M. rotundifolia* ketone.

Diosphenolene from Nitrosopulegone.—To a mixture of 50 g. of *d*-pulegone (n^{24}D 1.4861, α^{24}D 23.55°), 50 ml. of Skellysolve B, and 25 g. of amyl nitrite cooled in an ice-bath was added with stirring 13 drops of concentrated hydrochloric acid. The mixture became rather thick in ten minutes and was filtered. Repetition of the addition of acid to the cold filtrate gave three more crops of crystals which were washed with cold Skellysolve B. A total of 8.14 g. (15%) of air-dried crystals was obtained.

To 0.5 g. of the first crop covered with ether was added two drops of concentrated ammonia. This was allowed to stand until all was in solution and then 2 *N* sulfuric acid (about five drops) was added dropwise with stirring. The yellow crystals which appeared in the neutral mixture after separation and drying melted at 114.5–118°. Steam distillation of 0.32 g. of this crude product from 15 ml. of 10% sulfuric acid gave a few crystals in the condenser and white needles in the distillate upon cooling. These crystals gave a positive ferric chloride test and after recrystallization melted at 73–74° and failed to show depression in melting point when mixed with authentic diosphenolene. The ultraviolet absorption was in agreement with the previous spectrum of diosphenolene and showed a maximum absorption at 305 mμ (ε 9,200).

2-Acetoxy-4(8)-*p*-menthene-3-one (2-Acetoxypulegone).—A mixture of 85.5 g. of mercuric acetate and 41.0 g. of *d*-pulegone in 70 ml. of glacial acetic acid was stirred under gentle reflux for three hours. The liquid which had undergone numerous color changes was decanted from the layer of 47.7 g. of mercury into 800 ml. of water and extracted with three portions of ether. The organic layers were combined, washed twice with water, and dried over magnesium sulfate. Distillation after removal of ether and of acetic acid gave: 18.73 g. of recovered pulegone, b.p. 60–65° (3 mm.), n^{20}D 1.4863; 2.66 g. of an intermediate fraction, b.p. 75–92° (3 mm.), n^{20}D 1.4919; and 12.93 g. (44% of theoretical yield based upon recovered pulegone) of 2-acetoxypulegone, b.p. 96–98° (3 mm.), n^{20}D 1.4883. Redistillation of the main fraction through a short helices packed column gave a center cut, b.p. 102° (4 mm.), n^{22}D 1.4882, λ_{max}^{alc} 252 mμ (ε 6,010), α^{22}D −15.88.

Anal. Calcd. for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63. Found: C, 68.35; H, 8.33.

The yield was not maximum and some undecomposed organic mercury derivatives remained as shown by the appearance of some mercury during the distillation.

Diosphenol from Acetoxypulegone.—2-Acetoxypulegone (5.8 g.) was stirred under reflux for 30 minutes with 50 ml. of 8% aqueous potassium hydroxide solution. After cooling, the orange oil was extracted with ether, the ether extracts dried and ether removed under vacuum leaving 3.5 g. (72%) of an oily solid. Recrystallization of this from methanol gave diosphenol, m.p. 82.5–83°, λ_{max}^{alc} 272 mμ (ε 8,800), positive ferric chloride test, which showed no melting point depression when mixed with an authentic sample.

2-Hydroxypulegone.—To 7.7 g. (0.0385 equiv.) of 2-acetoxypulegone was added with stirring 0.16 *N* aqueous potassium hydroxide at such a rate as to maintain the *p*H of the mixture between 8 and 10. After the first half hour at 25° when 41 ml. was added, the temperature was raised to 40° with a water-bath. After six hours 241 ml. (calculated 240 ml.) had been added and the rate of consumption of alkali had decreased to a very small value. The mixture was cooled and extracted with ether. No solid could be separated from the aqueous solution by neutralization with dilute sulfuric acid. Evaporation of ether from the organic extract left 4.66 g. (72%) of yellow oil which was distilled giving 3.74 g., b.p. 73–78° (3 mm.), n^{23}D 1.5048, λ_{max}^{alc} 254 mμ (ε 5,670), αD −5.65°. The crude product itself corresponded rather closely to the calculated analysis and was not purified further.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.56. Found: C, 70.85; H, 9.50.

Diosphenolene from Hydroxypulegone.—A mixture of 3.4 g. of 2-hydroxypulegone, 12.5 g. of glacial acetic acid and 4.65 g. of bismuth oxide was stirred at 110° for 10 minutes. The liquid was decanted from the bismuth metal (about 2.5 g.) into 250 ml. of water and the ether extracts were washed with water to remove acetic acid. Addition of ether caused more white solid to precipitate. This was removed by filtration and the organic layer was separated from the filtrate. The aqueous layer was extracted twice more with ether and the combined organic layers were washed with water to remove acetic acid. After drying the ether solution, ether was removed under vacuum leaving 3.19 g. (94%) of a light orange oil which suddenly crystal-

lized to an oily solid. Recrystallization four times from methanol left 1.16 g. of white needles, m.p. 75–76°, λ_{max}^{alc} 304 mμ (ε 9,245). The material showed no mixed melting point depression with authentic diosphenolene prepared from piperitenone oxide. The ferric chloride test was very heavy dark green in color similar to the test with diosphenolene prepared in other ways.

Terpenoids. XXX.[1] The Structure of the Cactus Triterpene Chichipegenin

BY A. SANDOVAL, A. MANJARREZ, P. R. LEEMING,[2] G. H. THOMAS[3] AND CARL DJERASSI

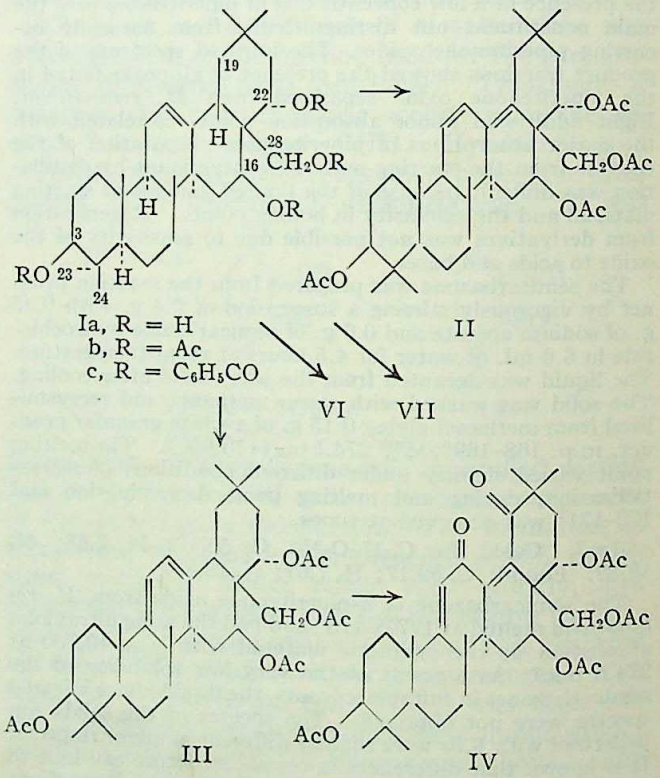
RECEIVED APRIL 17, 1957

Chichipegenin—isolated from various *Myrtillocactus* species and from *Lemaireocereus chichipe*—has been converted *via* its 28-trityl ether VIa to longispinogenin (Va). Coupled with other degradation experiments, this leads to the conclusion that chichipegenin is Δ^{12}-oleanene-3β,16β,22α,28-tetrol (Ia), thus falling into the earlier established oxygenation pattern established for cactus triterpenes.

As pointed out recently,[4] the most characteristic triterpene of the genus *Myrtillocactus* of the *Cactaceae* family is a new tetrol, $C_{30}H_{50}O_4$. This substance has been named "chichipegenin" since it occurs also in large amounts in a single species of the genus *Lemaireocereus, L. chichipe*[5] (see Experimental section), and the taxonomic implications of this observation have already been commented upon.[4,6] We should now like to record the approach employed in the structure elucidation of this interesting triterpene.

Chichipegenin did not exhibit any infrared absorption in the carbonyl region but showed a strong band typical of one or more hydroxyl groups. Acetylation or benzoylation under mild conditions afforded the corresponding tetraacetate Ib and tetrabenzoate Ic, thus accounting for all four oxygen atoms. Furthermore, the ease of acylation indicated that these hydroxyl groups must either be primary and/or equatorially oriented secondary alcoholic functions. Since eventual correlation with a known triterpene was required for a definitive structure proof, it was important to establish to which broad class of triterpenes chichipegenin belonged. This was accomplished by examining the reactivity of chichipegenin tetraacetate toward selenium dioxide.

Oxidation in boiling acetic acid smoothly led to a diene, which on the basis of its characteristic triple ultraviolet absorption maxima[7] could be assigned the heteroannular $\Delta^{11,13(18)}$-formulation II, thus



showing that chichipegenin was a member of the β-amyrin class of triterpenes. In order to eliminate position 19 as the site of one of the hydroxyl groups, the further oxidation of this diene II with selenium dioxide to the well known $\Delta^{9(11),13(18)}$-diene-12,19-dione IV[8] was attempted, but no pure product could be isolated. Reaction of chichipegenin tetraacetate Ib with N-bromosuccinimide did not lead to the desired $\Delta^{9(11),12,18}$-triene[9] but rather to an impure bromine-containing product in accordance with earlier observations in the queretaroic acid series.[10] However, with a limited amount of N-bromosuccinimide, it was possible to isolate

Digitized by Arya Samaj Foundation Chennai and eGangotri

another diene, which must be the homoannular $\Delta^{9(11),12}$-diene III since it exhibited a single ultraviolet absorption maximum at 281 mμ. Selenium dioxide oxidation[8] of the latter (III) gave the required diene-dione IV, demonstrating that C-19 in chichipegenin must have been unsubstituted.

A close companion of chichipegenin in several *Myrtillocactus* species[4] is myrtillogenic acid (Ve),[11] and it seemed attractive to speculate that both triterpenes were oxygenated at identical carbon atoms.[12] This possibility was ruled out by the experimental observation[4] that lithium aluminum hydride reduction of myrtillogenic acid (Ve) produced a tetrol, different from chichipegenin. It was necessary, therefore, to remove one or more hydroxyl groups in chichipegenin in order to achieve a correlation with a known triterpene and attempts at selective manipulation of the hydroxyl groups were initiated.

Chichipegenin did not form an acetonide and assuming the existence of a 3β-hydroxyl group—found in all cactus triterpenes[6]—this observation excluded hydroxyl groups at C-23, C-24,[13] C-2 (β)[14] and presumably also C-1 (β). The presence of a 1,2-glycol moiety was eliminated by the observed stability of chichipegenin toward lead tetraacetate, but the presence of a 1,3-glycol grouping in other parts of the molecule still had to be considered since 16β,28-diols such as longispinogenin (Va) do not form acetonides.

As described in the Experimental portion of this paper, chichipegenin is accompanied in the cactus *L. chichipe* by oleanolic acid and by longispinogenin (Va). This suggested that one of the hydroxyl groups of chichipegenin might be located at C-28, and since a model experiment with longispinogenin (Va) demonstrated the ready formation of a 28-trityl ether Vb, chichipegenin was subjected to similar treatment with triphenylmethyl chloride. The resulting trityl ether VIa yielded a triacetate VIb when heated with acetic anhydride and a triketone VIIb upon oxidation with chromium trioxide–pyridine. This demonstrated the presence of one primary and three secondary hydroxyl groups in chichipegenin. Furthermore, the spectral properties of the triketo-trityl ether VIIb required the absence of an enolizable α- or β-diketone grouping. Detritylation of VIIb by boiling with alcoholic sulfuric acid led in poor yield to a nortriketone VIIa, which gave a strongly positive ferric chloride reaction and exhibited an ultraviolet absorption maximum (λ_{max}^{EtOH} 290 mμ, λ_{max}^{KOH} 309 mμ) consistent with the presence of a β-diketone function.[15] The identical nor-trione VIIa could also be obtained in one step by direct chromium trioxide–acetic acid oxidation of chichipegenin (Ia), thus requiring a triol moiety of type A in chichipegenin. The direct formation of the nor-trione VIIa (D) from the trityl ether VIIb (B) is due to retro-aldolization of the intermediate keto alcohol C and finds its exact counterpart in a similar reaction sequence described recently with the sesquiterpene iresin.[16]

Partial structure A can be incorporated into an

(12) A precedent being the co-occurrence of longispinogenin (Va) and the corresponding acid, cochalic acid, in the same cactus (see Table II in ref. 6).

(13) 3β,23- and 3β-24-acetonides can be formed readily (see J. L. Beton, T. G. Halsall and E. R. H. Jones, *J. Chem. Soc.*, 2904 (1956)).

(14) The formation of a 2β,3β-acetonide has recently been demonstrated in the alfalfa sapogenin medicagenic acid (to be published).

(15) No good model appears to be available to predict the exact position of the ultraviolet absorption maximum of such a β-diketone (*cf.* E. R. Blout, V. W. Eager and D. C. Silverman, THIS JOURNAL, **68**, 566 (1946)).

intact β-amyrin skeleton only in rings D and E leading to structure I or VIII. However, chichipegenin cannot have a hydroxyl group at C-19 (as in VIII) because of the ease of acetylation, the formation of a tetraacetoxy diene-dione IV and the lack of ultraviolet absorption typical of an α,β-unsaturated ketone[17] shown by the trityl ether trione VIIb in alkaline solution. The above analysis leaves I as the only structural alternative for chichipegenin, but since this is based on a process of elimination which in turn is predicated on a normal triterpene skeleton—so far unproved—it was indispensable to relate chichipegenin to a triterpene of established constitution. This was accomplished in the following manner, starting with chichipegenin 28-trityl ether (VIa).

In contrast to chichipegenin (Ia) itself, which could be acetylated completely at room temperature, its trityl ether VIa under the same conditions furnished an amorphous product still exhibiting hydroxyl absorption in the infrared. This resistance to mild acetylation conditions was believed to be a reflection of the increased steric hindrance produced by the bulky trityl ether grouping and could only exert itself upon C-16 and/or C-22. That C-16 was probably not implicated was demonstrated by the smooth acetylation at room temperature of longispinogenin trityl ether (Vb) to the corresponding 3,16-diacetate Vc, thus suggesting that the amorphous acetylation product of chichipegenin trityl ether (VIa) should be represented as the 3,16-diacetoxy-22-ol-28-trityl ether (VIc).[18] The correctness of this assumption was established by chromium trioxide–pyridine oxidation to the crystalline 3,16-diacetoxy-22-ketone VIe and Wolff–Kishner reduction, which furnished longispinogenin trityl ether (Vb). The identity of the reduction product was confirmed by cleavage of the trityl ether and acetylation, whereupon longispinogenin triacetate (Vd) was obtained. Since the structure and stereochemistry of longispinogenin (Va) has been proved rigorously,[19] chichipegenin can now be given the systematic name Δ^{12}-oleanene-3β,16β-22α,28-tetrol (Ia).[20] Attention already has been called earlier[6] to the fact that the sixteen triterpenes which have so far been isolated in our laboratories from giant cacti all fall into a restricted oxygenation pattern which involves only rings D and E aside from position C-3. The structure of chichipegenin further supports this "rule" which may be of some utility in narrowing down structural alternatives when working with unknown cactus triterpenes.

(17) If structure VIII were the correct expression for chichipegenin, then the triketo trityl ether VIIb would contain a 19-keto function, and such β,γ-unsaturated ketones are readily isomerized with base to the corresponding conjugated ketone (see P. Bilham, G. A. R. Kon and W. C. J. Ross, *J. Chem. Soc.*, 540 (1942); L. Ruzicka, A. Grob, R. Egli and O. Jeger, *Helv. Chim., Acta*, **26**, 1218 (1943)).

(18) Similarly, benzoylation of the trityl ether VIa yielded a 3,16-dibenzoate VId which could be crystallized.

(19) C. Djerassi, L. E. Geller and A. J. Lemin, *Chemistry & Industry*, 161 (1954); THIS JOURNAL, **76**, 4089 (1954).

(20) The equatorial (α) orientation is assigned to the 22-hydroxyl group because of its ease of acetylation and benzoylation.

Experimental[21]

Isolation of Triterpenes from *Lemaireocereus chichipe*.—The fresh cactus (106 kg.) collected near Tehuacán, Puebla, and identified by Dr. Helia Bravo of the Instituto de Biologia (Universidad Nacional Autonoma de Mexico), was cut into small portions and dried for 7 days at 35°. The ground, dried material (32 kg.) was continuously extracted with hot ethanol and the dry extract (9.5 kg.) was washed well with acetone and then ether, leaving 4.5 kg. of "glycosidic" fraction. A 2-kg. portion of it was heated under reflux for 2 hr. with 10 l. of methanol and 2 l. of concd. hydrochloric acid, concentrated to one-half of its volume and diluted with water. Filtration produced 720 g. of solid while basification of the filtrate with ammonia did not reveal the presence of any alkaloids. A chloroform solution of the solid was shaken repeatedly with aqueous potassium hydroxide solution furnishing approximately 400 g. of neutral material and 300 g. of insoluble potassium salts.

The potassium salt was suspended in methanol and acidified with constant stirring yielding 270 g. of acid. A 5.0-g. sample was methylated in the standard manner with diazomethane and purified by chromatography giving 2.6 g. of pure **methyl oleanolate**, m.p. 198–200°, further characterized as the acetate (m.p. 214–216°).

In a typical chromatogram of the neutral fraction, a chloroform solution of 40 g. of solid was placed on a column of 2 kg. of alumina. Elution with the same solvent yielded 10.5 g. of oil while 26.5 g. of **chichipegenin (Ia)** was removed from chloroform–methanol (9:1). Repeated crystallization from chloroform–methanol afforded an analytical sample, m.p. 321–323°, $[\alpha]_D$ +43° (chloroform), +40° (pyridine).

Anal. Calcd. for $C_{30}H_{50}O_4$: C, 75.90; H, 10.62. Found: C, 75.39; H, 10.40.

Acetylation of chichipegenin could be accomplished at room temperature either with acetic anhydride–pyridine (overnight) or with acetic anhydride containing a trace of perchloric acid (30 min.). Recrystallization from chloroform–methanol led to the **tetraacetate Ib**, m.p. 280–282°, $[\alpha]_D$ + 26°.

Anal. Calcd. for $C_{38}H_{58}O_8$: C, 70.99; H, 9.09. Found: C, 70.96; H, 9.23.

Partial saponification of the tetraacetate (0.5 g.) was carried out by heating a methanolic solution (200 cc.) under reflux for 45 min. with 800 mg. of potassium carbonate and 10 cc. of water. After working up in the customary manner[22] there was isolated *ca.* 100 mg. of **chichipegenin (3 or 22)-monoacetate**, m.p. 280–282°, $[\alpha]_D$ +57°.

Anal. Calcd. for $C_{32}H_{52}O_5$: C, 74.37; H, 10.14. Found: C, 74.35; H, 10.14.

Benzoylation of chichipegenin (benzoyl chloride–pyridine, 14 hr., 23°) followed by chromatography and recrystallization from ether–methanol yielded the **tetrabenzoate Ic**, m.p. 245–247°, $[\alpha]_D$ +62°.

Anal. Calcd. for $C_{58}H_{66}O_8$: C, 78.32; H, 7.65. Found: C, 78.20; H, 7.47.

(21) All melting points were determined on the Kofler block. Unless noted otherwise, rotations were measured in 1-dcm. tubes in chloroform solution. Infrared spectra were obtained in part with a Perkin–Elmer (Instituto de Quimica) and in part with a Baird (Wayne State University) double beam spectrophotometer. The microanalyses were carried out by Geller Laboratories (Hackensack, N. J.), Dr. Franz Pascher (Bonn, Germany) and Dr. Alfred Bernhardt (Mülheim, Germany).

Similar treatment of the monoacetate led to **chichipegenin tribenzoate monoacetate**, m.p. 221–223°, $[\alpha]D$ +50°.

Anal. Calcd. for $C_{53}H_{64}O_8$: C, 76.76; H, 7.78. Found: C, 76.95; H, 7.70.

The ether and acetone washings of the "glycosidic" fraction were combined and evaporated to dryness (4.1 kg.) yielding an oily, dark colored mass. A 290-g. portion was dissolved in 200 cc. of dioxane and heated under reflux for 6 hr. with 200 g. of potassium hydroxide dissolved in 2 l. of methanol. After concentrating and diluting with water, the mixture was extracted continuously with ether. Concentration of the washed and dried ether solution gave 77 g. of **longispinogenin (Va)**, m.p. 249–252°, $[\alpha]D$ +57°, tetraacetate, m.p. 219–222°, $[\alpha]D$ +76°.

$\Delta^{11,13(18)}$-Oleadiene-3β,16β,22α,28-tetrol Tetraacetate (II).—A solution of 200 mg. of chichipegenin tetraacetate (Ib) in 25 cc. of glacial acetic acid was heated under reflux for 3 hr. with 200 mg. of freshly sublimed selenium dioxide. After working up in the usual way including chromatography and recrystallization from chloroform–methanol, there was obtained 102 mg. of the diene II, m.p. 192–193.5°, $[\alpha]D$ −114°; λ_{max}^{EtOH} 242, 250 and 260 mμ; log ϵ 4.43, 4.56 and 4.35.

Anal. Calcd. for $C_{38}H_{56}O_8$: C, 71.22; H, 8.81. Found: C, 71.58; H, 9.09.

$\Delta^{9(11),12}$-Oleadiene-3β,16β,22α,28-tetrol Tetraacetate (III).—A mixture of 2.0 g. of chichipegenin tetraacetate (Ib), 1.2 g. of N-bromosuccinimide and 100 cc. of carbon tetrachloride was heated under reflux for 2 hr. After filtering, washing with bicarbonate and water, drying and evaporating, there was obtained an oil which was heated under reflux with 25 cc. of collidine for 3 hr. After processing in the usual manner, there was obtained 0.5 g. of oil which was chromatographed on 20 g. of alumina. Elution with benzene furnished 285 mg. of solid which was recrystallized from chloroform–methanol to give the analytical sample, m.p. 323–325°, λ_{max}^{EtOH} 280 mμ, log ϵ 4.05.

Anal. Calcd. for $C_{38}H_{56}O_8$: C, 71.22; H, 8.81. Found: C, 71.77; H, 9.12.

$\Delta^{9(11),13(18)}$-Oleadiene-3β,16β,22α,28-tetrol-12,19-dione Tetraacetate (IV).—The above diene III (1.0 g.) was heated under reflux for 5 hr. with 1.0 g. of selenium dioxide and 200 cc. of acetic acid. The resulting oil (800 mg.) was chromatographed on 50 g. of alumina, and elution with benzene–ether (1:1) gave 100 mg. of material which crystallized from dilute acetone as light yellow needles, m.p. 171–173°, $[\alpha]D$ −69°, λ_{max}^{EtOH} 278 mμ, log ϵ 4.15; λ_{max}^{Nujol} 5.75, 6.05 and 6.20 μ.

Anal. Calcd. for $C_{38}H_{52}O_{10}$: C, 68.24; H, 7.84; O, 23.92. Found: C, 68.02; H, 7.87; O, 24.35.

Chichipegenin 28-Trityl Ether (VIa).—A solution of 2.0 g. of chichipegenin (Ia) and 6.0 g. of triphenylmethyl chloride in 160 cc. of 1:1 dioxane–pyridine was heated on the steam-bath for 8 hr. The crude product was isolated with ether and chromatographed on 400 g. of Merck acid-washed alumina. Elution with benzene afforded 4.2 g. of triphenylcarbinol while benzene–chloroform (1:1) eluted the desired trityl ether. Crystallization from benzene–hexane gave 2.3 g. of colorless needles, m.p. 261–270°, which were satisfactory for the next step. The analytical sample exhibited m.p. 263–272°, $[\alpha]D$ +70°, $\lambda_{max}^{CHCl_3}$ 6.22(w) and 6.70(m) μ.

Anal. Calcd. for $C_{49}H_{64}O_4$: C, 82.08; H, 9.00; O, 8.93. Found: C, 82.20; H, 9.16; O, 8.29.

Complete acetylation could be accomplished by heating a mixture of 300 mg. of the trityl ether, 15 cc. of pyridine and 15 cc. of acetic anhydride for 4 hr. on the steam-bath. Dilution with water and filtration yielded a solid which was chromatographed on 30 g. of Merck acid-washed alumina and eluted with benzene. Recrystallization from ethanol led to 200 mg. of the **triacetoxy trityl ether (VIb)**, m.p. 252–256°, $[\alpha]D$ +70°, no infrared hydroxyl absorption.

Anal. Calcd. for $C_{55}H_{70}O_7$: C, 78.34; H, 8.37; O, 13.28. Found: C, 78.48; H, 8.29; O, 12.85.

Δ^{12}-Oleanene-3β,16β,28-triol-22-one 3,16-Diacetate 28-Trityl Ether (VIe).—A solution of 1.5 g. of chichipegenin in 100 cc. of pyridine and 50 cc. of acetic anhydride was left at room temperature for 15 hr.[23] After diluting with water, the amorphous precipitate ($\lambda_{max}^{CHCl_3}$ 2.80 and 5.75 μ) was collected, and since it could not be crystallized, even after chromatography, it was oxidized directly with 1 g. of chromium trioxide in 30 cc. of pyridine for 20 hr. at room temperature. The product (62% over-all yield) was isolated with ether and crystallized from methanol; m.p. 287–290°, $[\alpha]D$ −44°; $\lambda_{max}^{CHCl_3}$ 5.77(broad), 6.20(v.w.), 6.68(m) and 7.95(s).

Anal. Calcd. for $C_{53}H_{66}O_6$: C, 79.64; H, 8.33; O, 12.01. Found: C, 79.66; H, 8.76; O, 11.46.

Longispinogenin 28-Trityl Ether (Vb). (a) **From Longispinogenin (Va).**—Longispinogenin (Va) (3.0 g.), triphenylmethyl chloride (10.0 g.) and 1:1 dioxane–pyridine (240 cc.) were heated on the steam-bath for 8 hr. Chromatography on 550 g. of Merck acid-washed alumina yielded 8 g. of triphenylcarbinol (benzene), 2.3 g. of the desired trityl ether (benzene–ether 3:1) and 0.7 g. of unchanged longispinogenin (chloroform–methanol 9:1). Crystallization from benzene–hexane afforded colorless needles of the dimorphic trityl ether, m.p. 208–210° and 268–280°, $[\alpha]D$ +35°.

Anal. Calcd. for $C_{49}H_{64}O_3$: C, 83.95; H, 9.20; O, 6.85. Found: C, 84.38; H, 9.32; O, 6.25.

Acetylation with acetic anhydride–pyridine at room temperature overnight yielded the **diacetoxy trityl ether (Vc)**, m.p. 209–211° and 227–232°, $[\alpha]D$ +69°.

Anal. Calcd. for $C_{53}H_{68}O_5$: C, 81.09; H, 8.74; O, 10.20. Found: C, 81.05; H, 8.72; O, 9.83.

(b) **By Wolff–Kishner Reduction of VIe.**—A mixture of 1.0 g. of the 22-keto trityl ether VIe, 100 cc. of diethylene glycol and 6 cc. of hydrazine hydrate was heated to reflux until all of the triterpene had dissolved (*ca.* 5 min.). The temperature was then allowed to fall and was kept at 110–130° for 1 hr. Solid potassium hydroxide (5 g.) was added and, after keeping for an additional hr. at that temperature, distillation was commenced until the temperature rose to 215°. After heating under reflux for 5 hr., the solution was poured into ice-water and the solid product was filtered. Chromatography on 50 g. of alumina and elution with benzene–ether (4:1) provided 400 mg. of solid which was recrystallized from benzene–hexane to yield needles of longispinogenin trityl ether (Vb) with m.p. 208–210° and 268–280°, $[\alpha]D$ +33°. The infrared spectra of the two samples (prepared according to (a) and (b)) were identical.

A 300-mg. sample of longispinogenin trityl ether from the Wolff–Kishner reduction was dissolved in 25 cc. of chloroform, and the solution was saturated with hydrogen chloride gas for 1.5 hr. After 20 hr. at room temperature, water was added, the layers were separated and the acid removed with bicarbonate solution. The residue from the chloroform layer was chromatographed on 15 g. of alumina, and elution with ether–chloroform (3:1) yielded 74 mg. of longispinogenin (Va), m.p. 253–256°, $[\alpha]D$ +57°. Acetylation at room temperature gave longispinogenin triacetate (Vd), m.p. 226–228°, $[\alpha]D$ +72°. Identity was confirmed in each case by mixture melting point determination and infrared comparison.

Δ^{12}-Oleanene-3,16,22-trione-28-ol Trityl Ether (VIIb).—Chichipegenin trityl ether (VIa) (0.6 g.) was added to 0.6 g. of chromium trioxide in 25 cc. of pyridine, and the mixture was kept at room temperature overnight. Dilution with water and extraction with ether produced emulsions which were broken up by filtration through a mat of Celite. The solid residue from the ether extract was chromatographed on 30 g. of Merck acid-washed alumina, and elution with benzene–ether (20:1) led to 300 mg. of the triketone. The analytical sample crystallized from benzene–hexane as colorless needles, m.p. 292–295°, $[\alpha]D$ −53°, λ_{max}^{KBr} 5.80(s), 6.2(w) and 6.68(m) μ. The substance gave no color with ferric chloride and exhibited no high ultraviolet absorption maximum in alcoholic alkali.[17]

Anal. Calcd. for $C_{49}H_{58}O_4$: C, 82.78; H, 8.22; O, 9.00. Found: C, 82.45; H, 8.02; O, 9.39.

28-Nor-Δ^{12}-Oleanene-3,16,22-trione (VIIa). (a) **From Chichipegenin (Ia).**—Chichipegenin (1.0 g.) was dissolved in 200 cc. of acetic acid, and a solution of 1.0 g. of chromium trioxide in 10 cc. of 90% acetic acid was added. After standing overnight, water was added, the product was extracted with ether and washed with 3% potassium hydroxide to leave 340 mg. of neutral oil. Crystallization from methanol afforded 90 mg. of yellowish needles, m.p. 253–257°, $[\alpha]D$ −45°, λ_{max}^{EtOH} 290 mμ, log ϵ 4.10; λ_{max}^{KOH} 309 mμ,

(23) When the reaction was performed with benzoyl chloride in pyridine, there was obtained after recrystallization from ethanol the 3,16-dibenzoate VId, m.p. 196–198.5°, $[\alpha]D$ +77°. *Anal.* Calcd. for $C_{44}H_{72}O_6$: C, 81.76; H, 7.85. Found: C, 82.09; H, 7.90.

log ϵ 4.65; $\lambda_{max}^{CHCl_3}$ 5.83, 6.09 and 6.21 (shoulder) μ. The substance gave a red color with ferric chloride.

Anal. Calcd. for $C_{29}H_{42}O_3$: C, 79.40; H, 9.65; O, 10.94. Found: C, 78.97; H, 9.27; O, 11.10.

(b) From the Trityl Ether VIIb.—When 1.0 g. of the trityl ether VIIb was heated under reflux for 8 hr. with 50 cc. of ethanol and 0.5 cc. of sulfuric acid and then cooled, there separated approximately 50 mg. of crystals. These were filtered and recrystallized from methanol whereupon they exhibited m.p. 248–251°, undepressed upon admixture with a sample prepared according to (a). The ultraviolet absorption spectrum and the red color with ferric chloride supported the identification of this substance.

Anal. Calcd. for $C_{29}H_{42}O_3$: C, 79.40; H, 9.65. Found: C, 79.41; H, 9.53.

Long-acting Testosterone Esters. Some Considerations on their Biological Utilization[1]

BY DAVID GOULD, LAWRENCE FINCKENOR, E. B. HERSHBERG, JAMES CASSIDY AND PRESTON L. PERLMAN

RECEIVED NOVEMBER 3, 1956

A series of testosterone 17-esters was prepared to find those with the best activity and duration. Several potent derivatives were found, including the entire family of aryloxyalkanoates. Injections of these esters in rodents are shown to be efficient and enduring sources of testosterone.

Since testosterone was established as the true androgenic hormone,[2] attempts have been made to potentiate its effect and prevent its rapid metabolic destruction.[3] The program reported here was carried out with this aim, and led to many esters considerably more valuable in potentiating the androgenic effect than testosterone propionate,[4] as well as a group of esters which are outstanding in the assays used with respect to intensity and duration of androgenic action. The results are given in Tables I-IV.

The acids corresponding to the esters, if they were not available commercially, were prepared by methods reported in the literature, mainly from "Beilstein: Handbuch der Organischen Chemie." The acid chlorides were made using thionyl chloride and generally isolated by vacuum distillation, though the residues were used when distillation caused decomposition. Although some of the acid chlorides had not been known previously, they are not reported here, since they were not characterized and analyzed. All of the esters were made according to the standard procedure given below, in which chilling was found to be essential for the ready preparation of pure products. In the case of oily esters, chromatography gave materials with the correct analyses.

The intensity and duration of androgenic action were tested in mice and rats, giving results which are shown qualitatively in the tables according to their relation to the action of testosterone propionate (TP). The effects were measured by weighing the seminal vesicles of castrated animals at various times after subcutaneous injection of the ester. We have considered that compounds effecting a maximum seminal vesicle weight less than $1/2$ of that due to TP are not of interest and such are rated "0." Conversely, compounds with maxima several times that of TP generally last correspondingly longer before falling below our cut-off point.

The original hypothesis on which this study was based stemmed from the maximal activity of the lowest melting members of the straight chain acid series of esters, *e.g.*, heptanoate and nonanoate.[4,5] This suggested that the more oil-soluble esters are most useful; therefore, a group of esters of branched chain acids was prepared (see Table I). The results show that, while none surpasses the heptanoate and nonanoate, several esters containing four to eleven carbons approached them in activity. The variation of the activity from good to poor of intermediate-length esters, all of them low melting solids or oils readily soluble in hydrocarbon solvents, shows the invalidity of the hypothesis. For example, the decreased activity of the 3,3-dimethylpentanoate compared to the 3-methylpentanoate is in disagreement.

It is, however, possible to make some generalizations. (1) All of the esters with dialkyl-substituted chains have poor activity. (2) The 2-alkyl-substituted esters (except isobutyrate) have a low order of activity. These statements suggest that steric hindrance plays an important role in decreasing the activity. Thus, fatty acids, such as trimethylacetic and diethylacetic, which are known to esterify at less than one-tenth the rate of acetic, and, therefore, also to hydrolyze with difficulty, due to hindrance caused by branching,[6] form testosterone esters whose intensity is so reduced that they are therapeutically useless.

Since no trend or advance in activity is observable in the fatty acid series, other types were prepared (Tables II-IV), especially a group of substituted cyclohexane-carboxylic acid esters (Table

II). Although these acids may be considered as disubstituted acetic acids, the ring ties the alkyl groups back so that hindrance is lessened, except in the case of the 2-methyl and trimethyl derivatives. The 3- and 4-alkylcyclohexane carboxylates generally have intensity about equal to the best fatty acid esters, but the peak activity is maintained better so that the duration of effective action is longer. Extension of the chain to the methylcyclohexylacetates decreases the potency and duration (Table IV). Further extension of the chain to phenyl or cycloalkyl propionates, butyrates, etc., gives esters of varying intensity and with duration similar to the heptanoate, with the exception of the 4-cyclohexylhexanoate whose activity curve climbs only slowly but is maintained high for an exceptionally long period of 14–18 weeks in rats (Table IV). The phenylacetate, 3-phenylpropionate and 3-cyclopentylpropionate which are given here for comparison have intensity and duration in oil similar to the heptanoate. Inexplicably, the 3-cyclopentylpropionate is, as an aqueous suspen-

sion, only equal to testosterone propionate in intensity and duration. Variation between activity of preparations in aqueous and oily vehicles and between mice and rats are observed in a few other cases, but generally only small differences exist and agreement is relatively good between the alternate procedures used here.

Further study beyond the series of alkylcyclohexane-carboxylates led to a new family of esters, the phenoxyalkanoates, having surprisingly enhanced intensity and duration[7] (Table III). The

4-chlorophenoxyacetate (in oil in mice) has given a maximum peak of over twice that of the propionate, which has not been observed with any other ester, and has, along with the 4-*t*-butylphenoxyacetate, lasted 16 weeks while the previously outstanding esters drop off at 8 weeks. In rats in aqueous suspension, the phenoxyacetate and the 4-*t*-butylphenoxyacetate have given maxima as high as three times that of the propionate and twice that of previously known esters, and the 4-*t*-butylphenoxyacetate has shown a useful level of activity for over 120 days.[8] Variations in substituents do not have the severe effects on activity seen in other families of esters. For example, even when the molecular weight is increased as in the 2,4,5-trichlorophenoxyacetate, activity is not lost. It is also of interest that the isomeric pair of 2-phenoxypropionates did not differ greatly, the observed variation probably being related to the solubilities.

In view of the consistently useful esters in this family, a more fundamental basis than solubility or hydrolytic rate might be suspected. The thought occurs that the phenoxyalkanoic acids are plant growth regulators[9] as are phenylacetic, phenylpropionic, and other unsaturated ring-substituted fatty acids. The anabolic activity of testosterone and the superior effect of these particular esters suggests the intriguing possibility that there may be a basic similarity in the biochemical mechanisms of control of growth in plants and animals.[1,7,10]

The potentiation of androgenic activity of these esters is seen more clearly in comparison with normal effects from endogenous testosterone. While no experiments have been designed for the purpose of determining these values for mice and rats, it is possible to obtain useful estimates of minima. Castrated rats are stated to be maintained properly on: 3×1 mg. TP/wk.,[11] 0.5–1.4 mg. T/day,[12] 1–2 mg. of androsterone/day[13] (equivalent to 0.1–0.2 mg. T/day),[14] 2×0.3 mg. T/day,[15] and 0.1–0.5 mg. TP/day.[16] Castrated mice are reported to be maintained by 65 γ TP/day.[17] Urinary ketosteroids in rats are stated to be: 0.15 mg./day[11]; 0.2–0.5 mg./day[14,18]; in mice, 0.5–1.9 mg./month.[19] Since steroidal metabolites in rodents are only found to the extent of $^1/_4$–$^1/_8$ of the injected testosterone,[20] the endogenous production of C-19 steroids may be calculated to be at least 8 mg./wk. in rats and 4 mg./month in mice. Although the ratio of testicular to adrenal orgin is not known for rodents, it is probably high,[21] and it is not unreasonable to assume from these figures and the maintenance doses that minimal figures for the endogenous production of testosterone at 1 mg./wk. in rats and 1 mg./mo. in mice. The latter figure is supported by Chai's estimate of 1.95 mg./mo. in mice.[17]

Using these figures, maintenance with endogenous testosterone in mice requires 4 mg. in 16 weeks while only 2.5 mg. of testosterone 4-chlorophenoxyacetate lasted for that period; and in rats, maintenance was observed with 7.5 mg. of the 4-*t*-butylphenoxyacetate for 17 weeks, a period requiring 17 mg. of endogenous testosterone. The high efficacy of these derivatives implies that they protect the testosterone from metabolism until it reaches the site of action. In any case, it would appear that these esters supply the hormone in a manner at least as efficient and perhaps more so than the intact testis.

Acknowledgment.—We are indebted to Walter Pummer, Eric Jorgensen and Gerold Krakower for aid in the preparation of some esters. We are especially indebted for the biological testing in rats to Dr. Solomon Margolin presently of Wallace Laboratories, New Brunswick, N. J.

Experimental[22]

Preparation of Acid Chlorides.—In a dry system, 100 g. of the acid was dissolved in 400 cc. of benzene and some benzene was distilled off to remove water. To this was slowly added 300 cc. of thionyl chloride, and the mixture was refluxed 12–16 hr.

The benzene and excess thionyl chloride were distilled off at atmospheric pressure in a dry system. If it was necessary to remove the last traces of thionyl chloride, another 100 cc. of benzene was distilled off. Finally, the pressure was reduced to 5–20 mm. and the acid chloride was distilled. Some high boiling acid chlorides were used without distillation.

General Procedure for Preparation of Testosterone Esters.—Five g. of testosterone was dissolved in 50 ml. of dry distilled pyridine. The solution was chilled to 0–10° in an ice-bath and 5 g. (or 1.25 equiv.) of acid chloride was added dropwise with good stirring. Stirring was continued for 12–15 hr. at room temperatures.

The mixture was poured with good stirring into a mixture of 400 g. of ice and 100 ml. of concd. sulfuric acid. If a precipitate was obtained, the product was filtered off, washed with 10% sodium carbonate and water (until neutral) and air-dried. The crude was then crystallized from methanol or methanol–benzene.

If the product did not solidify in the ice mixture, it was extracted several times with benzene and the benzene solution was washed with 10% sodium carbonate to remove the excess acid, with water until neutral, and dried over magnesium sulfate. The solution was evaporated, and the residue crystallized from methanol. If crystallization was not possible, the residue was chromatographed from hexane on alumina, removing oily impurities in the hexane eluates. Elution was continued with 1:1 hexane–benzene and with benzene to obtain the last of the ester. Ether eluted any unchanged testosterone. On standing or trituration with methanol, the benzene-containing fractions usually solidified. In any case, these fractions analyzed correctly, after sufficient drying *in vacuo*.

BLOOMFIELD, NEW JERSEY

(8) The last measurement still showed seminal vesicle weights greater than the TP maximum. It can be presumed that effective activity could be observed for a considerably longer duration.

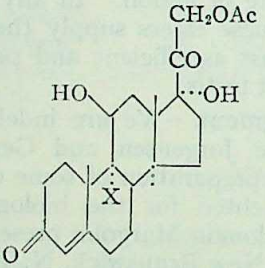
Transannular Hydrogen Transfer in the Steroid Series[1]

BY N. L. WENDLER, R. P. GRABER, C. S. SNODDY, JR., AND F. W. BOLLINGER

RECEIVED DECEMBER 10, 1956

The chemical transformations bearing on the transannular hydrogen transfer–rearrangement of 9β,11β-oxido-Δ⁴-pregnene-17α,21-diol-3,20-dione 21-acetate (II) are described.

The acid-catalyzed scission of the epoxide function in 9β,11β-oxido-Δ⁴-pregnene-17α,21-diol-3,20-dione 21-acetate (II) has been found to be directionally dependent on the nature of the acid catalyst employed. Whereas hydrogen halides and dilute mineral acids evoke normal scission to give the respective halohydrins (I, X = halogen)[2] and glycol (I, X = OH),[1,3] concentrated acids produce predominantly rearrangement of a duodirectional



I, X = halogen, OH

character. In the latter case the course of rearrangement is directed to a minor extent to give the corresponding 11-ketone, whereas the major product appearing results as a consequence of "2,6"-transannular migration of hydrogen.[4] Treatment of 9β,11β-oxido-Δ⁴-pregnene-17α,21-diol-3,20-dione 21-acetate (II) in chloroform solution at 0° with 60% perchloric acid caused the development of a red coloration with the steroid partitioning itself nearly completely in the aqueous phase. Subsequent isolation of the reaction product yielded 10–15% of cortisone acetate[5] together with 65% of an isomeric compound[6] formed as the major product.[7] The homoallylic character of this isomeric substance was suggested by the observation that its 11-mesylate derivative underwent acidolysis to a significant extent with configurational retention to give the corresponding ester derivative in a manner reminiscent of the *i*-steroid phenomenon.[8] This substance, as will be borne out by the chemistry subsequently to be discussed, proved to be 17α-hydroxy-Δ⁸⁽¹⁴⁾-dehydrocorticosterone 21-acetate (III), a structure hardly to have been anticipated on the basis of classical theoretical considerations.

In establishing the structure of III, it was subjected *inter alia* to oxidation with chromic acid in pyridine,[9] to give what subsequently proved to be the Δ⁴,⁸⁽¹⁴⁾-dienedione IV. This substance on treatment with sodium methoxide was readily isomerized to the completely conjugated Δ⁴,⁸⁽⁹⁾-dienedione V. The latter compound was found to be identical with material obtained from 9-bromocortisone acetate (VII) by dehydrobromination of the latter with refluxing pyridine.[10] On the other hand, elimination of the elements of hydrogen bromide from VII with lithium chloride in dimethylformamide[11] afforded the 14β-isomer VI also obtained from the Δ⁴,⁸⁽⁹⁾-dienedione V by isomerization with hydrogen chloride in chloroform. The 14β-isomer VI, unlike its epimer V, afforded a 17-acetate derivative on acetylation with acetic anhydride in pyridine at room temperature for 7 days or 6 hours at 100°. Model inspection suggests a greater degree of steric accessibility of the 17α-OH in the 14β-iso (*cis* C/D) series, a consequence of the orientational change of the 17α-OH from pseudo-axial to pseudo-equatorial.

Since the Δ⁴,⁸⁽⁹⁾-dienedione V exhibited a somewhat unusual ultraviolet absorption for this structure with a low band position at 236.5 mμ as well as

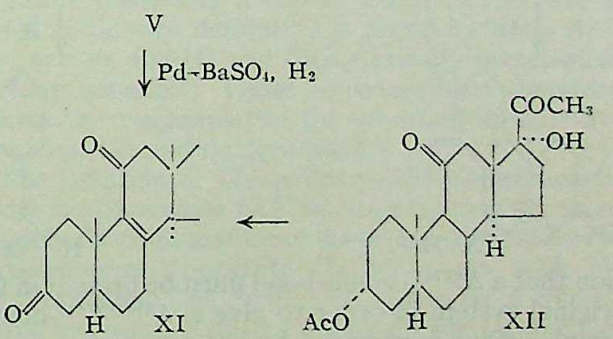
low intensity (ϵ 17,700),[12] it was considered advisable under the circumstances to secure this structure against the possibility that skeletal alteration had supravened. It was also desired to provide unequivocal confirmation for the configuration at C_{14}. Consequently the $\Delta^{4,8(9)}$-dienedione V was hydrolyzed and cleaved with periodic acid to afford the intermediate dienic acid VIII; subsequent reduction of VIII with lithium in liquid ammonia[13] followed by methylation with diazomethane and reoxidation with chromic acid gave the known methyl 17α-hydroxy-3,11-diketoallo-etianate (IX).[14] The latter compound was compared with an authentic sample prepared from allodihydrocortisone (X) by successive periodate cleavage and esterification. Additional corroboration for structure V which also served to resolve the feature of its unique ultraviolet absorption was provided by hydrogenation of the Δ^4-double bond of V to give the $\Delta^{8(9)}$-enedione XI which now exhibited the expected absorption for this system with λ_{max} 256 mμ (8,175). In contrast to V, IV absorbed 1 mole of hydrogen to give XXII exhibiting no ultraviolet absorption (see later). The $\Delta^{8(9)}$-enedione XI obtained from V by hydrogenation was found to be



identical with material isolated as an intermediate by-product from the conversion of pregnane-3α-17α-diol-11,20-dione 3-acetate (XII) to cortisone by a sequence in which bromination–dehydrobromination at C_9 occurred.[15] The identity of XI obtained by these two methods secures additionally the directional course of hydrogenation of V as giving the normal A/B-ring system (5β-H).

At this juncture it has been established that the major rearrangement product III possesses a normal steroid skeleton with unsaturation situated β,γ with respect to the 11-oxygen function. The exact assignment of the β,γ-double bond to the $\Delta^{8(14)}$-position was made possible in the following manner: III was hydrogenated to its 4,5-dihydro derivative XIII and the latter was dehydrated in the form of its 11-mesylate derivative by refluxing pyridine to provide the $\Delta^{9(11),8(14)}$-homoannular diene XIV with λ_{max} 271 mμ (ϵ, 4,600). Isomerization of XIV with hydrogen chloride in chloroform produced the $\Delta^{8,14}$-heteroannular diene XV, λ_{max} 246 mμ (ϵ, 21,500). In a similar manner III itself was converted

(12) This absorption approximates that for a lone Δ^4-3-ketone. C. Djerassi, A. J. Lemin, G. Rosenkranz and F. Sondheimer [J. *Chem. Soc.*, 2346 (1954)] report for 22a-spirosta-4,8-diene-3,11-dione an ultraviolet absorption spectrum with λ_{max} 236–242 mμ (ϵ, 20,800).

(13) The reduction of $\Delta^{(8)9}$-11-ketones with lithium in liquid ammonia has been shown in other series to proceed without involvement of C_{14} (E. Schoenewaldt, L. Turnbull, E. M. Chamberlin, D. Reinhold, A. E. Erickson, W. V. Ruyle, J. M. Chemerda and M. Tishler, THIS JOURNAL, **74**, 2696 (1952); F. Sondheimer, R. Yashin, G. Rosenkranz and C. Djerassi, *ibid.*, **74**, 2696 (1952)); see also ref. 5.

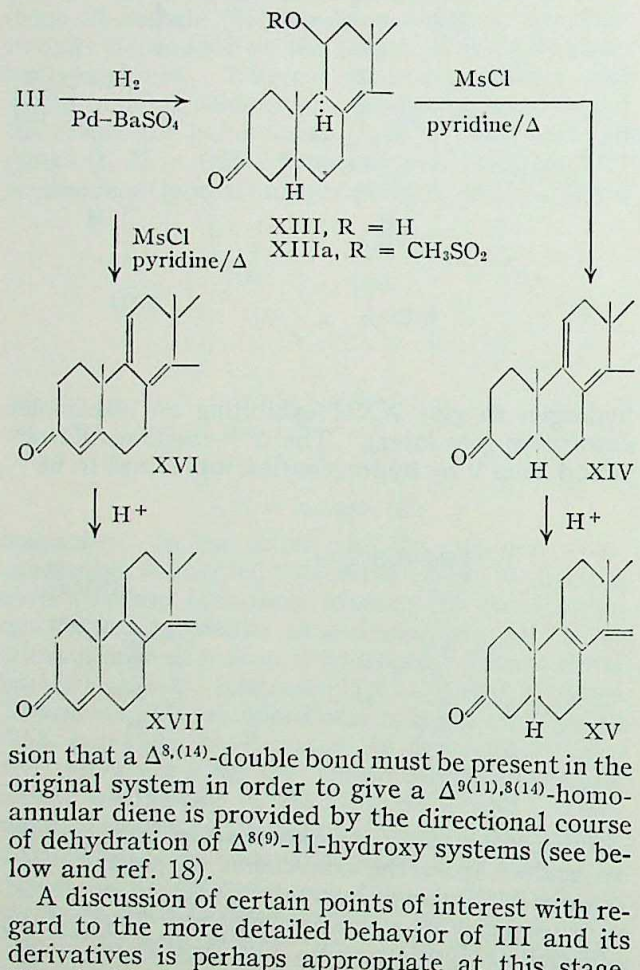
Digitized by Arya Samaj Foundation Chennai and eGangotri

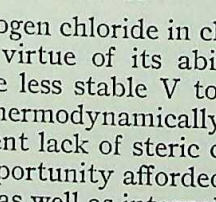
to XVI in which the homoannular diene chromophore manifested itself only as a shoulder at 271 mμ with the main band at 241 mμ (ε 21,600). Isomerization of XVI with hydrogen chloride in chloroform yielded the $\Delta^{4,8,14}$-trieneone XVII with λ_{max} 242 mμ (ε 37,400).[16] Formation of the homoannular dienes XIV as well as XVI establishes the position of β,γ-unsaturation at 8:14. If the double bond had been situated at the alternative 7,8-position, dehydration under the conditions employed should have resulted in formation of the $\Delta^{7,9(11)}$-diene XXV.[17] Additional confirmation for the conclu-



sion that a $\Delta^{8,(14)}$-double bond must be present in the original system in order to give a $\Delta^{9(11),8(14)}$-homoannular diene is provided by the directional course of dehydration of $\Delta^{8(9)}$-11-hydroxy systems (see below and ref. 18).

A discussion of certain points of interest with regard to the more detailed behavior of III and its derivatives is perhaps appropriate at this stage. The double bond at 8:14 appears to decrease the hindrance generally associated with 11β-hydroxyl groups thereby permitting III to be acetylated at room temperature with acetic anhydride in pyridine,[17] conditions which leave an 11β-OH in a saturated normal steroid system unaffected. This fact becomes additionally apparent when it is considered that the introduction of the 8:14 double bond permits the axial 11β-OH of a saturated ring C to assume an equatorial conformation in the resultant cyclohexene. 17α-Hydroxy-$\Delta^{8(9)}$-dehydrocorticosterone 21-acetate (XXIV), which can be isolated as a minor component from the dehydrobromination of I, (X = Br), with N-ethylpiperidine[19] (see later discussion), occupies an intermediate position between III and a normal saturated 11β-hydroxy steroid. Thus, conditions which completely acetylate III and leave 17α-hydroxycorticosterone 21-acetate unaffected (see above) cause acetylation of XXIV to the extent of *ca.* 30%, complete acetylation being achieved within a period of a week. Therefore the relative ease of acetylation of the 11β-OH in these systems may be said to bear the relationship $\Delta^{8(14)}$-11β-OH > $\Delta^{8(9)}$-11β-OH > 11β-OH.

The isomerization of the $\Delta^{4,8(14)}$-dienedione IV to the $\Delta^{4,8(9)}$-dienedione V together with the epimerization of the latter to its 14β-isomer, has produced several interesting consequences. Thus, whereas IV was isomerized by sodium methoxide exclusively to the less stable epimer V,[20] hydrogen chloride in chloroform failed to evoke this change.[21] Conversely V was irreversibly converted to the more stable isomer VI with hydrogen chloride in chloroform but remained isomerically unaffected with sodium methoxide. In view of the apparent stability at C_{14} of V to the basic conditions employed,[20] the unidirectional isomerization of IV → V appears to be rate determined and subject as well to steric control. The latter is possible if the 17α-OH in virtue of its spatial disposition is considered to participate as an internal proton-donor to the 14α-position in the manner depicted by XVIII. Isomeri-



XVIII

zation with hydrogen chloride in chloroform, on the other hand, by virtue of its ability to effect the conversion of the less stable V to the more stable VI should be a thermodynamically controlled process. The apparent lack of steric control at C_{14} follows from the opportunity afforded to exchange the C_{14}-H externally as well as internally.[22,23]

(16) B. M. Bloom, E. J. Agnello and G. D. Laubach, [*Experientia*, **12**, 27 (1956)] have recently reported the formation of this compound from the treatment of 14α,15α-oxido-Δ^4-pregnene-17α,21-diol-3,20-dione 21-acetate with *p*-toluenesulfonic acid in refluxing benzene. These authors report a molecular extinction of 28,600 at 240 mμ which is considerably lower than that observed by us.

(17) III is readily acylated under room temperature conditions.[6] Since it has been shown (ref. 5b) that $\Delta^{7(8)}$-11β-hydroxysteroids are *not* acetylated under these conditions, this constitutes further evidence excluding the $\Delta^{7(8)}$-position of the double bond in III. It has also been pointed out by Fried and Sabo (ref. 2) that the by-product which they obtained from II with hydrogen fluoride (see ref. 6) could not possess a $\Delta^{(7)}$-double bond for reasons of molecular rotation deviation.

(18) R. F. Hirschmann, C. S. Snoddy, Jr., and N. L. Wendler, THIS JOURNAL, **75**, 3252 (1953).

(19) The conditions employed by Fried and Sabo (ref. 2) for the conversion of I (X = Br) to the 9β,11β-oxide (II), namely, potassium acetate in refluxing ethanol, also give detectable amounts of XXIV as evidenced by paper strip analysis.

(20) Because of the lability of the cortical side chain to alkali [see N. L. Wendler and R. P. Graber, *Chemistry & Industry*, 549 (1956)] the conditions of sodium methoxide isomerization were limited to room temperature treatment for 10 minutes. In view thereof, the conclusions based on the results of these conditions are necessarily limited to them.

(21) IV was isomerized to VI, however, when heated at 100° for 2 hours in dimethylformamide containing hydrogen bromide (see footnote 22).

(22) The conversion of V → VI with hydrogen chloride in chloroform at 0° occurred to the extent of about 60% in 1 hour and was essentially complete after 18 hours. Complete isomerization of V → VI was also achieved with dimethylformamide containing one equivalent of hydrogen bromide for 2 hours at 100°.

(23) Certain analogies to this isomerization are afforded by observations concerned with the neopinone–codeinone change; see H. Conroy, THIS JOURNAL, **77**, 5760 (1955).

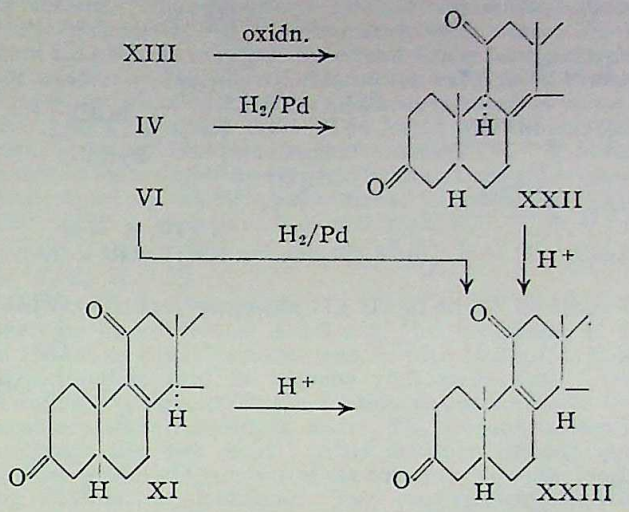
The isomerization of V → VI induced by lithium chloride in dimethylformamide containing one equivalent of pyridine hydrobromide (compare transformation VII → VI) was found not to occur to any detectable extent either with pyridine hydrobromide in pyridine or with lithium chloride in dimethylformamide alone. The interesting consequence arises that the combination-induced isomerization is concerted in nature[24] requiring both protonation of the C_{11}-C=O as well as assisted removal of the $C_{14\alpha}$-H by dimethylformamide.[25]

Hydrogenation of the Δ^4-double bond in all the systems possessing unsaturation in the functionally substituted C ring (*i.e.*, III, IV, V and VI) was observed to proceed predominantly to give the normal A/B ring system (5β-H).[5,26] The hydrogenation product of V, namely, XI was related as already mentioned (see above) to the natural 5β-H series. XI in turn was acid-isomerized to XXIII, also obtained from VI by hydrogenation. The hydrogenation product of III, namely, XIII on oxidation with chromic acid gave XXII also produced from IV by hydrogenation. The isomerization of XXII to XXIII with hydrogen bromide in dimethylformamide completed the interrelationship of the various 4,5β-dihydro derivatives.

The remaining point of constitution requiring clarification with regard to the immediate structures under consideration concerns the configuration at C_9. It was pointed out earlier that the major rearrangement product III on oxidation with pyridine–chromium trioxide for 18 hours afforded in good yield the $\Delta^{4,8(14)}$-dienedione IV which rapidly isomerized (10 minutes) with sodium methoxide to the $\Delta^{4,8(9)}$-dienedione V; it would appear therefore reasonably assured that III and IV are configurationally the same at C_9. In contrast to the $\Delta^{4,8(14)}$-dienedione IV, however, its 4,5β-dihydro derivative XXII, failed to isomerize: $\Delta^{8(14)} \rightarrow \Delta^{8(9)}$ with sodium methoxide or on an alumina column.[5b] These results appear to be consistent only with a structure possessing a $C_9\alpha$-H which in the case of the 4,5β-dihydro derivative is caged by a *cis* A/B ring system (5β-H) and thus sterically inaccessible to base attack.[27] These considerations therefore permit the assignment of the 9α-orientation of hydrogen to III and its derivatives.

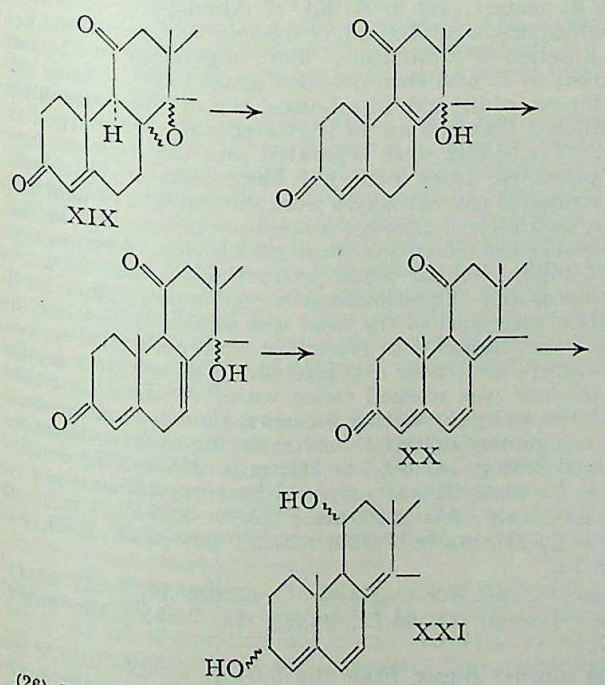


The isolation of 17α-hydroxy-$\Delta^{8(9)}$-dehydrocorticosterone 21-acetate (XXIV) as a by-product from the dehydrobromination of 9α-bromo-17α-hydroxycorticosterone 21-acetate (I, X = Br) with N-ethylpiperidine (see earlier) proved to be of considerable importance in its bearing on the mechanism of the rearrangement of II → III. The constitution of XXIV was established by oxidation with manganese dioxide to give the $\Delta^{4,8(9)}$-dienedione V as well as dehydration with mesyl chloride in pyridine to afford $\Delta^{4,7,9(11)}$-pregnatriene-17α,21-diol-3,20-dione 21-acetate (XXV). Of singular significance was the finding that XXIV on treatment with 60% perchloric acid was converted exclusively to the heteroannular $\Delta^{8,14}$-diene XVII thereby ruling it out as a possible intermediate in the conversion of II → III. In the same connection neither 9α,17α-dihydroxycorticosterone 21-acetate (I, X = OH)[1,3] nor 9α,11α-oxido-Δ^4-pregnene-17α,21-diol-3,20-dione 21-acetate[2] were appreciably affected by the acidic conditions employed for the conversion of II → III. These systems, it will be noted, are sterically ideal when compared with II for the intervention of a classical 1,2-Wagner shift of the 8β-H, and when extrapolated would lead to the 9β-H-epimer of III.

In the light of the foregoing observations, it may be concluded with reasonable certainty that the acid-catalyzed transformation of II → III proceeds from within a protonated species (*e.g.*,

(24) C. G. Swain. *Record of Chem. Prog.*, Kresge–Hooker Science Library, Wayne Univ., **12**, 21 (1951).

(25) A further base-induced transformation which sensibly involves at an intermediate phase an $\alpha\beta \rightarrow \beta\gamma$ change is concerned with the extremely insoluble 8,14-oxido derivative XIX formed from IV on treatment with perbenzoic acid. Treatment of XIX with sodium methoxide caused elimination of the epoxide function with formation of the $\Delta^{4,6,8(14)}$-trienedione XX, λ_{max} 337 mμ (ϵ 25,800). Structure XX was substantiated by lithium aluminum hydride reduction to give a product (XXI) exhibiting characteristic ultraviolet absorption for the $\Delta^{4,6,8(14)}$-triene chromophore at 285 mμ (ϵ 19,150) [*cf.* L. Dorfmann, *Chem. Revs.*, **53**, 47 (1953)]. The sequence involved in the formation of XX may reasonably be represented as



(26) It is noteworthy that in the sapogenin series, A. J. Lemin and C. Djerassi (THIS JOURNAL, **76**, 5672 (1954)) found the $\Delta^{4,8(9)}$-dienone system hydrogenated to give mainly the 4,5β-dihydro derivative.

(27) The steric accessibility of a 9β-H to base attack should not be adversely affected by hydrogenation of the Δ^4-double bond (see ref. 5b).

XXVI)[28] by way of transannular migration of hydrogen with its bonding pair from $C_{14\alpha} \rightarrow C_{9\alpha}$ with attending extrusion of the $C_8\beta$-H. Moreover, since hydrogen transfer of this type should proceed with steric control,[4,29] it follows that the stereochemistry of the product II becomes defined as formulated.[30]

Experimental[31]

Δ^4-Pregnene-9α,11β,17α,21-tetrol-3,20-dione 21-Acetate (I, R = OH).—A suspension of 4.025 g. (10.0 millimoles) of the oxide II in 66.7 ml. of purified dioxane and 33.3 ml. of 2.0 *N* aqueous perchloric acid was stirred at 25°. After a period of 1.5 hours, the solid had dissolved and the solution was light yellow. After a period of 3 days, the bright yellow solution was diluted with 200 ml. of saturated salt solution and extracted with 3 portions of ethyl acetate. The combined extracts were washed with water and 5% aqueous sodium bicarbonate until free of acid and finally with water and saturated salt solution. The washed extracts were dried by filtration through anhydrous magnesium sulfate and the solvents removed *in vacuo* to give 3.95 g. of a partly crystalline yellow residue. Crystallization from acetone–chloroform gave 2.50 g. (65%) of needles, m.p. 224–230° dec. An additional crystallization from acetone afforded 1.575 g. (41.6%) of **Δ^4-pregnene-9α,11β,17α,21-tetrol-3,20-dione**, m.p. 239–246.5° dec. A sample prepared for analysis by recrystallization from the same solvent was obtained as prisms, m.p. 243–249° dec., $[\alpha]^{26}D$ +152° (1.1, acetone), λ_{max} 242 mμ (ϵ 15,600); $\lambda\lambda^{Nujol}_{max}$ 2.9–3.0, 5.84 and 6.1 μ.

Anal. Calcd. for $C_{21}H_{30}O_6$: C, 66.64; H, 7.99. Found: C, 66.61; H, 7.90.

The mother liquor of the 2.50-g. sample above was treated with 8 ml. of pyridine and 8 ml. of acetic anhydride at 25° overnight. A small amount of crystalline solid which had separated was removed by filtration, washed several times with ether and dried, weight 0.109 g., m.p. 219–234°. This material was shown by paper-strip analysis to be a mixture of unidentified materials. The pyridine–acetic anhydride–ether filtrate was concentrated *in vacuo* to an oil. Water (50 ml.) was added to the concentrate and the oil extracted with 3 portions of ethyl acetate. The combined extracts were washed successively with water, 1 *N* hydrochloric acid, sodium bicarbonate solution and finally with water and saturated salt solution. The washed extracts were dried over magnesium sulfate and the solvent removed *in vacuo* to give 1.64 g. of a yellow-brown amorphous residue which was shown by paper-strip analysis to be substantially pure I (R = OH). Crystallization from acetone–ether afforded 0.84 g. (20%) of buff-colored prisms, m.p. 210–216°, undepressed on admixture with a sample prepared from the tetroldione by acetylation as described above. A sample prepared for analysis by recrystallization from acetone–ether was obtained as colorless needles, m.p. 212–214.5°, λ_{max} 242 mμ (ϵ 15,570); $\lambda\lambda^{Nujol}_{max}$ 2.92, 5.79–5.82, 6.1–6.15; $\lambda\lambda^{CHCl_3}_{max}$ 5.75(sh), 5.79, 6.0 and 6.15 μ. It was observed that several samples partly crystallized as prisms during melting, then finally melted at *ca.* 223°.

Anal. Calcd. for $C_{23}H_{32}O_7$: C, 65.69; H, 7.67. Found: C, 65.43; H, 7.51.

Δ^4-Pregnene-9α,17α,21-triol-3,11,20-trione 21-Acetate.—To a solution of 61.3 mg. (0.613 millimole) of chromium trioxide in 2 drops of water and 4.9 ml. of glacial acetic acid was added 386.2 mg. (0.92 millimole) of I (R = OH). The solid dissolved immediately and after 12 minutes the reaction mixture was diluted with 25 ml. of water. Extraction with 3 portions of ethyl acetate followed by the usual washing with water, sodium bicarbonate, etc., gave, after removal of the solvent, 358 mg. (93%) of a crystalline residue, m.p. 228.5–235°. Recrystallization from acetone–ether gave 241 mg. of needles, m.p. 236–242°. An additional recrystallization raised the m.p. to 237–243.5°, λ_{max} 238 mμ (ϵ 15,620); $\lambda\lambda^{Nujol}_{max}$ 2.96, 5.71, 5.75, 5.83, 6.0 and 6.16 μ; $\lambda\lambda^{CHCl_3}_{max}$, 5.7(sh), 5.79, 5.99 and 6.15 μ.

Anal. Calcd. for $C_{23}H_{30}O_7$: C, 66.01; H, 7.23. Found: C, 66.14; H, 7.02.

$\Delta^{4,8(14)}$-Pregnadiene-11β,17α,21-triol-3,20-dione 21-Acetate (III). (17α-Hydroxy-$\Delta^{8(14)}$-dehydrocorticosterone 21-Acetate.)—To a stirred, ice-cold solution of 8.05 g. (20.0 millimoles) of 9β,11β-oxido-Δ^4-pregnene-17α,21-diol-3,20-dione 21-acetate (II) in 80 ml. of ethanol-free chloroform was added dropwise 20.0 ml. of ice-cold 60% perchloric acid over a period of 2 minutes. The temperature of the mixture rose to 7° and then dropped again to 0°. After stirring for an additional 15 minutes, the orange-red solution was diluted with 200 ml. of ice-water which discharged the color. The layers were separated and the aqueous layer was extracted twice with 2:1 chloroform–ethyl acetate. The combined solvent layers were washed free of acid with water, and filtered through anhydrous magnesium sulfate. Removal of the solvents *in vacuo* gave 8.70 g. of yellow crystalline solid. To the crude product was added 35 ml. of chloroform and the suspension heated under reflux for 10 minutes; only part of the solid was soluble. The hot suspension was diluted with 175 ml. of benzene, cooled to room temperature for 1 hour and filtered. The colorless crystalline product was washed twice with 1:1 chloroform–benzene followed by three ether washes to remove small amounts of brown gummy material. After drying *in vacuo* there was obtained 3.84 g. (47.6%) of III, m.p. 246.5–257° dec. A sample for analysis was prepared by recrystallization from methanol, m.p. 255–260° dec., $[\alpha]^{25}D$ +293° (1.0, acetic acid), λ_{max} 240 mμ (ϵ 17,200); $\lambda\lambda^{Nujol}_{max}$ 2.93, 3.02, 5.75, 5.81 and 6.1 μ.

Anal. Calcd. for $C_{23}H_{30}O_6$: C, 68.63; H, 7.51; acetyl, 10.69. Found: C, 68.22, 68.53; H, 7.35, 7.13; acetyl, 11.47.

The mother liquor from the 3.84-g. sample above was taken to dryness *in vacuo*, wt. 4.77 g. Paper chromatographic analysis of this material showed it to contain additional amounts of III together with cortisone acetate and a

(28) The dotted lines in this formulation are intended to represent partial bond character with the steric connotations:

$$O\overset{\beta}{\cdots}C_9\overset{\alpha}{\cdots}H\overset{\alpha}{\cdots}C_{14}$$

(29) In recent years the occurrence of transannular hydrogen transfer in medium sized rings has been dramatically demonstrated. In this regard see: A. C. Cope, S. W. Fenton and C. F. Spenser, THIS JOURNAL, **74**, 5884 (1952); V. Prelog and K. Schenker, *Helv. Chim. Acta*, **35**, 2044 (1952); V. Prelog, K. Schenker and W. Küng, *ibid.*, **36**, 471 (1953); V. Prelog, H. J. Urech, A. A. Bothner-By and J. Würsch, *ibid.*, **38**, 1095 (1955); V. Prelog and V. Boarland, *ibid.*, **38**, 1776 (1955); V. Prelog and W. Küng, *ibid.*, **39**, 1394 (1956); A. C. Cope, T. A. Liss and C. W. Wood, *Chemistry & Industry*, 823 (1956).

(30) This instance of transannular-hydrogen transfer in an unbridged 6-membered ring system is unique in several respects: (1) transannular transfer occurs in a system wherein the centers involved are of fixed stereochemistry; (2) proton extrusion takes place as the ultimate step and (3) the product of this transfer reaction is the major one. Recenty A. C. Cope, H. E. Johnson and J. S. Stephenson (THIS JOURNAL, **78**, 5599 (1956)) have demonstrated transannular hydrogen transfer in the cyclohexane series in the performic acid-hydroxylation of cyclohexene.

(31) Unless otherwise indicated, the m.p.'s were taken on a micro-block and are not corrected; the samples were placed on the block at *ca.* 25° below the m.p. The rotations were observed in chloroform and the ultraviolet spectra in methanol.

Digitized by Arya Samaj Foundation Chennai and eGangotri

substantial amount of a more polar material. The amorphous yellow-brown mother liquor material was treated with 30 ml. of pyridine and 15 ml. of acetic anhydride and stirred at 25° overnight. At the end of this time a small amount of crystalline solid was present which was removed by filtration and washed 3 times with ether, wt. 0.394 g., m.p. 223–228°. The ether and excess reagents were removed *in vacuo* to give a partly crystalline residue which was treated with 20 ml. of ether and filtered to give an additional 0.409 g. of crystalline solid, m.p. 229–238°, undepressed on admixture with the sample above and with cortisone acetate.

The filtrate was diluted with 50 ml. of ethyl acetate and 50 ml. of water, the mixture shaken vigorously, separated and the aqueous layer extracted twice more with ethyl acetate. The combined extracts were washed successively with 1 *N* hydrochloric acid, water, 5% aqueous sodium bicarbonate, water and finally with saturated salt solution. The washed extracts were filtered through anhydrous magnesium sulfate and the solvents removed *in vacuo* to give 4.12 g. of amorphous solid. The latter was dissolved in benzene and chromatographed over 206 g. of neutral alumina. After development with benzene and 10% chloroform–benzene, the first fraction eluted (25% chloroform–benzene) weighed 0.155 g. and gave 46.5 mg. of an unidentified material as prisms, m.p. 202.5–207°. The succeeding 7 fractions (50% chloroform–benzene and chloroform) were examined by paper-strip analysis and found to contain diacetate IIIa (see below), in an amount estimated to be 1.57 g., thus raising the total amount of III formed in the perchloric acid reaction to 65.2%. Cortisone acetate was also present in fractions 4–8 and was estimated to amount to 0.316 g. Crystals were obtained from fractions 4–6 by crystallization from acetone–ether, total weight 0.230 g., each sample of which did not depress the m.p. of cortisone acetate. The latter 0.230-g. sample was combined with the two samples isolated above (weights 0.394 and 0.409 g.) and recrystallized from acetone to give 0.708 g. (8.8%) of needles, m.p. 230–233°, undepressed on admixture with cortisone acetate and identified by paper-strip comparison and infrared spectra.

Finally, the column was eluted with acetone and 25% methanol–acetone to yield 3 fractions, total weight 0.920 g. (10.9%), which crystallized on seeding with Δ^4-pregnene-9α,11β,17α,21-tetrol-3,20-dione 21-acetate (I, X = OH). The latter were combined and recrystallized from acetone–ether to give 0.598 g. (7.1%) of prisms, m.p. 215–218.5°, undepressed on admixture with authentic material and further identified by infrared comparison. Thus, the amounts of the three major products formed can be estimated as follows: III together with IIIa, 65.2%; cortisone acetate, 13.9%; (I, X = OH), 10.9%.

Treatment of 9α,11α-oxido-Δ^4-pregnene-17α,21-diol-3,20-dione 21-acetate with 60% perchloric acid as described above for the 9β,11β-oxide resulted in the recovery of unchanged starting material.

A sample of III was treated with 0.5 *N* perchloric acid in aqueous dioxane at 25° for 8 days in an effort to prepare the 21-alcohol. The product could not be crystallized but on acetylation with acetic anhydride and pyridine at 25° afforded the diacetate IIIa (see below). Hydrolysis of III with sodium methoxide in methanol–tetrahydrofuran by the procedure used in the hydrolysis of the dienedione V (see below) also gave only amorphous material. Again acetylation produced the diacetate IIIa (see below). In both experiments above, paper chromatographic examination of the total re-acetylated material showed it to be substantially pure diacetate.

Osmylation of III resulted in the recovery of starting material as the only recognizable crystalline entity. Likewise selective dehydrogenation of III with selenium dioxide in aqueous ethanol according to the procedure of Callow[32] for the oxidation of $\Delta^{8(14)}$-steroid olefins to $\Delta^{8,8(14)}$-dienes produced no change in the ultraviolet spectrum and the material was recovered unchanged.

$\Delta^{4,8(14)}$-Pregnadiene-11β,17α,21-triol-3,20-dione 11β,21-Diacetate (IIIa).—A solution of 1.61 g. (4.0 millimoles) of III in 10 ml. of pyridine and 10 ml. of acetic anhydride was allowed to stand at 25° for 18 hours. The excess reagents were removed *in vacuo* and the oily residue was dissolved in chloroform. The chloroform solution was washed successively with water, 1.0 *N* hydrochloric acid, water, 5% sodium bicarbonate solution, water and finally with saturated salt solution. The washed chloroform was filtered through anhydrous magnesium sulfate and concentrated *in vacuo* to give 1.98 g. of crude IIIa. The latter was substantially pure by paper chromatographic examination. A sample prepared for analysis by recrystallization from ether–petroleum ether (b.p. 30–60°) was obtained as prisms, m.p. 210–215°, $\lambda\lambda_{max}^{Nujol}$ 3.05, 5.74, 5.81 and 6.16(sh) μ.

Anal. Calcd. for $C_{25}H_{32}O_7$: C, 67.57; H, 7.27. Found: C, 67.52; H, 7.32.

8ξ,14ξ-Oxido-Δ^4-pregnene-11β,17α,21-triol-3,20-dione 21-Acetate.—A solution of 402.5 mg. (1.0 millimole) of III in 150 ml. of chloroform was treated with 14.3 ml. of 0.350 *M* perbenzoic acid in benzene (5.0 millimoles). After standing overnight at 0°, the solution was washed with 10% aqueous sodium thiosulfate, water, 5% aqueous sodium bicarbonate and with water. After filtration through magnesium sulfate and removal of the solvents, a residue weighing 480 mg. was obtained. Two recrystallizations from acetone–Skellysolve B gave 192 mg. of the oxide,[2b] m.p. 203–206° dec., λ_{max} 242 mμ (ϵ 14,000); $\lambda\lambda_{max}^{Nujol}$ 2.96, 3.01, 5.75, 5.78 and 6.05–6.1 μ.

Anal. Calcd. for $C_{23}H_{30}O_7$: C, 66.01; H, 7.23. Found: C, 65.90; H, 7.24.

$\Delta^{4,8(14)}$-Pregnadiene-11β,17α,21-triol-3,20-dione 11β-Mesylate-21-acetate (IIIb).—To a solution of 1.0 g. of III in 8 ml. of pyridine cooled to 0° was added dropwise with cooling 0.75 ml. of methanesulfonyl chloride. The mixture was allowed to stand at 0–5° for 18 hours. To the mixture was added 10 g. of ice and after 15 minutes the product was extracted with ether. The ether extract was washed successively with dilute aqueous hydrochloric acid, potassium bicarbonate solution and water, dried over anhydrous magnesium sulfate and concentrated to dryness *in vacuo*. After crystallization from ether the product amounted to 1.1 g. (92%), m.p. 145–147° dec. (reported[2b] m.p. 151–152° dec.).

Acidolysis of IIIb.—A solution of 750 mg. of IIIb in 5 ml. of propionic acid was treated with 750 mg. of potassium bicarbonate and heated in a nitrogen atmosphere at 100° for 1 hour. The reaction mixture was evaporated *in vacuo* and water added to precipitate the product. The latter was isolated by ether extraction and the ether extract washed free of acid, dried and concentrated. The residue obtained after concentration was chromatographed on neutral alumina to yield a small amount of $\Delta^{4,8(14)}$-pregnadiene-11β,17α,21-triol-3,20-dione 11-propionate-21-acetate, m.p. 250–255°; the latter was identical by mixed m.p. and infrared comparison with an authentic sample prepared by propionylation of II with propionic anhydride in pyridine.[2b]

Similar treatment of IIIb with sodium acetate in acetic acid afforded a product containing IIIa by paper chromatography. A considerable amount of XVI and/or XVII appears to accompany the acidolysis reactions.

$\Delta^{4,8(14)}$-Pregnadiene-17α,21-diol-3,11,20-trione 21-Acetate (IV). ($\Delta^{8(14)}$-Dehydrocortisone Acetate).—To a solution of 402.5 mg. (1.0 millimole) of $\Delta^{4,8(14)}$-pregnadiene-11β,17α,21-triol-3,20-dione 21-acetate (III) in 4 ml. of pyridine was added a solution of 333 mg. (3.33 millimoles) of chromium trioxide in 0.33 ml. of water and 1.0 ml. of pyridine. The mixture was allowed to stand at 25° overnight and then diluted with 30 ml. of water and 20 ml. of ethyl acetate. A brown insoluble solid was removed by filtration through Celite and the residue washed thoroughly with water and ethyl acetate. The layers of the filtrate were separated and the aqueous layer extracted twice with ethyl acetate. The combined ethyl acetate layers were washed successively with dilute hydrochloric acid, water and saturated salt solution, and filtered through anhydrous magnesium sulfate. After removal of the solvent, 365 mg. (91.1%) of nearly colorless crystalline solid was obtained. Two recrystallizations from acetone–Skellysolve B afforded 172 mg. (42.9%) of prismatic needles, m.p. 225–229° dec., $[\alpha]^{25}D$ +449° (0.95), λ_{max} 239 mμ (ϵ 15,650); $\lambda\lambda_{max}^{Nujol}$ 3.1, 5.75, 5.80, 5.89, 6.02 and 6.15 μ; $\lambda\lambda_{max}^{CHCl_3}$ 3.00–3.05, 5.75 (sh), 5.80, 5.90, 6.02 and 6.15 μ.

Anal. Calcd. for $C_{23}H_{28}O_6$: C, 68.98; H, 7.05. Found: C, 69.21; H, 7.22.

In another run, 8.05 g. (20.0 millimoles) of III was

(32) R. K. Callow, *J. Chem. Soc.*, 462 (1936).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

oxidized exactly as described above to give 7.57 g. (94.6%) of crude IV; one recrystallization from ethyl acetate gave 5.79 g. (72.4%) of pure IV, m.p. 227–231°, λ_{max} 238 mμ (ε 16,350).

An attempt to hydrolyze the dienedione IV to its **21-alcohol** by treatment with 0.50 *N* perchloric acid in aqueous dioxane at 25° for 8 days gave only amorphous material which, however, on reacetylation with pyridine and acetic anhydride afforded the original 21-acetate.

Treatment of IV with selenium dioxide[32] produced no change in the ultraviolet spectrum and the material was recovered unchanged.

The epimerization of Δ^7-11-ketones with a 9β-hydrogen to the natural 9α-configuration has been reported by Bladon, *et al.*[5b]; the procedure involves treatment with a specially prepared alumina. A sample of IV was adsorbed on this alumina, allowed to stand at 25° for 18 hours, and then eluted. The material was recovered unchanged.

Attempts to isomerize the $\Delta^{4,8(14)}$-dienedione IV to a $\Delta^{4,8(9)}$-dienedione (V or VI) with either (a) lithium chloride in dimethylformamide at 100° for two hours, or (b) hydrogen chloride in ethanol-free chloroform at 0° for one hour failed. In the latter case, the product was contaminated by a chlorine-containing impurity, which, however, was converted to the original dienedione IV by short treatment with refluxing pyridine.

$\Delta^{4,8(14)}$-Pregnadiene-17α,21-diol-3,11,20-trione 17α,21-Diacetate.—A 235-mg. (0.587 millimole) sample of IV in 8.0 ml. of glacial acetic acid and 3.0 ml. of acetic anhydride was treated with 235 mg. of *p*-toluenesulfonic acid monohydrate and the resulting yellow solution stored at 25° overnight. Addition of 50 g. of ice caused the separation of a yellow-brown oil which was extracted with four portions of chloroform. The combined extracts were washed four times with water, once with 5% aqueous sodium bicarbonate, again with water and finally with saturated salt solution. After filtration through anhydrous magnesium sulfate and removal of the solvent an amorphous residue was obtained. One crystallization from acetone–ether gave 169 mg. (65%) of needles, m.p. 212–214°, λ_{max} 238 mμ (ε 15,100); $\lambda\lambda_{max}$ 5.70, 5.75, 5.86, 5.97 and 6.10 μ (no hydroxyl bands in the 3.0 μ region were observed).

Anal. Calcd. for $C_{25}H_{30}O_7$: C, 67.86; H, 6.83; acetyl, 19.45. Found: C, 67.67; H, 6.82; acetyl, 20.8.

A solution of 114.6 mg. (0.25 millimole) of the diacetate above in 3.0 ml. of chloroform was treated with 1.96 ml. of 0.383 *M* perbenzoic acid in benzene (0.75 millimole) and the mixture stored at 0° overnight. The mixture was then extracted twice with 10% sodium thiosulfate solution, washed twice with water, once with 5% sodium bicarbonate solution, again with water and finally with saturated salt solution. Filtration through anhydrous magnesium sulfate and removal of the solvents *in vacuo* gave a colorless crystalline residue, weight 125 mg. One recrystallization from acetone–ether afforded 92.9 mg. (81%) of **8ξ,14ξ-oxido-Δ^4-pregnene-17α,21-diol-3,11,20-trione 17α,21-diacetate** as needles, m.p. 209–211°, depressed on admixture with the starting diacetate, λ_{max} 238 mμ (ε 16,600); $\lambda\lambda_{max}^{Nujol}$ 5.7, 5.75, 5.85, 5.99 and 6.15 μ (no hydroxyl bands in the 3.0 μ region were observed).

Anal. Calcd. for $C_{25}H_{30}O_8$: C, 65.49; H, 6.60. Found: C, 65.59, 65.46; H, 6.43, 6.51.

$\Delta^{4,8(9)}$-Pregnadiene-17α,21-diol-3,11,20-trione 21-Acetate (V). ($\Delta^{8(9)}$-Dehydrocortisone Acetate). (A). By Pyridine Dehydrobromination of 9α-Bromo-Δ^4-pregnene-17α,21-diol-3,11,20-trione 21-Acetate (VII).—The pyridine dehydrobromination of 9α-bromocortisone acetate (VII)[2] was carried out as follows. A solution of 2.41 g. (5.0 millimoles) of VII in 36 ml. of dry purified pyridine was heated under reflux for one hour in an atmosphere of nitrogen. The yellow solution was then concentrated *in vacuo* to give a yellow crystalline residue which was dissolved in 50 ml. of ethyl acetate and 50 ml. of water. The layers were separated and the water layer extracted with two 50-ml. portions of ethyl acetate. The yellow extracts were combined and washed twice with 1.25 *N* hydrochloric acid, with water, with 5% aqueous sodium bicarbonate, again with water and finally with saturated salt solution. The solution was filtered through anhydrous magnesium sulfate and concentrated to dryness *in vacuo* to give 2.01 g. (100%) of yellow crystals, m.p. 233–241° dec. Paper chromatographic analysis of this crude material showed only one spot. Recrystallization from acetone afforded 1.395 g. (69.7%) of yellow prisms, m.p. 241–248° dec. One additional recrystallization did not raise the m.p.; the m.p. (cap.) was 249–250° dec., $[\alpha]^{25}D$ +422° (1.05), λ_{max} 236.5 mμ (ε 17,700); $\lambda\lambda_{max}^{Nujol}$ 2.99, 5.72, 5.80, 6.04 and 6.24 μ.

Anal. Calcd. for $C_{23}H_{28}O_6$: C, 68.98; H, 7.05. Found: C, 69.04; H, 6.75.

The corresponding **21-alcohol** derived from V was prepared by two methods as follows: (a) **By Sodium Methoxide Hydrolysis.**—A 200.5-mg. (0.5 millimole) sample of V in 20 ml. of tetrahydrofuran and 8 ml. of methanol was placed under nitrogen and 0.54 ml. of 0.97 *N* sodium methoxide in methanol (0.525 millimole) added. The mixture was stirred for 10 minutes at 25° and neutralized with a slight excess of glacial acetic acid. The solvents were removed *in vacuo* and the residue dissolved in 25 ml. of water and 25 ml. of ethyl acetate. The layers were separated and the aqueous layer re-extracted with two portions of ethyl acetate. The combined extracts were washed with water, 5% aqueous sodium bicarbonate solution, water and with saturated salt solution, filtered through magnesium sulfate and taken to dryness *in vacuo* to give 170 mg. (95%) of a partly crystalline yellow residue. One crystallization from acetone–ether gave 63 mg. of bright yellow prisms, m.p. 239–243° dec. A sample recrystallized for analysis melted (cap.) at 249–252° dec., λ_{max} 237 mμ (ε 17,900); $\lambda\lambda_{max}^{Nujol}$ 3.0, 5.87, 6.01–6.08 and 6.25 μ.

Anal. Calcd. for $C_{21}H_{26}O_5$: C, 70.37; H, 7.31. Found: C, 70.16; H, 7.18.

A small sample of the material, m.p. 239–243°, was acetylated with acetic anhydride and pyridine and the product shown by paper strip, mixed m.p., and infrared comparison to be authentic V.

(b) **By Potassium Bicarbonate Hydrolysis.**—A suspension of 1.20 g. (3.0 millimoles) of V in 36 ml. of methanol was heated to reflux in an atmosphere of nitrogen; 9 ml. of 1.0 *M* aqueous potassium bicarbonate (9.0 millimoles) was then added. The solid dissolved in one minute and the light reddish-brown solution was refluxed for 5 minutes. The reaction mixture was neutralized with 0.9 ml. of glacial acetic acid and the methanol removed *in vacuo*. The solid which separated was extracted with 1:1 ethyl acetate–chloroform and the extracts washed with water, 5% aqueous sodium bicarbonate, water and saturated salt solution. After drying by filtration through magnesium sulfate, the solvents were removed *in vacuo* to give 1.04 g. (96.7%) of yellow crystals. Two recrystallizations from acetone afforded material, m.p. 240.5–252° dec., identical by infrared comparison with material prepared by sodium methoxide hydrolysis.

(B) **By Alkaline Isomerization of the $\Delta^{4,8(14)}$-Dienedione IV.**—A solution of 2.00 g. (5.0 millimoles) of the dienedione IV in 300 ml. of tetrahydrofuran and 50 ml. of methanol was placed under a nitrogen atmosphere and 16.62 ml. of 0.376 *N* sodium methoxide in methanol (6.25 millimoles) was added with stirring at 23°. After 10 minutes, 0.50 ml. of glacial acetic acid was added to neutralize the solution and the reaction mixture was concentrated *in vacuo* to a yellow gum. The residue was dissolved in 100 ml. of water and 250 ml. of ethyl acetate, the mixture shaken and separated, and the aqueous layer extracted twice with ethyl acetate. The combined extracts were washed with water, 5% aqueous sodium bicarbonate, water and saturated salt solution, filtered through anhydrous magnesium sulfate and the solvents removed *in vacuo* to give a pale yellow foam, weight 1.835 g. A 10-mg. sample of the product was reacetylated with pyridine and acetic anhydride for one-half hour at 65°. Paper-strip analysis of this material showed it to consist mainly of two components, one with an R_f value the same as the starting dienedione IV and the other with an R_f value the same as the isomeric dienedione V. The remainder of the product was crystallized from acetone to give 293 mg. (16.5%) of yellow prisms, m.p. 235–245° dec., undepressed on admixture with the 21-alcohol of V prepared above. The infrared spectra of the two samples were identical. In another run, a product, m.p. 225–230° dec., was obtained in the same manner. A sample of this material on acetylation with pyridine and acetic anhydride gave, after one recrystallization, material of m.p. 227.5–236° dec., undepressed on admixture with V and identical in the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

infrared; this acetylated material depressed the m.p. of the starting dienedione acetate IV.

The mother liquor of the 293-mg. sample above was acetylated in the usual manner and 250 mg. of this material separated by chromatography on Whatman No. 4 paper. Additional V was isolated from the more polar spot and IV was obtained from the less polar spot, m.p. 218.5–227°, identical by mixed m.p. and infrared with the starting material IV.

(C) By Oxidation of XXIV.—To a solution of 100 mg. (0.248 millimole) of $\Delta^{4,8(9)}$-pregnadiene-11β,17α,21-triol-3,20-dione 21-acetate (XXIV) in 10 ml. of chloroform was added 1.0 g. (11.5 millimoles) of manganese dioxide.[33] The mixture was stirred for 22 hours at room temperature (22°), filtered, the residue washed with chloroform and the filtrate concentrated to yield 79.7 mg. of crude material. This mixture was chromatographed on Whatman No. 4 paper to yield 16 mg. (16%) of unoxidized starting material and 23 mg. (27%, based on starting material consumed) of crude $\Delta^{4,8(9)}$-pregnadiene-17α,21-diol-3,11,20-trione 21-acetate (V). The crude material was crystallized twice from acetone–hexane to yield 10.9 mg. (13%, based on starting material consumed) of product, m.p. 232–239° dec., identical with previously obtained material by mixed m.p., infrared spectral comparison and paper strip comparison.

Several experiments carried out on the dienedione V are worthy of mention. In an early attempt to ascertain the disposition of double bonds in V, a sample was reduced with lithium aluminum hydride to give an oily mixture of products which had only end absorption in the ultraviolet. Treatment of a sample of V with selenium dioxide in aqueous alcohol gave only unchanged starting material.[32] Two unsuccessful attempts to isomerize V to the epimeric dienedione VI were carried out (compare below). A solution of V in 60% aqueous perchloric acid was held at 25° and sampled at intervals. Even after 23 hours, no VI could be detected by paper-strip analysis although considerable hydrolysis of the 21-acetate function had occurred and a small amount of an unknown by-product formed. Finally, treatment of V with lithium chloride in dimethylformamide at 100° under nitrogen for 23 hours gave only unchanged starting material by m.p., infrared, and paper-strip analysis.

$\Delta^{4,8(9)}$-17α-Hydroxy-3,11-diketoetiadienic Acid (VIII).—A mixture of 358.5 mg. (1.0 millimole) of the 21-alcohol of V and 250.8 mg. (1.1 millimoles) of periodic acid dihydrate in 50 ml. of tetrahydrofuran and 12 ml. of water was allowed to stand at 25° overnight. Removal of the tetrahydrofuran *in vacuo* caused the separation of a yellow oil which was extracted with three portions of ethyl acetate. The combined extracts were washed twice with water and once with saturated salt solution, filtered through anhydrous magnesium sulfate and concentrated *in vacuo* to give a yellow crystalline residue, weight 365 mg. Recrystallization from acetone gave 216 mg. of the etio-acid VIII, m.p. 228–232° dec. A sample prepared for analysis by recrystallization from acetone–ether had the m.p. (cap.) 238.5–240.5° dec., λ_{max} 235 mμ (ϵ 18,300); $\lambda\lambda_{max}^{Nujol}$ 2.92–3.05, 5.75, 6.0–6.12 and 6.27 μ.

Anal. Calcd. for $C_{20}H_{24}O_5$: C, 69.75; H, 7.02. Found: C, 69.41; H, 7.23.

Methyl 17α-Hydroxy-3,11-diketoalloetianate (IX).—To the deep blue solution obtained from 113 mg. (16.3 millimoles) of lithium dissolved in 50–60 ml. of liquid ammonia was added with stirring a solution of 172.6 mg. (0.5 millimole) of the etio-acid VIII in 18 ml. of dry tetrahydrofuran. After 10–15 minutes, the solution was no longer blue. Therefore, an additional 104 mg. (15.0 millimoles) of lithium was added. Again, after 1 hour, a third portion of lithium was introduced, 115 mg. (16.6 millimoles). After a total time of 5 hours, the deep blue solution was treated with portions of solid ammonium chloride and the resulting nearly colorless solution allowed to evaporate until the ammonia had disappeared. Water was added to the remaining solution and the tetrahydrofuran removed *in vacuo*. The aqueous solution was acidified with 6 *N* hydrochloric acid and the organic material extracted with five portions of ethyl acetate. After washing the combined extracts with water, they were extracted with five portions of 5% aqueous sodium bicarbonate. Acidification of the combined bicarbonate extracts and extraction with ethyl acetate gave 160 mg. of light brown amorphous solid which showed no maxima in the ultraviolet.

The crude reduced acid was dissolved in 5 ml. of methanol and 20 ml. of ether and treated with an excess of ethereal diazomethane. Removal of the solvents gave 170 mg. of crude methyl ester which was dissolved in 5 ml. of glacial acetic acid and treated with 93 mg. (0.93 millimole) of chromium trioxide in 5 drops of water and 6.0 ml. of acetic acid. After standing at 25° for three hours, the acetic acid was removed *in vacuo*. To the residue was added 75 ml. of water and the reoxidized ester extracted with 3 portions of ethyl acetate. The combined extracts were washed with water, 5% aqueous sodium bicarbonate, water and with saturated salt solution, then dried by filtration through anhydrous magnesium sulfate and the solvent removed *in vacuo* to give 110 mg. of a colorless oil. One recrystallization from acetone gave 33 mg. of plates, m.p. 199–215°, undepressed on admixture with a sample of authentic IX, m.p. 198–208°. An additional recrystallization gave 13 mg., m.p. 212.5–226.5°, which by paper-strip comparison consisted of IX together with a small amount of a second more polar material. Therefore, the combined mother liquors were concentrated to dryness and chromatographed over 4.75 g. of neutral alumina. The fractions eluted with benzene and 10% chloroform–benzene were combined, wt. 45.2 mg., and recrystallized to give 23 mg., m.p. 199–211°.

Anal. Calcd. for $C_{21}H_{30}O_5$: C, 69.58; H, 8.34. Found: C, 69.65; H, 8.73.

This material was identical by mixed m.p., infrared and paper-strip comparison with authentic IX prepared from allopregnane-17α,21-diol-3,11,20-trione[34] by successive periodic acid cleavage followed by esterification with diazomethane.

It was ascertained independently that Δ^4-17α-hydroxy-3,11-diketoetienic acid, the acid obtained from cortisone on periodic acid cleavage, on reduction with lithium and ammonia as described above, followed by esterification with diazomethane and reoxidation with chromium trioxide lead mainly to the same alloester IX.

$\Delta^{4,8(9)}$-14-Isopregnadiene-17α,21-diol-3,11,20-trione 21-Acetate (VI). (A) By Lithium Chloride–Dimethylformamide Dehydrobromination of 9α-Bromo-Δ^4-pregnene-17α,-21-diol-3,11,20-trione 21-Acetate (VII).—A mixture containing 7.23 g. (15.0 millimoles) of the bromoketone VII and 7.5 g. (0.177 mole) of lithium chloride in 75 ml. of dimethylformamide was heated for 2 hours at 100° in an atmosphere of nitrogen. The solution was then cooled to 60° and 225 ml. of water added in portions. After cooling at 0° for two hours, the suspension was filtered, the crystalline residue washed thoroughly with water and dried *in vacuo*, weight 5.47 g. (91%), m.p. 186–193°. This material was shown to be essentially pure VI by paper strip analysis. One recrystallization from ethyl acetate gave 4.65 g. (77%), m.p. 193–196°, identical in all respects to material prepared by acid isomerization of V (see below). A sample prepared for analysis had the m.p. 195–198°, $[\alpha]^{25}D$ +348° (0.87), λ_{max} 237.5 mμ (ϵ 19,700); $\lambda\lambda_{max}^{CHCl_3}$ 2.92–2.98, 5.71, 5.79, 5.99 and 6.17 μ.

Anal. Calcd. for $C_{23}H_{28}O_6$: C, 68.98; H, 7.05. Found: C, 69.20; H, 7.25.

(B) By Isomerization of the Dienedione V. (a) *Via* Hydrogen Chloride in Chloroform.—Dry hydrogen chloride was passed into an ice-cold solution of 2.00 g. (5.0 millimoles) of V in 150 ml. of ethanol-free chloroform. Within 5 minutes, the solution was orange-red in color and a red oil had separated. The introduction of hydrogen chloride was continued for 1 hour. Addition of 100 ml. of water discharged the red color and the oil redissolved to give a yellow chloroform layer which was separated and washed free of acid with three portions of water. Filtration through anhydrous magnesium sulfate and removal of the solvent gave a partly crystalline pale yellow residue, wt. 2.10 g.; paper-strip analysis indicated this to be a mixture of V and VI in the ratio of *ca.* 40:60. This material was chromatographed over 210 g. of neutral alumina. The fractions eluted with 25% chloroform–benzene and 35% chloroform–

(33) Manganese dioxide prepared according to the procedure of M. Harfenist, A. Bavley and W. A. Lazier, *J. Org. Chem.*, **19**, 1608 (1954).

Digitized by Arya Samaj Foundation Chennai and eGangotri

benzene and which were mainly VI by paper-strip analysis were combined, wt. 515 mg., and recrystallized. After removal of a small first crop, wt. 87 mg., which was mainly V, the mother liquor on concentration afforded 286 mg. (14.3%) of VI, m.p. 186–194°, undepressed on admixture with material prepared in (A) above, and identical by paper-strip comparison and infrared.

The experiment above was repeated using 40.0 mg. (0.10 millimole) of V in 4.0 ml. of ethanol-free chloroform. After passing in hydrogen chloride for 1 hour, the solution and oil were stored at 0° for 18 hours and then worked up as described above. The crude product was shown to be essentially pure VI by paper strip analysis and on recrystallization afforded 25.1 mg. (62.8%) of crystals, m.p. 188.5–193°, identical to that prepared in (A) above by mixed m.p., paper-strip and infrared comparison.

(b) *Via* **Lithium Chloride–Dimethylformamide–Hydrogen Bromide.**—A mixture of 50.0 mg. (0.125 millimole) of V and 53.0 mg. (1.25 millimoles) of lithium chloride in 0.625 ml. of 0.20 *N* hydrogen bromide (0.125 millimole) in dimethylformamide was heated for 2 hours in an atmosphere of nitrogen. Addition of 6.0 ml. of water and saturation with sodium chloride caused the separation of crystals which were removed by filtration, washed thoroughly with water and dried *in vacuo* to give 45.3 mg. (90.6%) of needles, m.p. 180–191°, undepressed on admixture with material prepared by hydrogen chloride isomerization of V. The identity was confirmed by paper-strip and infrared comparison.

(c) *Via* **Lithium Chloride–Dimethylformamide–Pyridine Hydrobromide.**—A solution of 200 mg. (0.50 millimole) of V, 64 mg. (1.50 millimoles) of lithium chloride and 80 mg. (0.5 millimole) of pyridine hydrobromide in 5.0 ml. of dimethylformamide was heated for 2 hours at 100° under nitrogen. The mixture was cooled to 25° and 5.0 ml. of water added. The crystalline solid which separated was removed by filtration, washed three times with water and dried *in vacuo* to give 80 mg. of crude V, m.p., 225–235°, identified by paper-strip comparison. Recrystallization gave 32 mg., m.p. 229–235° dec. Addition of 50 ml. of saturated salt solution to the aqueous dimethylformamide filtrate above caused the separation of an additional 105 mg. of crystals, m.p. 177–193°, identified as substantially pure VI by paper-strip comparison. Recrystallization afforded 67.5 mg. of pure VI, m.p. 193–197°, undepressed on admixture with material prepared *via* hydrogen chloride isomerization and identified by paper-strip comparison.

(C) By Isomerization of the Dienedione IV with Lithium Chloride–Dimethylformamide–Hydrogen Bromide.—A solution of 100 mg. (0.25 millimole) of the dienedione IV in 0.51 ml. of dimethylformamide containing 100 mg. of lithium chloride (0.236 millimole) was treated with 1.0 ml. of 0.337 *N* hydrogen bromide (0.337 millimole) in dimethylformamide and heated on a steam-bath for 1 hour. The reaction mixture was diluted with water to afford 70–75 mg. of crystalline $\Delta^{4,8}$-dienedione VI which after recrystallization (Norite) from acetone–ether melted at 191–192.5° and was not depressed on admixture with authentic material. The infrared spectra of the two samples were essentially the same.

$\Delta^{4,8(9)}$-14-Isopregnadiene-17α,21-diol-3,11,20-trione 17α,21-Diacetate (VIa).—The 17α,21-diacetate VIa was prepared by treatment of 100 mg. of VI with 3 ml. each of pyridine and acetic anhydride for 7 days at 25°. The excess reagents were then removed *in vacuo* at 25° and the residue dissolved in ethyl acetate. The ethyl acetate solution was washed with water, 1.25 *N* hydrochloric acid, water, 5% aqueous sodium bicarbonate, water and saturated salt solution and dried by filtration through anhydrous magnesium sulfate. Removal of the solvent *in vacuo* gave an amorphous residue, weight 115 mg., which was estimated to contain *ca.* 95% of the 17α,21-diacetate by paper-strip analysis. Separation of the diacetate from unchanged VI was carried out by chromatography on Whatman No. 4 paper. Elution of the diacetate band gave 106 mg. of oily residue which on crystallization from acetone–ether afforded 72.5 mg. of VIa as needles, m.p. 183–185°, $[\alpha]^{25}D$ +275° (0.965), λ_{max} 237.5 mμ (ϵ 19,900); $\lambda\lambda_{max}^{Nujol}$ 5.74, 5.80, 6.04 and 6.30 μ (no hydroxyl bands observed).

Anal. Calcd. for $C_{25}H_{30}O_7$: C, 67.86; H, 6.83. Found: C, 67.87; H, 6.47.

The 21-alcohol derived from VI was prepared by treatment of VI with (a) sodium methoxide in methanolic tetrahydrofuran or (b) potassium bicarbonate in aqueous methanol as described above for the 21-alcohol of the dienedione V. The material could not be crystallized, but reacetylation of small samples followed by paper-strip analysis indicated that no other structural change had occurred. The corresponding etio-acid **$\Delta^{4,8(9)}$-17α-hydroxy-3,11-diketo-14-isoetiadienic acid** was prepared by periodic acid oxidation of the amorphous 21-alcohol as described above. The m.p. after recrystallization from acetone–ether was 235.5–239° dec., λ_{max} 241 mμ (ϵ 19,350); $\lambda\lambda_{max}^{Nujol}$ 2.82–3.0, 5.79 and 6.0–6.2 μ. The m.p. was depressed on admixture with the epimeric acid VIII.

Anal. Calcd. for $C_{20}H_{24}O_5$: C, 69.75; H, 7.02. Found: C, 69.68; H, 6.99.

Several attempts to back-isomerize VI at C_{14} were unsuccessful, thus: (1) Treatment of VI with anhydrous hydrogen chloride in ethanol-free chloroform at 0° for 1 hour gave back unchanged starting material, identified by mixed m.p. and by paper-strip comparison with authentic material, and (2) heating VI at 100° for 1 hour in pyridine in the presence of pyridine hydrobromide gave only unchanged VI identified as above.

$\Delta^{8(9)}$-Pregnene-17α,21-diol-3,11,20-trione 21-Acetate (XI).—A solution of 200 mg. (0.5 millimole) of the yellow dienedione V in 15 ml. of methanol was stirred in an atmosphere of hydrogen in the presence of 50 mg. of 5% palladium-on-barium sulfate. In about 0.5 hour, 12.3 ml. of hydrogen had been absorbed and the uptake ceased. The colorless solution was filtered and the methanol removed *in vacuo* to give 203 mg. of crude XI, m.p. 207–213°. One recrystallization raised the m.p. to 212–216°, $[\alpha]^{25}D$ + 157° (0.78),[35] λ_{max} 256 mμ (ϵ 8,175); $\lambda\lambda_{max}^{CHCl_3}$ 2.85–2.92, 5.72(sh), 5.79, 5.85, 6.01 and 6.21 μ.

Anal. Calcd. for $C_{23}H_{30}O_6$: C, 68.63; H, 7.51. Found: C, 68.69; H, 7.29.

The m.p. of the material above was not depressed when mixed with $\Delta^{8(9)}$-pregnene-17α,21-diol-3,11,20-trione 21-acetate, m.p. 210–216°, isolated as a by-product in the conversion of pregnane-3α,17α-diol-11,20-dione to cortisone acetate[15]; the infrared spectra were identical.

A sample of XI on base hydrolysis and reacetylation resulted in recovery of XI unchanged.

$\Delta^{8(14)}$-Pregnene-11β,17α,21-triol-3,20-dione 21-Acetate (XIII).—A slurry consisting of 3.62 g. of $\Delta^{4,8(14)}$-pregnadiene-11β,17α,21-triol-3,20-dione 21-acetate (III), 2.5 g. of 5% palladium-on-barium sulfate and 130 ml. of methanol was purged with hydrogen and hydrogenated with magnetic stirring at atmospheric pressure. The steroid dissolved during the hydrogenation. The uptake of hydrogen amounted to 103% of the theoretical amount of 1 mole per mole of steroid. The mixture was filtered, the filtrate evaporated to dryness *in vacuo* and the crystalline material dried for 1 hr. at 100° and 0.1 mm. The product, m.p. 188–199°, was obtained in quantitative yield. Three crystallizations from acetone–hexane yielded material, m.p. 195–197°, $[\alpha]^{25}D$ +165° (1.0), no maximum in the ultraviolet; $\lambda\lambda_{max}^{CHCl_3}$ 2.8, 2.92, 5.75(sh), 5.80 and 5.87 μ.

Anal. Calcd. for $C_{23}H_{32}O_6$: C, 68.29; H, 7.97. Found: C, 68.16; H, 7.88.

Attempted hydrogenation of XIII over platinum-in-methanol and over platinum-in-acetic acid resulted in no further hydrogen uptake. Reduction of XIII with lithium aluminum hydride followed by attempted oxidation with selenium dioxide[31] produced no change in the ultraviolet spectrum.

$\Delta^{8(14)}$-Pregnene-11β,17α,21-triol-3,20-dione 11β-Mesylate 21-Acetate (XIIIa).—To a solution of 0.404 g. (1.0 millimole) of $\Delta^{8(14)}$-pregnene-11β,17α,21-triol-3,20-dione 21-acetate (XIII) in 5 ml. of pyridine cooled to 0° was added dropwise with cooling 1.0 ml. of methanesulfonyl chloride (13 millimoles). The mixture was allowed to stand at 0° for 24 hours. To the mixture was added 10 g. of ice and

(35) On several occasions the hydrogenation product exhibited unusual behavior. Paper-strip analysis indicated a less polar constituent as the major product separable by chromatography on neutral alumina, having a m.p. 173–177° and infrared ($CHCl_3$) and ultraviolet the same as XI with slightly lower extinction. This compound changed on standing in the solid state to the more polar XI, m.p. 212–216°. This behavior might be interpreted as the consequence of a boat ⇄ chair conformational transition induced by lattice forces.

after 15 minutes the product was extracted with ethyl acetate. The ethyl acetate extract was washed successively with water, 1.6% phosphoric acid, 5% sodium bicarbonate solution, water, dried over magnesium sulfate and concentrated to dryness *in vacuo*. The residue was crystallized from acetone–hexane to yield 0.255 g. (53%) of XIIIa, m.p. 142–144° dec., $[\alpha]^{25}D$ +131.5° (1.0).

Anal. Calcd. for $C_{24}H_{34}O_8S$: C, 59.71; H, 7.10; S, 6.64. Found: C, 59.76; H, 6.82; S, 6.72.

$\Delta^{8(14),9(11)}$-Pregnadiene-17α,21-diol-3,20-dione 21-Acetate (XIV).—A solution of 100 mg. (0.208 millimole) of $\Delta^{8(14)}$-pregnene-11β,17α,21-triol-3,20-dione 11-mesylate-21-acetate (XIIIa) in 1.0 ml. of pyridine was refluxed for 2 hours. After addition of 10 ml. of water the mixture was extracted with three 10-ml. portions of ethyl acetate. The combined ethyl acetate extracts were washed with water, 1.6% phosphoric acid, 5% sodium bicarbonate solution, water and saturated salt solution, dried over magnesium sulfate and concentrated *in vacuo*. The crude product was treated with decolorizing charcoal and crystallized from acetone–hexane, m.p. 180–185°, $[\alpha]^{24}D$ +79° (1.0), λ_{max} 271 mμ (ϵ 4,600); $\lambda\lambda_{max}^{Nujol}$ 2.91, 5.73, 5.80, 5.85 and 5.91 μ.

Anal. Calcd. for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82. Found: C, 71.22; H, 7.88.

Reduction of XIV with lithium aluminum hydride gave an amorphous product, λ_{max} 271 mμ (ϵ 4,210).

$\Delta^{8(14)}$-Pregnadiene-17α,21-diol-3,20-dione 21-Acetate (XV).—A solution of 150 mg. (0.39 millimole) of $\Delta^{8(14),9(11)}$-pregnadiene-17α,21-diol-3,20-dione 21-acetate (XIV) in 10 ml. of chloroform was treated with gaseous hydrogen chloride at 0° for 1 hour. The mixture was evaporated to dryness, treated with decolorizing charcoal and crystallized from acetone–hexane, m.p. 210–214°, $[\alpha]^{23}D$ −26.2° (1.0), λ_{max} 246 mμ (ϵ 21,500); $\lambda\lambda_{max}^{Nujol}$ 2.9, 5.75(sh), 5.79, 5.87, 6.11 and 6.20 μ.

Anal. Calcd. for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82. Found: C, 71.46; H, 7.55.

$\Delta^{4,8(14),9(11)}$-Pregnatriene-17α,21-diol-3,20-dione 21-Acetate (XVI).—By a method analogous to the preparation of XIV from XIIIa, $\Delta^{4,8(14)9,(11)}$-pregnatriene-17α,21-diol-3,-20-dione 21-acetate (XVI) was obtained from $\Delta^{4,8(14)}$-pregnadiene-11β,17α,21-triol-3,20-dione 11β-mesylate 21-acetate (IIIb). The product was obtained as needles from acetone, m.p. 182–186°, $[\alpha]^{24}D$ +120° (1.0), λ_{max} 241 mμ (ϵ 21,600), 270 mμ(sh) (ϵ 4,700); $\lambda\lambda_{max}^{CHCl_3}$ 2.85–2.90, 5.73, 5.78, 6.00 and 6.15 μ.

Anal. Calcd. for $C_{23}H_{28}O_5$: C, 71.88; H, 7.30. Found: C, 71.66; H, 7.11.

$\Delta^{4,8,(14)}$-Pregnatriene-17α,21-diol-3,20-dione 21-Acetate (XVII). (A).—By treatment with gaseous hydrogen chloride in chloroform as previously described for conversion of XIV to XV, $\Delta^{4,8(14),9(11)}$-pregnatriene-17α,21-diol-3,20-dione 21-acetate (XVI) was converted to $\Delta^{4,8(9),14}$-pregnatriene-17α,21-diol-3,20-dione 21-acetate, m.p. 188–192°, $[\alpha]^{24}D$ +143°, λ_{max} 242 mμ (ϵ 37,400); $\lambda\lambda_{max}^{CHCl_3}$ 2.90–2.95, 5.73(sh), 5.78, 6.00 and 6.1(sh) μ.

Anal. Calcd. for $C_{23}H_{28}O_5$: C, 71.88; H, 7.30. Found: C, 71.64; H, 7.56.

(B).—The method which employed 60% perchloric acid for conversion of II to III converted 17α-hydroxy-$\Delta^{8(9)}$-dehydrocorticosterone 21-acetate (XXIV) exclusively to $\Delta^{4,8(9),14}$-pregnatriene-17α,21-diol-3,20-dione 21-acetate (XVII) identical with material of method A by mixed m.p. and by ultraviolet spectrum.

8ξ,14ξ-Oxido-Δ^4-pregnene-17α,21-diol-3,11,20-trione 21-Acetate (XIX). (A) By Perbenzoic Acid Oxidation of the Dienedione IV.—A solution of 801 mg. (2.0 millimoles) of the dienedione IV in 20 ml. of chloroform was treated with 17.25 ml. of 0.348 *M* perbenzoic acid in benzene (6.0 millimoles) and the mixture stored overnight at 0°. During this time rosettes of needles had separated and were removed by filtration and washed once with ether, once with 10% aqueous sodium thiosulfate, three times with water, three times with ether and dried *in vacuo*, wt. 756.4 mg. (90.8%), m.p. 247.5–260° dec. Extraction of the filtrate and washings was effected with ethyl acetate, the extracts were washed with water, aqueous sodium thiosulfate and aqueous sodium bicarbonate in the usual manner, and afforded an additional 115 mg. of crude product. Recrystallization of this latter sample from methanol gave 39.4 mg. (4.6%), m.p. 249–262° dec. A sample prepared for analysis by recrystallization from acetone–methanol had the m.p. 245–250° dec. (the m.p. of this oxide was dependent on the state of subdivision and the rate of heating), λ_{max} 238 mμ (ϵ 14,600); $\lambda\lambda_{max}^{Nujol}$ 2.9, 5.74, 5.80, 5.90 and 6.04 μ.

Anal. Calcd. for $C_{23}H_{28}O_7$: C, 66.33; H, 6.78; acetyl, 10.30. Found: C, 66.10; H, 6.59; acetyl, 9.72.

(B) Pyridine–Chromium Trioxide Oxidation of 8ξ,14ξ-Oxido-Δ^4-pregnene-11β,17α,21-triol-3,20-dione 21-Acetate.—Oxidation of 126 mg. (0.30 millimole) of the oxide of III, m.p. 203–206° dec., with chromium trioxide in pyridine (see oxidation of III to IV) afforded, after one crystallization from acetone, 88 mg. of XIX, m.p. 242–254° dec., undepressed on admixture with material prepared in (A) above. The infrared spectra were identical.

The 21-alcohol of the oxide XIX was prepared as follows: a 208.2-mg. (0.50 millimole) sample of XIX in 75 ml. of dioxane was mixed with 25.0 ml. of 2.0 *N* aqueous perchloric acid and the mixture stored at 25° for 6 days; 200 ml. of saturated salt solution was added and the organic material extracted with three portions of ethyl acetate. The combined extracts were washed with water until neutral, then with saturated salt solution, filtered through anhydrous magnesium sulfate and the solvents removed to give a granular crystalline residue, weight 180 mg., m.p. 210–225° dec. Recrystallization twice from acetone–ether afforded 92.5 mg. of micro-needles, m.p. 222–226° dec., λ_{max} 240 mμ (ϵ 12,700); $\lambda\lambda_{max}^{Nujol}$ 2.78, 3.04, 5.83, 5.89 and 6.07 μ; $\lambda\lambda_{max}^{CHCl_3}$ 5.84, 5.99 and 6.1 μ.

Anal. Calcd. for $C_{21}H_{26}O_6$: C, 67.36; H, 7.00. Found: C, 67.59; H, 6.80.

In order to prove that no changes other than hydrolysis had occurred, a 30-mg. sample of the 21-alcohol was acetylated with acetic anhydride and pyridine at 25°. Within 10 minutes the solution had deposited crystalline material. After standing overnight at 25°, ice and water were added and the excess acetic anhydride decomposed. Filtration gave 31 mg. of XIX, m.p. 252–260° dec., undepressed on admixture with authentic material. Comparison of the infrared spectra confirmed the identity.

A number of unsuccessful experiments were performed in an effort to transform the oxide XIX into other products. These are briefly as follows: (1) an attempt to epimerize XIX at C-9 on special alumina[5b] gave unchanged starting material; (2) treatment with excess ozone in ethyl acetate at −80° gave 25% of unchanged XIX and an amorphous mixture of unidentified products; (3) subjection of a sample of XIX to the action of osmium tetroxide in pyridine–benzene gave 62% recovery of starting material with no other products isolated; (4) on treatment with periodic acid in dilute aqueous dioxane, XIX was recovered unchanged; and (5) heating a sample of XIX with lithium chloride in dimethylformamide for two hours at 100° again gave unchanged starting material. Under more strongly acidic conditions, however, the oxide XIX was not recovered, but no pure products could be isolated. The acidic conditions employed were as follows: (1) acetic acid, acetic anhydride and *p*-toluenesulfonic acid at 25° overnight; (2) treatment of a chloroform solution of XIX with 60% aqueous perchloric acid at 0° for 15 minutes; and (3) the action of dry hydrogen chloride in chloroform at 0° for one hour.

$\Delta^{4,6,8(14)}$-Pregnatriene-17α,21-diol-3,11,20-trione (XX).[25]—A suspension of 521 mg. (1.25 millimoles) of the oxide XIX in a mixture of 75 ml. of tetrahydrofuran and 25 ml. of methanol was placed under a nitrogen atmosphere and 4.16 ml. of 0.376 *N* sodium methoxide in methanol (1.56 millimoles) added with stirring. After 7 minutes, the solid had dissolved to give a pale purple-yellow solution and after 8 minutes, the reaction was quenched by the addition of 0.20 ml. of glacial acetic acid. The solvents were removed *in vacuo* at 25° and the sirupy residue taken up in ethyl acetate. After washing the solution with water, 5% aqueous sodium bicarbonate solution, water and saturated salt solution, it was filtered through anhydrous magnesium sulfate and the ethyl acetate removed *in vacuo* to give a yellow amorphous solid, weight 445 mg., $\lambda\lambda_{max}$ 237 mμ, $E_{1\,cm.}^{1\%}$ 279 and 336 mμ, $E_{1\,cm.}^{1\%}$ 270. Two crystallizations from acetone afforded 89.5 mg. (19%) of XX, m.p. 225–235° dec., λ_{max} 337 mμ (ϵ 25,800); $\lambda\lambda_{max}^{Nujol}$ 3.0, 5.82, 6.1 and 6.26 μ; $\lambda\lambda_{max}^{CHCl_3}$ 3.0, 5.82, 6.02 and 6.23 μ.

Anal. Calcd. for $C_{21}H_{24}O_5$: C, 70.77; H, 6.79. Found: C, 70.49; H, 7.04.

A sample of the trienedione XX prepared above was acetylated with acetic anhydride and pyridine at 25° overnight. Isolation in the usual manner gave the 21-acetate of XX, m.p. 218–225° dec., λ_{max} 334 mμ (ε 27,500), $\lambda\lambda_{max}^{CHCl_3}$ 3.0, 5.72(sh), 5.79, 6.01 and 6.22 μ; $\lambda\lambda_{max}^{Nujol}$ 2.95, 5.74, 5.80, 5.85, 6.0 and 6.23 μ.

Anal. Calcd. for $C_{23}H_{26}O_6$: C, 69.33; H, 6.58. Found: C, 69.06; H, 6.83.

The disposition of double bonds in the trienedione XX was ascertained by reduction with lithium aluminum hydride. A 40-mg. (0.122 millimole) sample of XX in 10 ml. of tetrahydrofuran was added over 20 minutes to a stirred solution of 106 mg. (2.8 millimoles) of lithium aluminum hydride in 10 ml. of tetrahydrofuran. The addition was carried out in an atmosphere of nitrogen. After heating under reflux for 1.5 hours, the reaction was worked up by adding ethyl acetate, saturated aqueous sodium sulfate and anhydrous magnesium sulfate. Filtration and removal of the solvents afforded a gummy residue. This was dissolved in ethyl acetate, the solution washed twice with water, once with saturated salt solution, dried, filtered and the solvent removed *in vacuo* to give 20.9 mg. of amorphous solid XXI, λ_{max} 284.5 mμ (ε 19,150).

Hydrogenation of 132 mg. (0.37 millimole) of XX over 50 mg. of palladium-on-barium sulfate in 10 ml. of methanol also was carried out. The absorption of hydrogen continued at a steady rate until 18.4 ml. had been consumed (0.74 millimole or 2 moles/mole). The solution was filtered and the methanol removed *in vacuo*. Acetylation with acetic anhydride in pyridine at 60–70° for one hour followed by isolation in the usual manner gave 160 mg. of amorphous solid exhibiting only end absorption in the ultraviolet. This product was chromatographed on neutral alumina and the fractions eluted with 20 and 30% chloroform in benzene were combined, weight 104 mg. Two crystallizations, from ether–Skellysolve B and then from acetone–ether, gave 14.5 mg. of crystals, m.p. 193–203° with previous softening; $\lambda\lambda_{max}^{CHCl_3}$ 2.76, 2.84–2.97, 5.72(sh), 5.79(sh) and 5.83 μ. A mixture with the $\Delta^{8(14)}$-enedione XXII was depressed.

$\Delta^{8(14)}$-Pregnene-17α,21-diol-3,11,20-trione 21-Acetate (XXII). (A) By Hydrogenation of IV.—A solution of 400.5 mg. (1.0 millimole) of the dienedione IV in 20 ml. of methanol was stirred in a hydrogen atmosphere at 25° and atmospheric pressure in the presence of 100 mg. of 5% palladium-on-barium sulfate. In 1.5 hours, the absorption of hydrogen ceased, 23.2 ml. having been taken up. The solution was filtered and the solvent removed *in vacuo* to give an amorphous residue. This material exhibited only end absorption in the ultraviolet. One recrystallization from ethyl acetate afforded 330 mg. of XXII, m.p. 196–198.5°, $\lambda\lambda_{max}^{Nujol}$ 2.85, 5.73, 5.79 and 5.86 μ; $[\alpha]^{25}D$ +306 (0.8). This material was identical by mixed m.p. and infrared spectrum with material prepared by oxidation of XIII (see below).

Anal. Calcd. for $C_{23}H_{30}O_6$: C, 68.63; H, 7.51. Found: C, 68.37; H, 7.37.

A 100-mg. (0.25 millimole) sample of XXII in 2.5 ml. of tetrahydrofuran and 1.5 ml. of methanol was placed under a nitrogen atmosphere and treated with 4.64 ml. of 0.118 *N* sodium methoxide in methanol (1.10 millimoles). The amber solution was held at 23° for 1 hour, then neutralized with 0.2 ml. of glacial acetic acid. The residue on concentration to dryness *in vacuo* was treated with 1.0 ml. of acetic anhydride and 2.0 ml. of pyridine and allowed to stand overnight at room temperature (23°). After concentration to dryness *in vacuo* 101 mg. of yellow crystalline material was obtained. Paper chromatographic analysis and the infrared spectrum showed the material to be essentially unchanged. One recrystallization from ethyl acetate–ether yielded colorless needles which did not depress the m.p. of starting material.

A sample of XXII was dissolved in chloroform and gaseous hydrogen chloride was bubbled through the solution for 1 hour at room temperature. The product after concentration to dryness showed an ultraviolet spectrum unchanged from that of starting material.

A sample of XXII together with 3 equivalents of lithium chloride were dissolved in dimethylformamide. The mixture was heated on the steam-bath under nitrogen for 2 hours, then cooled to room temperature, diluted with water and saturated salt solution and the product obtained by filtration. The product, m.p. 188–191°, did not depress the m.p. of starting material. The ultraviolet spectra of the product and the starting material were identical.

(B) By Oxidation of XIII.—To a solution at 0° consisting of 0.404 g. (1.0 millimole) of $\Delta^{8(14)}$-pregnene-11β,17α,21-triol-3,20-dione 21-acetate (XIII) in 4 ml. of pyridine was added dropwise with cooling 0.333 g. of chromium trioxide (3.33 millimoles) dissolved in 0.33 ml. of water and 0.50 ml. of pyridine. The mixture was allowed to stand for 18 hours at room temperature. After dilution with 80 ml. of water and 20 ml. of ethyl acetate the mixture was filtered. The residue was washed with ethyl acetate and the aqueous phase extracted with ethyl acetate. The ethyl acetate phase was washed successively with water, 0.5 *N* phosphoric acid and water, then filtered through anhydrous magnesium sulfate. The crude product after concentration *in vacuo* amounted to 0.361 g. (90%). Two recrystallizations from ethyl acetate–ether yielded a product identical with that of method A by m.p. 194–198°, mixed m.p., infrared spectrum and paper-strip comparison.

$\Delta^{8(9)}$-14-Isopregnene-17α,21-diol-3,11,20-trione 21-Acetate (XXIII). (A) By Hydrogenation of the Dienedione VI.—A solution of 800 mg. (2.0 millimoles) of VI in 40 ml. of methanol was hydrogenated as described above in the presence of 100 mg. of 5% palladium-on-barium sulfate. The absorption of hydrogen ceased in *ca.* 15 minutes, 49 ml. having been taken up. After filtration to remove the catalyst, the solvent was removed *in vacuo* to yield a colorless crystalline residue, weight 815 mg., m.p. 177–181°. One recrystallization from ethyl acetate–ether gave 750 mg. (93%) of XXIII, m.p. 178–181°, λ_{max} 248 mμ (ε 8,450), $\lambda\lambda_{max}^{CHCl_3}$ 2.85, 2.95, 5.73, 5.79, 5.83, 6.0 and 6.18 μ.

Anal. Calcd. for $C_{23}H_{30}O_6$: C, 68.63; H, 7.51. Found: C, 68.56; H, 7.49.

(B) By Isomerization of the Enedione XI.—Treatment of 100 mg. of XI with anhydrous hydrogen chloride in ethanol-free chloroform at 0° for one hour as described above for the conversion of V to VI gave 97 mg. of crude product, m.p. 161–190°. Crystallization from ethyl acetate–ether gave 30 mg., m.p. 198–208°, which on recrystallization had the m.p. 206–213°, undepressed on admixture with the starting enedione XI. The mother liquor of the 30 mg. sample on concentration and seeding with XXIII prepared by hydrogenation afforded 17 mg. of crystals, m.p. 174–180°, undepressed on admixture with authentic XXIII and possessing an identical infrared spectrum.

A sample of the low-melting, less polar form of XI[24] described above gave essentially the same results on isomerization with hydrogen chloride in chloroform.

The enedione XXIII was stable to the action of hydrogen chloride in chloroform at 0° for one hour, the conditions under which it is formed from XI.

(C) By Isomerization of the Enedione XXII.—Isomerization of XXII with hydrogen bromide–lithium chloride–dimethylformamide exactly as described above for the conversion of IV to VI (method C) gave on dilution with water essentially pure XXIII, m.p. 176–178°, λ_{max} 248 μ (ε 8,400). The m.p. was undepressed on admixture with material prepared by hydrogenation and the infrared spectra were identical. The above isomerization occurred also when the lithium chloride was omitted.

$\Delta^{4,8(9)}$-Pregnadiene-11β,17α,21-triol-3,20-dione 21-Acetate (17α-Hydroxy-$\Delta^{8(9)}$-dehydrocorticosterone 21-Acetate) (XXIV).—A solution consisting of 62.0 g. (0.128 mole) of 9α-bromo-17α-hydroxycorticosterone 21-acetate (I, X = Br) and 400 ml. of tetrahydrofuran was added to 400 ml. of N-ethylpiperidine and the mixture refluxed for 7.5 hours. The mixture was concentrated *in vacuo* to about 450 ml., filtered and the precipitate washed with three 50-ml. portions of distillate. The precipitate was then washed with water until free of bromide ion; the water washes were caught separately and discarded. The residue amounting to 39.0 g. (75.5%) was chiefly 9β,11β-oxido-Δ^4-pregnene-17α,21-diol-3,20-dione 21-acetate (II), as determined by m.p., mixed m.p. and paper-strip analysis.

The filtrate upon concentration to dryness *in vacuo* yielded 16.74 g. of a steroid mixture. Of this mixture, a 5.00-g. aliquot was chromatographed on neutral alumina. Fractions were eluted with mixtures of benzene and chloroform and the composition of these determined by paper chromatography. $\Delta^{4,8(9)}$-Pregnadiene-11β,17α,21-triol-3,20-dione 21-acetate (XXIV) shows an R_f of 0.09 (benzene–formamide–Eluting system, cortisone 21-acetate and 9β,-

11β-oxido-Δ^4-pregnene-17α,21-diol-3,20-dione 21-acetate (II) show R_f 0.33 and 0.50, respectively. Fractions amounting to 2.04 g., rich in product were rechromatographed on neutral alumina to yield 0.667 g. of purified compound, m.p. 195–215° dec. Treatment with decolorizing charcoal and three crystallizations from acetone–hexane yielded analytical material, m.p. 213–216° dec., $[\alpha]^{24}D$ +219° (1.0), λ_{max} 238 mμ (ϵ 16,400); $\lambda\lambda_{max}^{Nujol}$ 2.82, 2.89, 5.81, 6.00 and 6.19 μ.

Anal. Calcd. for $C_{23}H_{30}O_6$: C, 68.69; H, 7.51. Found: C, 68.65; H, 7.58.

$\Delta^{4,8(9)}$-Pregnadiene-11β,17α,21-triol-3,20-dione 11β,21-Diacetate (XXIVa).—A solution consisting of 102.5 mg. (0.255 millimole) of $\Delta^{4,8(9)}$-pregnadiene-11β,17α,21-triol-3,20-dione 21-acetate (XXIV), 1 ml. of pyridine and 1 ml. (10.6 millimoles) of acetic anhydride was allowed to stand for 1 week at room temperature (24°). The mixture was diluted with 20 ml. of water, filtered and the residue washed with water. The precipitate amounting to 81.5 mg. (71.4%) was recrystallized from acetone–hexane to yield 65.4 mg. (57.3%) of product, m.p. 201–204°, $[\alpha]^{25}D$ +224° (1.0), λ_{max} 237 mμ (ϵ 16,000); $\lambda\lambda_{max}^{Nujol}$ 2.96, 5.79, 5.97 and 6.13 μ.

Anal. Calcd. for $C_{25}H_{32}O_7$: C, 67.55; H, 7.26. Found: C, 67.52; H, 7.51.

$\Delta^{4,7,9(11)}$-Pregnatriene-17α,21-diol-3,20-dione 21-Acetate (XXV).—To a solution of 304 mg. (0.756 millimole) of 17α-hydroxy-$\Delta^{8(9)}$-dehydrocorticosterone 21-acetate (XXIV) and 3.75 ml. of pyridine cooled to 0° was added dropwise with cooling 0.75 ml. (10 millimoles) of methanesulfonyl chloride. The mixture was allowed to stand at 0° for 24 hours. To the mixture was added 10 g. of ice and after 15 minutes the product was extracted with ethyl acetate. Concentration of the washed, dried extract yielded 189 mg. (64.9%) of crude triene. The crude material was treated with decolorizing charcoal and crystallized twice from acetone–hexane to yield 85 mg. (29%) of pale yellow needles, m.p. 199–203°, $[\alpha]^{27}D$ +236° (1.0); $\lambda\lambda_{max}$ 242.5 mμ (ϵ 26,200), 237.5(sh) and 250(sh) mμ (ϵ 24,900 and 22,100), $\lambda\lambda_{max}^{CHCl_3}$ 2.9, 5.74(sh), 5.78, 6.0 and 6.12 μ.

Anal. Calcd. for $C_{23}H_{28}O_5$: C, 71.85; H, 7.34. Found: C, 71.53; H, 7.31.

Reduction of XXV with lithium aluminum hydride in tetrahydrofuran yielded an amorphous product; $\lambda\lambda_{max}$ 237, 244 mμ (ϵ 7,780, 8,510), 251(sh) mμ (ϵ 6,130).

Synthetic Studies in Resin Acids. II[1]

BY USHARANJAN GHATAK, NARENDRA NATH SAHA[2] AND PHANINDRA CHANDRA DUTTA[3]

RECEIVED FEBRUARY 18, 1957

The conversion of $>C{=}O$ to $>C<^{CH_3}_{CO_2H}$ has been studied for the case of cyclohexanone and 10-methyldecalone. Two successful methods were achieved for cyclohexanone and one of these was also effective for the decalone system. The second procedure, involving action of methylmagnesium iodide on ethyl 10-methyldecalidene-1-cyanoacetate, failed because reduction rather than addition occurred. The significance of the above syntheses for the preparation of diterpenoid resin acids is noted.

In the synthesis of compounds related to diterpenoid resin acids, the conversion of the tricyclic ketones[1,4] to the corresponding *gem*-methylcarboxylic acids, is of considerable importance. The purpose of the present investigation was to seek suitable means for this conversion, using cyclohexanone and 10-methyldecalone as model compounds. In this communication the essential steps for two procedures, which were successful for the synthesis of 1-methyl-1-carboxy-cyclohexane VII are described. A recent publication,[5] which appeared subsequent to our preliminary communication[6] embodying these methods, has also supported these results.

In procedure I, ethyl cyclohexane-1-carbethoxy-1-acetate obtained from the dicyano-ester[7] was the starting material. The silver salt of the monoester IV afforded the bromoester V on treatment with bromine. Hunsdiecker degradation promised to be a useful route to rather inaccessible bromides of the neopentyl type and hence it has been utilized successfully to build up the quaternary methyl group. The bromide V on reduction with zinc and acetic acid yielded VI, from which VII was obtained on alkaline hydrolysis. VII was further characterized by conversion to its amide.[8] In procedure II, VIII was obtained through the conjugate addition[9] of methyl Grignard reagent to III in the presence of cuprous iodide.[10] The controlled hydrolysis of VIII and pyrolysis of the acidic product yielded the nitrile IX. Attempts at acidic or alkaline hydrolysis of the nitrile were unsuccessful. The nitrile IX was then allowed to react with phenylmagnesium bromide leading to X, which on further reaction with the same reagent gave a mixture of the corresponding carbinol and the dehydrated product. This mixture was directly oxidized to VII.

With the idea that these two procedures in the case of unsymmetrical ketones should lead to dif-

ferent epimers[11] and also for the reasons stated before,[1b] 10-methyldecalone (XI) was selected as the second starting ketone. In this case the stereochemistry of the final products, which were expected to result by the above routes, was of special interest in connection with the synthesis of the natural resin-acids, represented by abietic acid and podocarpic acid or their congeners. It was believed that the conjugate addition to the unsaturated cyano-ester XIII, of ions or components of Grignard complex probably through ions and/or radicals,[12] might be markedly influenced stereochemically[13] by the presence of the angular methyl group (*e.g.*, in XI). The degree of stereospecificity may not be the same in both cases and one of the reasons might be that the general pattern of homolytic reactions is singularly free from powerful electrostatic forces, which operate in ionic reactions in addition to steric factors. The first of the above routes proved successful and led to 1,10-dimethyldecalin-1-carboxylic acid, the stereochemistry of which may be either as shown in I or II.

From consideration of the steric courses of reactions and results in a closely related work,[14] it can be concluded with confidence that the product obtained is II. That the synthetic acid did not belong to the podocarpic acid series (*e.g.*, I) was also apparent from the comparatively less drastic conditions,[15] that were required for the isolation of the acid II.

The ketone XI was obtained from 10-methyldecalin-1,3-dione.[16] This was converted to the chloro-ketone XII which in its turn was reduced catalytically with or without the addition of pyridine. The formation of the isomeric 3-ketone appeared less likely from steric considerations, and structure XI was confirmed through the isolation of 1-methylnaphthalene by action of methylmagnesium iodide and subsequent dehydrogenation. The desired ketone XI condensed[17] with ethyl cyanoacetate to afford XIII. The dicyano-ester XIV was obtained in an excellent yield by addition of hydrocyanic acid[18] to XIII. The dibasic acid XV was isolated in a highly crystalline form and the partial hydrolysis of the diester led to the half-ester XVI. Hunsdiecker degradation of the latter yielded XVII, which was reduced to XVIII. Finally acid II was obtained by hydrolyzing the ester with methanolic potassium hydroxide.

During the course of this investigation, the remote possibility of the formation of XXX in place of XVIII was considered and discarded on the basis of hydrolytic experiments. Attempts at hydrolysis under mild conditions led to the re-

covery of the ester thereby ruling out the structure XXX.

In the second route which was expected to lead to acid I, reaction of XIII with methylmagnesium iodide in the presence of cuprous iodide did not proceed as anticipated on the basis of reaction in the cyclohexane series; the product isolated was a complex mixture as revealed by infrared studies and was characterized by a strong hydroxyl band (3 μ) and a doublet (7.25 and 7.3μ) of a *gem*-dimethyl group. The neutral material was subjected to controlled alkaline hydrolysis. The acid from the base-soluble portion, was decarboxylated and the nitrile so obtained was converted into the corresponding phenyl ketone. The analytical values of it and of the related dinitrophenylhydrazone indicated that the ketone should be represented by XXI. This was further confirmed by the mixed melting point determination of this derivative, prepared from an authentic sample of the ketone XXI (*vide infra*). It is now apparent that the major product of the Grignard reaction is XXIII, resulting from the reduction of the double bond. Consequently XX represents the structure of the nitrile. This observation parallels action of Grignard reagents on azo-compounds[19] or hindered ketones.[20] There are recorded[21] some cases of reduction of alkalidene cyano-acetates with Grignard reagents from higher aliphatic as well as aromatic halides. In the original reaction mixture some amount of the compound XXII, quite analogous to that isolated in the case of the tricyclic ketone,[14] was most probably present but the isolation of the same or of the corresponding dehydration product in a pure state could not be accomplished.

To prepare an authentic dinitrophenylhydrazone of XXI, the unsaturated cyano-ester XIII was reduced with aluminum amalgam to XXIII which through the same series of reactions as described before, yielded the corresponding ketone. Fractional crystallization of the dinitrophenylhydrazones revealed that this ketone was a mixture of stereoisomers, one of which was identical with the ketone XXI described above.

Finally to trace the origin of this abnormal type of reaction induced by the Grignard reagent and to evaluate the steric effect of the angular methyl group, α-decalone was converted to XXIV, which led to the normal addition product XXV and the corresponding ketone XXVIII in good yields. Similarly XXVI from 3,3-dimethylcyclohexanone behaved in a normal way leading to XXVII, which yielded XXIX. In both cases the ketones were characterized through well-defined semicarbazones.

Evidently the powerful non-bonded interaction between the angular methyl group and the axially oriented intermediate complex,[22] incorporating the cyanoacetic ester residue in the normal addition product, was responsible for this abnormal reaction-path, indicating once more the importance of steric factors in the abnormalities of Grignard reactions.

Acknowledgments.—We are indebted to Prof. Norman Kharasch, Department of Chemistry, University of Southern California, for kindly reading this manuscript. Our grateful thanks are also due to Dr. R. Schwyzer, Basle, Switzerland, and to Mrs. Chhabi Dutta, University College of Science, Calcutta, for micro-analyses.

Experimental[23]

Ethyl 1-Bromomethylcyclohexane-1-carboxylate (V).—Ethyl cyclohexane-1-carbethoxy-1-acetate (15 g., 0.062 mole) was hydrolyzed with a solution of potassium hydroxide (4.5 g., 0.08 mole), water (4.5 ml.) and ethanol (81 ml.). The crude half-ester (11.1 g.) in alcohol (20 ml.) was neutralized (phenolphthalein) with 1 *N* sodium hydroxide solution and converted into the silver salt. It was dried at 50–60° and finally under vacuum at 110° for 15 hours. The salt (11 g.) was suspended in dry carbon tetrachloride (50 ml.) and gradually treated with a solution of bromine (2 ml.) in the same solvent (10 ml.) at the reflux temperature. Silver bromide was collected and the carbon tetrachloride layer was washed with 5% sodium carbonate solution. Distillation afforded 6.9 g. (43%), b.p. 105–107° (4 mm.).

Anal. Calcd. for $C_{10}H_{17}O_2Br$: C, 48.2; H, 6.8. Found: C, 48.2; H, 6.8.

Ethyl 1-Methylcyclohexane-1-carboxylate (VI).—A mixture of the bromide (3.75 g., 0.0145 mole), zinc dust (7.2 g., 0.11 g. atom) and glacial acetic acid (24 ml.) was refluxed for 8 hours. The reaction mixture was poured into water, neutralized with sodium carbonate and finally extracted with ether. The pleasant-smelling ester, 1.5 g. (61%), distilled at 62–63° (4 mm.).

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.6; H, 10.6. Found: C, 70.3; H, 10.5.

On hydrolysis with methanolic potassium hydroxide (20%), the free acid was obtained; m.p. 36° (lit.[6] 38°). The corresponding amide melted at 67–68° (lit.[6] 68–69°).

Ethyl 1-Methylcyclohexylcyanacetate (VIII).—To the Grignard reagent prepared from magnesium (3.7 g., 0.152 g. atom), methyl iodide (27.7 g., 0.195 mole) in ether (60 ml.) cuprous iodide (1 g., 0.0026 mole) was added, followed by the slow addition of the unsaturated cyano-ester (25 g., 0.129 mole) in ether (50 ml.). On refluxing for 2 hours the reaction mixture was worked up and purified by treating with a solution of sodium cyanide (7.2 g.) in aqueous alcoholic solution. The colorless ester, 19.6 g. (72.7%), boiled at 157° (12 mm.), $n^{35}D$ 1.4613.

Anal. Calcd. for $C_{12}H_{19}NO_2$: C, 68.9; H, 9.1. Found: C, 69.3; H, 9.4.

Methylcyclohexylacetonitrile (IX).—The cyano-ester VIII (15 g., 0.071 mole) was hydrolyzed with a solution of potassium hydroxide (5.25 g., 0.093 mole) in water (3.7 ml.) and ethanol (120 ml.). The acidic product (10 g.) was decarboxylated at 200° for a half-hour and the nitrile was obtained as a colorless mobile liquid; 5 g. (51.4%), b.p. 80° (3 mm.).

Anal. Calcd. for $C_9H_{15}N$: C, 78.8; H, 10.9. Found: C, 79.1; H, 10.8.

ω-(Methylcyclohexyl)-acetophenone (X).—To a solution of phenylmagnesium bromide, from magnesium (5.2 g., 0.219 mole) and bromobenzene (34 g., 0.216 mole), in ether (100 ml.) was added the nitrile (14.7 g., 0.107 mole) in ether (20 ml.). The reaction mixture was refluxed for one hour and after removal of most of the ether, it was again heated on the water-bath for another hour. On decomposition of the complex the ketone was isolated as a pale-yellow mobile liquid, b.p. 150–155° (6 mm.), 21.3 g. (92.2%).

Anal. Calcd. for $C_{15}H_{20}O$: C, 83.3; H, 9.2. Found: C, 83.1; H, 9.05.

The 2,4-dinitrophenylhydrazone crystallized as orange needles from ethyl acetate, m.p. 215°.

Anal. Calcd. for $C_{21}H_{24}N_4O_4$: C, 63.6; H, 6.0. Found: C, 63.3; H, 5.8.

Methylcyclohexylcarboxylic Acid (VII).—The above ketone (15 g., 0.069 mole) was again treated with the Grignard reagent from magnesium (3.3 g., 0.136 mole) and bromobenzene (21.67 g., 0.138 mole) in the usual way. A

viscous liquid (14 g.) was finally obtained, b.p. 197–200° (2 mm.).

Anal. Calcd. for $C_{21}H_{26}O$: C, 85.7; H, 8.8. Calcd. for $C_{21}H_{24}$: C, 91.3; H, 8.7. Found: C, 89.3; H, 8.2.

The above compound (10 g.) was oxidized with chromic anhydride (9 g.) in water (6 ml.) and acetic acid (56 ml.) at room temperature and finally on the boiling water-bath for 2 hours. The reaction mixture was subjected to steam distillation and from the distillate the cyclohexane acid, m.p. 36°, was isolated. The amide melted at 66–67° alone or mixed with the previous sample.

1-Keto-3-chloro-10-methyl-Δ^2-octalin (XII).—10-Methyldecalin-1,3-dione was prepared from 2-methylacetylcyclohexene[24] with a slight modification. The diketone (27 g., 0.15 mole) in chloroform (50 ml.) was refluxed on the water-bath for 3 hours with phosphorus trichloride (7.5 g., 0.055 mole). The solvent was distilled off under reduced pressure. It was cooled and treated with an excess of ice-cold water. The ethereal extract was washed with cold sodium hydroxide solution (2%). On removal of the solvent, the residue distilled at 126–128° (6 mm.) as a colorless liquid; 17 g. (57.1%).

Anal. Calcd. for $C_{11}H_{15}OCl$: C, 66.4; H, 7.5. Found: C, 66.4; H, 7.5.

1-Keto-10-methyldecalin (XI).—The enol-chloride (14.2 g.) in ethanol (40 ml.) was hydrogenated with palladium–carbon (2 g., 5%) at room temperature. The hydrogenated product was worked up and the ketone, 10 g. (84%), boiled at 130–132° (12 mm.) as a sweet-smelling colorless liquid.

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.5; H, 10.8. Found: C, 79.4; H, 10.8.

The semicarbazone was obtained in a quantitative yield, m.p. 204–205°, and crystallized from dilute ethanol in shining flakes, m.p. 206–207°.

Anal. Calcd. for $C_{12}H_{21}N_3O$: N, 18.8. Found: N, 18.8.

1-Methylnaphthalene.—The ketone (3 g., 0.018 mole) was allowed to react with methylmagnesium iodide, prepared from magnesium (2.4 g., 0.098 g. atom). The carbinol was dehydrated by distillation (85 mm.) in the presence of a crystal of iodine. The hydrocarbon (2.4 g.) distilled at 140–142° (85 mm.). To a solution of the hydrocarbon (1.4 g.) in carbon tetrachloride (6 ml.) was added bromine (1.4 g.). The residue, on removal of the solvent, was mixed with collidine (4 ml.) and refluxed for 15 minutes in an atmosphere of nitrogen. The reaction mixture was poured into ice-cold 6 *N* hydrochloric acid and extracted with ether. The diene (0.4 g., b.p. 130–140° (85 mm.)), was dehydrogenated in a sealed tube at 300–325° for 50 hours with selenium (1.6 g.). The hydrocarbon was purified by distillation over sodium and converted into a picrate. On crystallization from ethanol, this melted at 139–140° (lit.[25] 140–141°) alone or mixed with an authentic sample.

Ethyl 10-Methyldecalidene-1-cyanoacetate (XIII).—The ketone XI (2.5 g., 0.015 mole) was condensed with ethyl cyanoacetate (3.4 g., 0.03 mole) in benzene (6 ml.) and acetic acid (1.5 ml.) in the presence of ammonium acetate (0.4 g. added in 4 lots) by refluxing for 36 hours in a flask fitted with a constant water-separator. The product was extracted with benzene and thoroughly washed with water. On removal of the solvent and low boiling products, the unsaturated ester, 2.6 g. (66.4%), was collected at 175–180° (4 mm.).

Anal. Calcd. for $C_{16}H_{23}NO_2$: C, 73.5; H, 8.8. Found: C, 73.5; H, 8.4.

Ethyl 10-Methyldecalin-1-cyano-1-cyanoacetate (XIV).—To a cold solution of the unsaturated ester XIII (8.5 g., 0.033 mole) in ethanol (130 ml.) was added sodium cyanide (4.8 g., 0.098 mole), dissolved in the minimum quantity of water and subsequently diluted with ethanol (30 ml.). The temperature of the reaction mixture was raised to 38° whereupon the solution turned pale red. It was cooled and acidified with concentrated hydrochloric acid (5.4 ml.). On allowing the solution to stand for one hour at room temperature, it was poured into an excess of ice-cold dilute hydrochloric acid. The chloroform extract afforded a thick yellowish liquid, 8 g. (85.4%) at 180–185° (0.3 mm.).

Anal. Calcd. for $C_{17}H_{24}N_2O_2$: C, 70.8; H, 8.3. Found: C, 70.8; H, 8.2.

10-Methyldecalin-1-succinic Acid (XV).—A solution of the dicyano-ester XIV (10 g., 0.035 mole) in acetic acid (20 ml.) was treated with a mixture of concentrated sulfuric acid (20 ml.) and water (20 ml.) and the mixture was refluxed slowly on an oil-bath for 25 hours. The mixture was cooled and diluted with ice-cold water (40 ml.). A crystalline solid separated out. The solid was filtered and washed with petroleum ether (b.p. 40–60°) to remove the adhering oil. A white crystalline solid (3.8 g.) was obtained, m.p. 173–174°. The filtrate was diluted with an excess of water and extracted with ether. The ethereal layer was mixed with petroleum ether washings. The crude mixture (4 g.), left after the removal of the solvents, was again hydrolyzed as before. On working up the reaction mixture a colored solid was obtained and this on crystallization from ethyl acetate–acetic acid after boiling with charcoal, yielded a further lot of the crystalline acid (0.6 g., m.p. 172–174°). The total yield was 4.4 g. (50%). This was recrystallized from acetic acid containing a little water and it melted at 175°.

Anal. Calcd. for $C_{14}H_{22}O_4$: C, 66.1; H, 8.6. Found: C, 65.9; H, 8.5.

The acid (2.5 g.) in methanol (25 ml.) was esterified with an excess of an ethereal solution of diazomethane. After removal of the solvent, the residue afforded a colorless liquid, 2.55 g. (92%), boiling at 147° (0.15 mm.).

Anal. Calcd. for $C_{16}H_{26}O_4$: C, 68.1; H, 9.2. Found: C, 68.5; H, 9.2.

10-Methyldecalin-1-carbomethoxy-1-acetic Acid (XVI).—To a solution of the diester (2.3 g.) in methanol (13 ml.) was added a solution of potassium hydroxide (0.6 g.) in water (1 ml.). The solution was allowed to stand at room temperature for 3 hours and finally refluxed for 3 hours on the water-bath. The reaction mixture was cooled and excess alkali neutralized with acetic acid. After removal of methanol under suction, the residue was diluted with water and extracted with ether to remove neutral materials. The alkaline solution was acidified whereupon a crystalline solid, 1.8 g. (82.3%), separated out. This on crystallization from ethyl acetate separated as shining needles and melted at 161–162°.

Anal. Calcd. for $C_{15}H_{24}O_4$: C, 67.2; H, 8.9. Found: C, 67.4; H, 9.0.

Methyl 10-Methyl-1-bromomethyldecalin-1-carboxylate (XVII).—The half-ester (1.3 g.) in methanol (50 ml.) was neutralized with 1 *N* sodium hydroxide solution. A little more than the calculated quantity of silver nitrate solution was added with stirring and the white silver-salt precipitated out. The mixture was filtered and the precipitate was thoroughly washed with water and finally dried at 110–120° for 15 hours in vacuum. The silver salt (1.8 g.) was suspended in carbon tetrachloride (35 ml.) and treated with a solution of bromine (0.92 g.) in the same solvent (5 ml.) and worked up as before. The bromo-ester, 1.25 g. (85%), boiled at 135–140° (0.2 mm.).

Anal. Calcd. for $C_{14}H_{23}O_2Br$: C, 55.4; H, 7.5. Found: C, 55.2; H, 7.6.

Methyl 1,10-Dimethyldecalin-1-carboxylate (XVIII).—A mixture of the bromo-ester (1.0 g.), zinc dust (2.0 g.) and acetic acid (17 ml.) was refluxed for 15 hours. The reaction was poured into water while hot and thoroughly extracted with ether. It afforded 0.35 g. (47.4%) which boiled at 120–122° (4 mm.).

Anal. Calcd. for $C_{14}H_{24}O_2$: C, 75.0; H, 10.7. Found: C, 75.1; H, 10.7.

1,10-Dimethyldecalin-1-carboxylic Acid (II).—The ester (*ca.* 0.25 g.), recovered from an unsuccessful attempt at hydrolysis with 10% methanolic potassium hydroxide, was again refluxed for 32 hours with potassium hydroxide (1.5 g.) in methanol (5 ml.). The reaction mixture was diluted with water, and methanol was removed by passing in steam. The alkaline solution was extracted with ether to remove any neutral matter. On acidification with cold hydrochloric acid, it afforded a crystalline acid (*ca.* 0.1 g.). On crystallization from aqueous acetone it afforded small cubes, m.p. 120°.

Anal. Calcd. for $C_{13}H_{22}O_2$: C, 74.2; H, 10.4. Found:

Methyl 10-Methyldecalin-1-cyanoacetate (XIX).—To the Grignard reagent prepared from magnesium (4.7 g., 0.193 g. atom) and methyl iodide (12.5 ml., 0.201 mole) in ether (50 ml.), pure benzene (70 ml.) was added. To the hot solution, left after removal of ether from the water-bath, was added cuprous iodide (1.0 g.). The reagent was cooled in ice and the unsaturated cyano-ester XIII (11.8 g., 0.045 mole) in benzene (10 ml.) was added dropwise. The mixture was allowed to stand in an ice-bath for 30 minutes and finally refluxed for 2 hours. The complex was decomposed and the benzene layer was washed with water and 2% sodium bisulfite solution. On removal of the solvent, the residue was dissolved in alcohol (50 ml.) and purified by treatment with a solution of sodium cyanide (5 g.) in aqueous alcoholic solution. On working up the reaction mixture in the usual way, the product (8.5 g.) distilled at 120–170° (1.5 mm.). A high-boiling residue remained in the distillation flask. The distillate (8.5 g.) was hydrolyzed with a solution of potassium hydroxide (12.5 g.) in methanol (125 ml.) at room temperature for 6 hours and on reflux for one hour. On acidification, methanol was distilled off and a neutral material, 3.5 g. (31.1%), was isolated boiling at 135–145° (4 mm.). On acidification of the alkaline extract the cyano-acid (3.5 g.) was re-esterified with an excess of diazomethane. The cyano-ester, 3 g. (26.6%), boiled at 155–160° (1 mm.).

Anal. Calcd. for $C_{15}H_{23}NO_2$: C, 72.2; H, 9.2. $C_{16}H_{25}NO_2$: C, 73.0; H, 9.5. Found: C, 72.1; H, 9.0.

The neutral fraction on redistillation boiled at 138–140° (4 mm.).

Anal. Calcd. for $C_{16}H_{27}NO$: C, 77.1; H, 10.8. $C_{17}H_{29}NO$: C, 77.5; H, 11.0. Found: C, 76.7; H, 10.4.

In the infrared, the compound was characterized by strong bands at 3 μ (OH), 4.4 μ (CN) and a doublet at 7.25 and 7.3 μ (*gem*-dimethyl group). There was no absorption in the carbonyl or in the double-bond region.

Three grams of this product was mixed with *phosphorus pentoxide* (4.8 g.) under benzene (20 ml.) and the mixture was refluxed for 2 hours on the water-bath. A yellowish liquid (2 g.) was obtained boiling at 120–125° (3 mm.); λ_{max}^{alc} 220 mμ, log ϵ 3.8.

Anal. Calcd. for $C_{16}H_{25}N$: C, 83.1; H, 10.8; N, 6.0. $C_{17}H_{27}N$: C, 83.2; H, 11.0; N, 5.7. Found: C, 83.3, 82.9; H, 10.7, 10.7; N, 5.8.

10-Methyldecalin-1-acetonitrile (XX).—The cyano-acid (1.5 g.) was heated in an oil-bath at 200–205° for a half-hour until the evolution of carbon dioxide was over. A mobile liquid, 0.7 g. (57.6%), distilled at 128–130° (6 mm.).

Anal. Calcd. for $C_{13}H_{21}N$: C, 81.7; H, 10.9. $C_{14}H_{23}N$: C, 81.9; H, 11.2. Found: C, 82.1; H, 10.5.

ω-(10-Methyldecalin-1)-acetophenone (XXI).—Phenylmagnesium bromide from magnesium (0.88 g., 0.0362 mole) and bromobenzene (5.7 g., 0.0363 mole) was diluted with benzene (15 ml.). On distilling off most of ether a solution of the nitrile (2.4 g., 0.0125 mole) in benzene (10 ml.) was added and the mixture was refluxed for 4 hours. The phenyl ketone, 2.8 g. (83%), was obtained, b.p. 165–170° (0.7 mm.). It formed a **2,4-dinitrophenylhydrazone**, which on crystallization from ethyl acetate afforded orange shining flakes, m.p. 207°.

Anal. Calcd. for $C_{25}H_{30}N_4O_4$: C, 66.6; H, 6.6; O, 14.2. $C_{26}H_{32}N_4O_4$: C, 67.2; H, 6.9; O, 13.8. Found: C, 66.7, 66.6; H, 6.5, 6.3; O, 14.5, 14.4.

The ketone was regenerated from this derivative on treatment with stannous chloride in aqueous acetone.[26]

Anal. Calcd. for $C_{19}H_{26}O$: C, 84.4; H, 9.6. $C_{20}H_{28}O$: C, 84.5; H, 9.8. Found: C, 84.2; H, 9.9.

Ethyl 10-Methyldecalin-1-cyanoacetate (XXIII).—To aluminum amalgam (5.0 g.) under moist ether (300 ml.) was added the unsaturated cyano-ester XIII (5.0 g.). The mixture was allowed to stand for 48 hours with occasional addition of water (5 ml., total 20 ml.). During this period, almost all the aluminum foil had disappeared. The ethereal layer was decanted off. The sludge was dissolved in ice-cold hydrochloric acid and the turbid solution was again extracted with ether. The combined ethereal extracts were worked up and the saturated ester, 4.4 g. (87.3%), was obtained boiling at 147–148° (0.3 mm.).

Anal. Calcd. for $C_{16}H_{28}NO_2$: C, 73.0; H, 9.5. Found: C, 73.2; H, 9.5.

The cyano-acid (2.8 g.) obtained from the alkaline hydrolysis of the cyano-ester XXIII (4 g.) afforded on pyrolysis the nitrile, 1.8 g. (79.4%), b.p. 130° (7 mm.).

Anal. Calcd. for $C_{13}H_{21}N$: C, 81.7; H, 10.9. Found: C, 81.9; H, 10.9.

The nitrile (1.0 g.) yielded the phenyl ketone (1.1 g.), b.p. 150–160° (0.5 mm.). **The 2,4-dinitrophenylhydrazone** melted at 160–165°, which on repeated crystallization from ethyl acetate furnished shining orange flakes, m.p. 205–206°, alone or mixed with sample described before.

Anal. Calcd. for $C_{25}H_{30}N_4O_4$: C, 66.6; H, 6.6. Found: C, 67.0; H, 6.6.

Ethyl 3,3-Dimethylcyclohexylidenecyanoacetate (XXVI).—3,3-Dimethylcyclohexanone[27] (24 g., 0.190 mole) was condensed with ethyl cyanoacetate (46 g., 0.407 mole) as before. The product, 26 g. (62%), was collected at 130–132° (4 mm.).

Anal. Calcd. for $C_{13}H_{19}NO_2$: C, 70.6; H, 8.6. Found: C, 70.4; H, 8.9.

Ethyl 1,3,3-Trimethylcyclohexylcyanoacetate (XXVII).—Methylmagnesium iodide from magnesium (4.8 g., 0.197 g. atom) was added to the above ester (11.0 g., 0.049 mole) in the presence of cuprous iodide (1.0 g.) as a catalyst and the expected cyano-ester, 7.5 g. (64.6%), boiled at 138–140° (6 mm.).

Anal. Calcd. for $C_{14}H_{23}NO_2$: C, 70.9; H, 9.7. $C_{13}H_{21}NO_2$: C, 69.9; H, 9.4. Found: C, 71.1; H, 10.0.

(1,3,3-Trimethylcyclohexyl)-acetone (XXIX).—The nitrile (1.7 g., 0.0103 mole) from hydrolysis and decarboxylation of the above cyano-ester (5.0 g.) was converted into methyl ketone by allowing it to react with methylmagnesium iodide from magnesium (0.7 g., 0.0288 g. atom) and methyl iodide (5 g., 0.0352 mole). The ketone (1.3 g., 69.4%) was obtained as a sweet-smelling liquid boiling at 96° (6 mm.).

Anal. Calcd. for $C_{12}H_{22}O$: C, 79.1; H, 12.0. $C_{11}H_{20}O$: C, 78.5; H, 11.9. Found: C, 78.7; H, 12.0.

The semicarbazone was obtained as silky white needles after recrystallization from dilute ethanol; m.p. 165–166°.

The Constitution of a Wheat Starch Dextrin[1]

BY G. M. CHRISTENSEN AND F. SMITH

RECEIVED MARCH 11, 1957

An "acid converted" wheat starch dextrin of the "canary" type was investigated to determine the structural transformations brought about by the process of dextrinization. The dextrin was subjected to periodate and methylation studies. It is shown that dextrinization of starch involves transglycosidation and the development of a more highly branched structure.

Pyro-dextrins, the gum-like substances extensively used in the adhesives industry, are prepared by pyrolysis of native starches with or without acids under a wide variety of conditions. Although various theories have been advanced,[2-6] little precise information is available concerning the mechanism of the reaction and the structural changes that occur during the dextrinization of starch.

In a previous paper[7] periodate oxidation studies on an "acid-converted" corn starch dextrin showed that the amount (5%) of D-glucose stable to periodate oxidation is greater than in the parent native starch. The methylation results showed[7] (a) that while the hydrolyzate of methylated amylopectin contains 2,3,4,6-tetra-, 2,3,6-tri- and 2,3-di-*O*-methyl-D-glucose and (b) while the hydrolysate of methylated amylose contains 2,3,4,6-tetra- and 2,3,6-tri-*O*-methyl-D-glucose, the hydrolysate from the methylated corn starch dextrin contained ten different methyl derivatives of D-glucose, namely: 2,3,4,6-tetra-, 2,3,6-tri-, 2,3,4-tri-, 2,4,6-tri-, 2,3-di-, 2,6-di-, 3,6-di-, 2-, 3- and 6-*O*-methyl-D-glucose. Although the dextrin was prepared from the native starch, consisting of amylopectin and amylose, the nature and amounts of these ten cleavage fragments seemed to warrant the tentative conclusion that dextrinization not only involves a reduction in the molecular weight of the starch, a fact long recognized from physico-chemical studies, but that in addition, considerable transglycosidation occurs with the production of a highly branched structure.

This paper is concerned with the structural changes that take place when wheat starch is dextrinized in the presence of an acid catalyst, as revealed by methylation and periodate oxidation studies. Investigations into the dextrinization of amylose and of amylopectin are now being carried out, and they will form the subject of later communications.

The wheat starch dextrin was fractionated from aqueous solution with ethanol (Table I) and the major fraction (no. 10) purified by acetylation (Table II).

A sample of the purified dextrin, regenerated from the acetate, was subjected to periodate oxidation (Table III), sodium borohydride reduction and acid hydrolysis.[8] The periodate oxidation studies indicated that the molecule had an average repeating unit of 8 anhydroglucose residues. Since wheat starch, which is a mixture of the linear and branched chain components, has an average repeating unit of 20–25 glucose residues,[9a] it is apparent that a profound change in structure takes place during the dextrinization process. This value of 8 for the average repeating unit of the dextrin agrees reasonably well with the value of 9.5 from the analysis of the acid hydrolysis products of the dextrin polyalcohol which showed that for every molar proportion of glycerol there were 7.5 molar proportions of erythritol and 1 molar proportion of glucose.

In addition, since the wheat starch dextrin contains approximately 10% glucose that is immune to periodate cleavage, it is clear that new linkages must be produced during dextrinization (the original starch has not been investigated, but by analogy with other starches the amount of glucose stable to periodate is probably no more than 0.5%).[8,10]

Treatment of the dextrin first with methyl sulfate and then with silver oxide and methyl iodide furnished the methylated dextrin, which was found to be essentially homogeneous. After methanolysis of the methylated dextrin, followed by acid hydrolysis, the mixture of methylated sugars was separated by partition chromatography on a cellulose–hydrocellulose column[11] using butanone:water azeotrope[12] as the irrigating solvent and the components identified by preparing suitable crystalline compounds (Table IV).

The hydrolyzate from the methylated wheat starch dextrin was found to consist of 2,3,4,6-tetra- (12.2%), 2,3,6-tri- (74.8%), 2,3-di- (3.9%), 2,6-di- (7.9%), 2- (0.9%) and 3-*O*-methyl-D-glucose (0.3%). Since the dextrin was made from native starch, extensive structural deduction cannot be made, but it is apparent, however, from the percentage (12.2) of 2,3,4,6-tetra-*O*-methyl-D-glucose, that the dextrin must be much more highly branched than the parent wheat starch. It is noticeable that the amounts of tetra- and di-*O*-methylglucose are approximately the same, a result required by the general structural concept that the

number of terminal, non-reducing ends should be the same as the number of branches in the molecular complex. Since the tetra-*O*-methyl-D-glucose arises from those glucose units which give rise to formic acid upon periodate oxidation, it is of interest to note that the average repeating unit (8) from periodate oxidation studies agrees with the value (8.3) from methylation studies.

The characterization of 2,6-di-*O*-methyl-D-glucose in relatively large amounts (7.9%) reveals the fundamental difference in structure between the dextrin and the parent starch since the methylated starch does not give rise to appreciable amounts of 2,6-di-*O*-methyl-D-glucose.[9a,c,9b,9c] This finding also shows that the dextrinization process not only causes degradation of the starch molecule but that it must also involve the generation of new 1,3-glycosidic linkages. The same phenomenon was observed in the previous studies on the "acid converted" corn starch dextrin.[7] The presence of these 1,3-linkages in the dextrin is also supported by the fact that the parent dextrin contains approximately 10% glucose that is immune to periodate oxidation.

Although the fraction of the wheat starch dextrin subjected to study comprised only 37% of the original dextrin, it seems likely that the same general transformations during dextrinization would be revealed by studies of the other dextrin fractions; the correctness of this view will form the subject of a later investigation.

From the above results, therefore, it seems reasonable to deduce that the physical properties of the dextrins, especially their adhesive, gum-like properties and solubility characteristics, must be attributed, at least in part, to the fact that the dextrins have a highly branched structure, the building units of which are mutually joined by a wide variety of glycosidic bonds.

Experimental

The partition chromatographic analyses were carried out with solvent A, butan-1-ol:ethanol:water (4:1:5),[13] solvent B, butanone:water azeotrope[12] or solvent C, propan-1-ol:water azeotrope.[14] The spray reagent used for the development of color with glucose methyl ethers was *p*-anisidine:trichloroacetic acid:water (1:5:250).[15] Unless stated otherwise all concentrations were carried out *in vacuo* at a bath temperature of 45–50°.

Preparation of the Wheat Starch Dextrin.—Commercial wheat starch was heated for 3 hr. at 120° and then for 5 hr. at 140° in the presence of 2 *N* hydrochloric acid added previously as a spray with mixing. The amount of 2 *N* acid used per gram of starch corresponded to that required to give a *p*H of 3 when added to a mixture of starch (1 part) and water (2 parts); this was predetermined in a separate experiment. The "canary" dextrin so obtained had a slight yellow color, and 95% of it was soluble in water.

Fractional Precipitation of the Wheat Starch Dextrin.—The dextrin (50 g. as prepared and without pre-drying) was dissolved in water (200 ml.) and fractionally precipitated by the addition of increasing amounts of ethanol. Each fraction was redissolved in water and the solution poured with stirring into an excess of ethanol. The white amorphous precipitate was removed by centrifugation and washed successively with ethanol, ethyl ether and light petroleum ether and then dried *in vacuo* at 50°. The results of this fractionation are recorded in Table I.

Table I

Fractional Precipitation of Dextrin from Aqueous Solution with Ethanol

Fraction no.	1	2	3	4	5	6	7	8	9	10	11	12
Wt., g.	1.5	2.4	2.2	2.6	0.6	1.0	0.4	1.7	7.1	18.5	2.1	5.8

[a] P = Purple; L = Lavender; R = Red-brown.

Acetylation of Starch Dextrin.—A solution of the dextrin (17.6 g., fraction 10, Table I) in formamide (100 ml.) was slowly added, with stirring during 3 hr., to a mixture of pyridine (100 ml.) and acetic anhydride (100 ml.) cooled in an ice-bath.[16] After standing for 10 hr. at room temperature the reaction mixture was poured, with stirring, into 8–10 volumes of ice-water to precipitate the acetate. The white amorphous precipitate was filtered, washed successively with absolute ethanol, ether and petroleum ether and dried *in vacuo*. The acetylated dextrin (yield 24 g.) showed $[\alpha]^{25}D$ +158° in chloroform (*c* 0.6). After reacetylation with 5 parts of pyridine–acetic anhydride (1:1) for 3 hr. at 55°, the dextrin acetate (23.5 g.) showed $[\alpha]^{25}D$ +155° in chloroform (*c* 0.6).

The acetyl value was determined by dissolving a sample of the acetylated material in a small volume of acetone, adding an excess of 0.1 *N* NaOH and warming for 2 hr. at 50°. After cooling, the excess alkali was back titrated with 0.1 *N* sulfuric acid; a blank was carried out at the same time (Found: Ac, 44.7%).

The acetylated dextrin (18.5 g.) was fractionally precipitated from chloroform solution by adding increasing quantities of petroleum ether in the usual manner. The results are given in Table II.

Table II

Fractional Precipitation of Dextrin Acetate

Fraction no.	1	2	3	4	5	6
Total petr. ether added, ml.	10	35	55	75	115	145

$[\alpha]^{25}D$ ($CHCl_3$, *c* 1)	+158°	+156°	+157°	+151°	+166°	...

Fractions 1, 2 and 3, being essentially the same, were combined and used for the experiments which follow.

Deacetylation of Dextrin Acetate.—A solution of the acetate (3 g.) in 10% (w./w.) aqueous potassium hydroxide (10 ml.) and acetone (15 ml.) was stirred for 1 hr. at room temperature and for 0.5 hr. at 50°. The solution was cooled, neutralized with acetic acid and poured into ethanol. The dextrin precipitate was collected (centrifuge), redissolved in water, reprecipitated with ethanol as before and finally dried *in vacuo* at 45°, giving a white amorphous powder which had $[\alpha]^{24}D$ +132° in water (*c* 0.6).

Periodate Oxidation of Wheat Starch Dextrin.—The dextrin fraction (0.9 g.) was oxidized with 0.1 *N* sodium periodate (100 ml.) at 5° in the dark and aliquots of the reaction solution periodically withdrawn in order to follow

the rate of periodate consumption and formic acid production in the usual way.[17] Blank experiments were conducted at the same time. The results are summarized in Table III.

TABLE III

PERIODATE OXIDATION OF STARCH DEXTRIN

Reacn. time, hr.	$[\alpha]^{25}D$	Mols. of anhydrohexose per mol. of formic acid produced	Mols. of periodate consumed per mol. anhydrohexose unit
0.08	+77°	25.9	0.66
52	+19	12.7	1.01
138	+19	9.0	1.06
213	+18	7.9	1.06

Reduction of the Periodate Oxidized Dextrin with Sodium Borohydride.—The periodate oxidation reaction mixture was treated with barium chloride solution to precipitate the iodate and excess periodate and the solution centrifuged. Four times the theoretical amount of sodium borohydride was then added to the supernatant solution at room temperature to reduce the dextrin polyaldehyde. The solution was agitated periodically for 3 hr., after which time the evolution of hydrogen ceased and the reduced polysaccharide slowly precipitated from the solution. The precipitated dextrin polyalcohol was removed from the solution, washed with cold ethanol, redissolved in water and reprecipitated with alcohol. The material was then acidified with acetic acid and evaporated to dryness to decompose the residual borohydride. Methanolic hydrogen chloride (30 ml. of 1%) was added, and after shaking for 5 minutes the solution was evaporated *in vacuo* at 40° (bath temperature) to remove borate.[18] The residue was retreated with 1% methanolic hydrogen chloride to ensure complete removal of borates. The dextrin polyalcohol was hydrolyzed by treatment with 0.5 *N* HCl at room temperature for 2 hr. with constant stirring followed by warming at 50° for 1 hr.

The hydrolysis solution was neutralized with $BaCO_3$, filtered and passed through Amberlite IR-120 cation and then through Duolite A_4 anion exchange resin to remove inorganic ions, and evaporated to a sirup. The hydrolyzate showed $[\alpha]^{25}D$ +8.5° in water (*c* 2.7).

Determination of Glucose, Erythritol and Glycerol in the Dextrin Polyalcohol.—A small portion of the sirupy hydrolysate of the dextrin polyalcohol was placed on Whatman No. 1 filter paper and developed with solvent C. Glucose, erythritol and glycerol were located in the boundaries of the paper and the three compounds were then quantitatively separated and eluted from the paper with a known volume of water.[19]

The quantitative determination of glucose was carried out colorimetrically with the phenol–sulfuric acid reagent,[20] and chromotropic acid was used for the quantitative determination of glycerol and erythritol.[21,22]

The molar ratios of glucose:erythritol:glycerol in the hydrolysate of the dextrin polyalcohol was found to be 1.0: 7.5:1.0, respectively.

Methylation of Dextrin Acetate.—Wheat dextrin acetate (8.5 g.) was dissolved in acetone (190 ml.) and methylated with methyl sulfate (90 ml.) and sodium hydroxide (250 ml. of 30%) according to the method of Haworth.[23] The reaction was completed by heating for 0.5 hr. on the boiling water-bath when the methylated dextrin separated readily from the reaction mixture. This precipitate was washed by decantation with boiling water to remove salts and then dissolved in acetone in preparation for the next methylation. The mother liquor was extracted with chloroform and the combined extracts dried (Na_2SO_4) and concentrated. The residue was dissolved in acetone and added to the acetone solution of that portion of the dextrin that precipitated from the reaction mixture. Three additional methylations were applied as above, and the product was isolated each time by heating the reaction mixture (chloroform extraction was not necessary).

The methylated dextrin was subjected to three treatments with Purdie reagents using silver oxide (6 g.) and methyl iodide (30 ml.), the reaction mixture being refluxed for 18 hr. After recovering the excess of the methyl iodide, the product was isolated by extraction with acetone, traces of silver iodide being removed by centrifugation. Evaporation gave the methylated dextrin as a brown sirup (4.20 g.).

Fractional Precipitation of Methylated Dextrin.—The methylated dextrin (4.10 g.) was dissolved in acetone (40 ml.) and fractionally precipitated by adding petroleum ether in the usual way. Examination of the five fractions obtained in this manner showed that the product was essentially homogeneous; $[\alpha]D$ +182° in chloroform (*c* 1). Found: OMe, 43.5.

Methanolysis of Methylated Dextrin.—The methylated dextrin (3.30 g.) from a composite of fractions 2, 3 and 4 above was refluxed for 10 hr. with 2.5% methanolic hydrogen chloride. After 3 hr. the rotation of the solution became constant, $[\alpha]^{24}D$ +85° in methanol (*c* 3).

The solution was neutralized (Ag_2CO_3), filtered and the clear yellow solution evaporated with a current of air to avoid possible loss of the methyl 2,3,4,6-tetra-*O*-methyl-D-glucoside. Any residual solvent was removed *in vacuo* at 40°.

Separation of the Cleavage Products of the Methylated Dextrin.—The methyl glycosides (3.42 g.) were heated at 98° with *N* H_2SO_4 (40 ml.) for 19 hr. The solution became cloudy upon adding the acid, and the initial rotation could not be determined, but after 1 hr. it showed $[\alpha]^{25}D$ +49.5° and did not appear to change thereafter. The solution was neutralized ($BaCO_3$), filtered and the residue washed with water. The filtrate and washings were combined and extracted twice with chloroform. The sirup (1.75 g.) from the combined chloroform extracts and that (1.43 g.) from the aqueous layer were separately subjected to partition chromatography on a cellulose–hydrocellulose column using solvent B, the fractions being collected in test-tubes using an automatic fraction collector, during a period of 120 hr.[11]

The methylated sugars were isolated by concentrating the appropriate fractions and provisionally identified by paper chromatography using solvents A, B and C in the usual way. Results of the column chromatography are recorded in Table IV.

TABLE IV

COLUMN CHROMATOGRAPHY OF THE HYDROLYSATE OF METHYLATED STARCH DEXTRIN

2,3,4,6-tetra-*O*-methyl-D-glucose, m.p. and mixed m.p. 101–102°; lit.[25] m.p. 102°.

2. **2,3,6-Tri-*O*-methyl-D-glucose.**—Component 2 (Table IV, 2.29 g.) crystallized spontaneously and after recrystallization from ethyl ether, gave 2,3,6-tri-*O*-methyl-D-glucose, m.p. and mixed m.p. 112–115°, $[\alpha]^{24}D$ +62° equilibrium value in water (*c* 1); lit.[26] m.p. 121–123°, $[\alpha]D$ +70.5° equilibrium value in water. Treatment of the trimethyl sugar with *p*-nitrobenzoyl chloride in the usual way[27] gave the 1,4-di-*p*-nitrobenzoate of 2,3,6-tri-*O*-methyl-D-glucose, m.p. and mixed m.p. 190–191°, $[\alpha]^{24}D$ −32° in chloroform (*c* 2); lit.[27] m.p. 189–190°, $[\alpha]D$ −33° in chloroform.

3. **2,3-Di-*O*-methyl-D-glucose.**—Component 3 (Table IV, 0.119 g.) crystallized spontaneously from ethyl ether and methanol, giving 2,3-di-*O*-methyl-D-glucose, m.p. and mixed m.p. 85–86°, $[\alpha]^{24}D$ +49° in methanol (*c* 4); lit.[28] m.p. 85–87°, $[\alpha]D$ +48.3° in acetone. Treatment with aniline gave the characteristic N-phenyl-D-glucopyranosylamine 2,3-dimethyl ether, m.p. and mixed m.p. 134°, $[\alpha]^{22}D$ −83° in chloroform (*c* 4) (after recrystallization from ethyl acetate); lit.[29] m.p. 134°.

4. **2,6-Di-*O*-methyl-D-glucose.**—Component 4 (Table IV, 0.240 g.), a sirup, showed $[\alpha]^{24}D$ +63° equilibrium value in water (*c* 5); lit.[30,31] $[\alpha]D$ +63.3° in water. Chromatographic analysis using solvents A and B indicated that it was 2,6-di-*O*-methyl-D-glucose. Treatment with *p*-phenylazobenzoyl chloride in pyridine gave the 1,3,4-triazobenzoate of 2,6-di-*O*-methyl-D-glucose, m.p. and mixed m.p. 202–206° (after recrystallization from ethyl acetate–petroleum ether), $[\alpha]^{23}D$ −260° in chloroform (*c* 0.1); lit.[31] m.p. 205–207°, $[\alpha]_{6252}$ −275° in chloroform.

5. **2-*O*-Methyl-D-glucose.**—Component 5 (Table IV, 0.029 g.) crystallized spontaneously and afforded 2-*O*-methyl-D-glucose, m.p. and mixed m.p. 157–158°, $[\alpha]^{24}D$ +65° equilibrium value in water (*c* 1) (after recrystallization from ethanol); lit.[32–34] m.p. 157–158°, $[\alpha]$ +66° equilibrium value in water.

6. **3-*O*-Methyl-D-glucose.**—Component 6 (Table IV, 0.01 g.) crystallized spontaneously from ethanol and appeared to be essentially pure 3-*O*-methyl-α-D-glucose, m.p. and mixed m.p. 157–158°, $[\alpha]^{24}D$ +56° equilibrium value in water (*c* 1); lit.[23,35] m.p. 161°, $[\alpha]D$ +55.5° equilibrium value in water.

In addition to the six components identified above, column chromatography of the hydrolysate of the methylated dextrin yielded 10 mg. of material whose R_f value, 0.062, corresponded to D-glucose. However, the substance failed to crystallize, and since its rotation, $[\alpha]^{24}D$ +17° in water (*c* 0.2), showed that only one-third of it could be D-glucose, it was not examined further.

Acknowledgments.—The authors thank General Mills, Inc., Minneapolis, for the sample of wheat starch dextrin through the courtesy of Mr. Robert Hamilton. They are also grateful to General Mills, Inc., and to the Corn Industries Research Foundation for financial support.

Lignin. VIII. Molecular Weights of Lignin Sulfonates during Delignification by Bisulfite–Sulfurous Acid Solutions

BY EZIO NOKIHARA,[1] M. JEAN TUTTLE, VINCENT F. FELICETTA AND JOSEPH L. MCCARTHY

RECEIVED SEPTEMBER 17, 1956

The average molecular weight has been estimated of the sodium lignin sulfonates dissolved from hemlock, spruce and maple woods into bisulfite–sulfurous acid solutions after several periods of treatment at elevated temperatures. With the gymnosperm woods, it is found that lower molecular weight lignin sulfonates are obtained first, and then as the time of treatment is extended, the average molecular weight of the dissolved lignin sulfonates increases to a maximum, decreases to a minimum and finally begins to rise again. These changes are attributed to the effects of the following three processes which are thought to be proceeding simultaneously but at different rates: hydrolysis of hydrolyzable bonds in the lignin polymer, polycondensation of some lignin molecules with others and diffusion of soluble lignin sulfonates from the wood tissue into solution. With maple wood, the molecular weights of the dissolved lignin sulfonates obtained are about constant and strikingly smaller than those observed for the gymnosperm lignins].

Introduction

In prior reports from this Laboratory, diffusion[2a] and light scattering[2b] methods have been described for the estimation of the average molecular weights of lignin sulfonate preparations. Fractionation of such preparations followed by estimation of the molecular weights of the lignin sulfonates in the resultant fractions has provided information concerning the distribution in lignin sulfonate molecular weights.[2c] Since these distributions were found to be somewhat different for several preparations examined, the present research was undertaken to obtain more knowledge concerning the average molecular weights and the distribution in molecular weights of lignin sulfonates which exist at various stages of delignification of wood by use of bisulfite–sulfurous acid solutions.

Experimental

A description previously has been given[2b] of the preparation of the Western Hemlock wood meal (*Tsuga heterophylla;* 10 to 30 mesh; ethanol–benzene and hot water extracted; 6.14% H_2O and 5.15% OCH_3) used for the experiments. Delignifications were carried out by sealing into a Pyrex tube 1.00 or 4.50 g. of wood meal with ten times its weight of an aqueous solution which contained 50 g. of SO_2/liter and 9.67 g. of Na_2O/liter for series I, and 90 g. of SO_2/liter and 9.67 g. of Na_2O/liter for series II. Each bomb was placed in a steel tube which was closed, fastened to a "Ferris" wheel in an oil-bath at 135° (±0.1°) and rotated

[a] Same as footnotes *a*, *b* and *d* for Table I. [b] Sulfate in samples 3A and 12 was 0.34 and 1.89 g. SO_3/liter, respectively.

at 25 r.p.m. for the desired time. The bombs were cooled, opened and the contents were filtered. The wood residues were washed with distilled water, dried overnight at 60° and 1 mm. pressure, then weighed and analyzed. The filtrates and washings were combined, diluted with distilled water to about 100 times the original wood weight, then stored at 3° after adding a few drops of toluene to prevent or minimize microörganism action (Tables I and II).

For the experiments with spruce (*Picea sitchensis*) and maple (*Acer saccharum*), small air-dry wood blocks obtained from Professor H. D. Erickson of the College of Forestry of this University were reduced to a fine meal by use of a cross cut saw. Delignifications were conducted using solutions containing 41.2 g. of SO_2/liter and 10.2 g. of Na_2O/liter at 135° (±0.1°) for various periods of time (Table III).

One sample of the hemlock lignin sulfonates was fractionated. Preliminary to this fractionation, toluene was evaporated from an aliquot of the solution containing the lignin sulfonates, and metal cations were then removed using a Dowex 50 resin column. The solution was then extracted five times with ether to remove such non-lignin substances as conidendrin and furfural which absorb ultraviolet radiation, and residual ether and sulfurous acid were removed under vacuum. Usually the solution was neutralized to pH 5, vacuum evaporated to 50 ml., then concentrated to 10 ml. or less in a vacuum desiccator over $CaCl_2$.

For fractionation, a 7-ml. aliquot was weighed exactly and added to a culture tube (1.5″ × 7″) containing 300 mg. % of crystalline NaCl. To secure the first fraction, at 25 ± 0.1°, 133 ml. of dry ethanol was added dropwise with vigorous stirring which was continued for an additional five minutes. The contents were then transferred to a centrifuge bottle and centrifuged for about five minutes after which the clear solution was poured off, vacuum evaporated at 50° with periodic additions of distilled water to complete ethanol removal and then made to 50 ml. with distilled water and designated as fraction A. Precipitate in the culture tube was then dissolved in 10 ml. of 0.5 *N* NaCl and combined with that in the centrifuge bottle, and the fractionation of this solution was then continued in general as already described with appropriate ethanol additions, and the results as well as final alcohol concentrations are given in Table IV.

Analyses for methoxyl were conducted by the Zeisel method. Ultraviolet absorbances were determined from 2500 to 3100 Å. at 50-Å. intervals on aliquots of lignin sulfonate solutions from which sulfur dioxide had been removed and after dilution such that absorbance was not more than about 0.80. Lignin sulfonate concentrations were estimated for the experiments with spruce and maple from measurements of absorption at 2800 Å. Two absorptivity ratios, A_{2800} Å./$A_{min.}$ and A_{2800}Å./A_{3100} Å., were calculated. The acidity of some of the samples weas measured after expelling sulfur dioxide and diluting ten times. Sulfate in certain samples was determined by a conductometric method.[3]

Discussion

The degrees to which lignins were removed from hemlock wood by treatment with sodium bisulfite–sulfurous acid solutions have been estimated from determinations of methoxyl in the original wood and in the wood residues (Tables I and II) assuming that the methoxyl content of lignin or lignin sulfonates is approximately constant. As shown in Fig. 1, delignification of hemlock is nearly completed after about 8 hr. treatment at 135° where the solution contains about 4.0% "free" SO_2 or after about 3 hr. with 8.0% "free" SO_2.

The several hemlock lignin sulfonate solutions obtained were diluted appropriately, absorbances for 2800 Å. radiation were measured and the absorbances were calculated back to the uniform basis of the undiluted reaction mixture. These absorbances are plotted in Fig. 2 against the degree of delignification estimated from methoxyl. An apparently linear relationship is obtained up to about 90 or 95% delignification indicating that, within this range, the absorptivities of lignin sulfonates on a methoxyl basis are approximately constant and thus that the degree of delignification can be estimated from measurements of ultraviolet absorbance.

[a] For fractions A, B, C, D, E, F and G final ethanol concentrations were 95, 90, 85, 80, 76, 73 and 70% by volume, respectively. H designates the material insoluble in 70% ethanol. [b] Weight percentages of lignin sulfonates in fractions were estimated from absorbances observed at 2800 Å. [c] Units of D_A are $10^7 \times$ cm.²/sec. [d] Average D_A for unfractionated samples estimated from values found for fractions. [e] Average molecular weight for unfractionated sample estimated from average D_A calculated from values found for fractions.

Diffusion coefficients,[2a] "D_A," of the sodium lignin sulfonates of Tables I and II were measured by a solution-to-gel method at 25° in 0.02 *M* NaCl after the samples had been de-ashed, extracted with ether, neutralized and then evacuated; the samples of Table III were prepared for diffusion by pulling air through the solutions for at least 24 hr.: for Table IV, diffusions were carried out on the final fractionated samples after ethanol removal. Molecular weights were estimated from diffusion coefficients using a previously developed correlation.[2b]

The relationship between the average diffusion coefficient, D_A, and the diffusion coefficient for an individual molecular species, D_i, is

$$\frac{1}{D_A^{0.5}} = \Sigma_{(wi}\left(\frac{1}{D_i^{0.5}}\right)$$

where w_i = weight fraction of i-th species. The approximate relation between D_i and the molecular weight, M_i, is

$$D_i \cong \frac{b}{M_i^{1/a}}$$

where b and a are constants. Thus the particular average molecular weight, M_A, obtained in the present work is, approximately

$$M_A = [\Sigma(w_i)(M_i)^{0.5a}]\ 2/a \cong [\Sigma(w_i)(M_i)^{1.5}]^{0.67}$$

since $a \cong 3$.

On this basis lignin removals from spruce and maple woods were also estimated (Table III) and the rates of delignification found (Fig. 1) are roughly as expected for the concentration of about 3.1% "free" SO_2 which was used in the delignification solution.

The yield of hemlock wood residue decreases and approaches a limiting asymptotic value as delignification proceeds. However, when delignification is almost completed and this limiting value is nearly reached, the percentage of wood residue begins to decline again and continues to decline at a somewhat increased rate (Fig. 1). This increased degradation and solution of the carbohydrate residue is caused by a large increase in the acidity of the delignification solution as reflected in the *p*H values given in Tables I and II. The increase in acidity is in turn caused at least largely by formation of sulfate which is shown by analyses to be present at a much higher concentration after the acidity increase than before. Corresponding with this in-

creased acidity is a substantial increase in absorbance (Fig. 2) which may arise from lignin hydrolysis or condensation reactions or formation of such sugar derivatives as furfural and hydroxymethylfurfural which absorb ultraviolet radiation.[4]

Examination of the ultraviolet absorption spectra of the several solutions showed that the usual spectra[2] was obtained for the samples up to about 90% delignification. The wave length of the minimum absorption was about 2580 Å. in the first samples obtained and this shifted to longer wave lengths as delignification proceeded. The absorptivity ratios, $A_{2800\ Å.}/A_{2600\ Å.}$ and $A_{2800\ Å.}/A_{3100\ Å.}$, were largest in the first samples obtained and decreased and became nearly constant as treating time was extended toward completion of delignification, thus indicating an increase in molecular weight in view of prior work.[2c] However, after the solutions underwent the substantial increase in acidity, the values for the ratios again decreased.

The average molecular weights of the dissolved lignin sulfonates in the several solutions were estimated from diffusion coefficients, and the results are given in Tables I–III and are graphed in Fig. 1. With hemlock and spruce woods, it is found that the molecular weights of the lignin sulfonates first obtained are about 2000–4000. As delignification proceeds, the molecular weight increases and reaches a maximum value in the range of about 11,000 when the delignification has been nearly completed. Continuation of treatment brings about a decrease in molecular weight to a minimum value of about 5000 and thereafter an increase is again observed. Similar trends were observed at concentrations of 40, 50 and 90 g. total SO_2/liter, although the changes occurred more rapidly in the solutions of higher acidity.

With maple wood, the molecular weight of the lignin sulfonates is found to be strikingly smaller, *i.e.*, of the order of 1000–1500. These values remain nearly constant as the time of treating is increased. In prior work in this Laboratory by Dr. J. C. Aggarwala similar low average molecular weights have been indicated for the lignin sulfonates from a bamboo (*Dendrocalamus strictus*), since it was found[5] that only some 15% of the original methoxyl remains associated with the non-dialyzable bamboo lignin sulfonates, whereas around 50% of the methoxyl in gymnosperm lignin sulfonates is usually non-dialyzable.

The lignin sulfonate samples obtained in one set of experiments with hemlock wood were fractionated by a "reprecipitation" method and the results are summarized in Table IV and Fig. 3. The lignin sulfonates obtained after 0.5 hr. reaction time, which comprise about one-quarter of the total lignins, are found to be distributed predom-

inantly in the molecular weight range of about 500 to 10,000. However after 3 hr. when the delignification has been nearly completed, the molecular weights are found to range on up to around 100,000. Longer reaction time to a total of 10 hr. brings about a general shift in the cumulative distribution curve into a substantially lower range of molecular weights while still further treatment again shifts the curve but this time into a higher range of molecular weights.

These results, together with others previously obtained here and in other laboratories, are believed to provide additional evidence in support of the following concepts: (a) that lignins are branched chain polymers existing in woody tissue at least mostly as relatively large molecules, probably combined with each other and/or with carbohydrates to make three dimensional networks; (b) that the bonds between the lignin structural units are of at least two types, one relatively easily hydrolyzable in acidic aqueous solution and the other not; (c) that for removal of lignin from wood into acidic aqueous solution, hydrolysis of some linkages between structural units must occur to set free segments or "ζ-lignins" from the presumed proto lignin polymer and also these segments must have already been sulfonated or must become sulfonated to the degree necessary to permit them to dissolve in water; (d) that lower molecular weight lignins are first removed during delignification because the distribution of hydrolyzable and of hydrolyzed linkages may be approximately random, and the smaller ζ-lignins diffuse out from the wood residue into solution more rapidly than the larger fragments which are removed later with the result that the average molecular weight increases as delignification proceeds; (e) that acidic hydrolysis of the ζ-lignin sulfonates continues even after they have become dissolved in the aqueous medium so that although the average molecular weight observed for dissolved lignin sulfonates reaches a maximum at about the time that the delignification is completed, thereafter the molecular weight decreases as hydrolysis proceeds, (f) that the average molecular weight of the lignin sulfonates finally reaches a minimum value at which presumably all of the hydrolyzable linkages have been hydrolyzed to provide an "ω-lignin"; and (g) that an increase may then become evident in the average molecular weights of the lignins as a result of progress of irreversible condensation reactions, perhaps of the phenol-carbonyl type, which have presumably continued throughout the delignification process and can finally bring about condensation of the lignin sulfonates to a water-insoluble state.

Additional research is in progress toward the development of a quantitative formulation of these relationships.

Lignin. IX. Molecular Weights of Lignin Sulfonates as Influenced by Certain Acidic Conditions

BY VINCENT F. FELICETTA AND JOSEPH L. MCCARTHY

RECEIVED SEPTEMBER 17, 1956

Lignin has been removed incrementally by treating hemlock wood in five steps with sodium bisulfite–sulfurous acid solutions of progressively increasing acidity. Low molecular weight lignins were removed first, and the later removed lignins were found generally to be of progressively increasing molecular weight. The lignin sulfonates in each increment were hydrolyzed in bisulfite–sulfurous acid solutions and a substantial decrease in molecular weights occurred. Generally similar results were obtained when purified non-dialyzable lignin sulfonates were hydrolyzed in acidic bisulfite–sulfurous acid solutions and also in hydrochloric acid solutions. Hydrolysis proceeds only to a limiting degree and condensation seems to occur simultaneously but more slowly. The new end groups may be carbonyl and phenolic hydroxyl.

Introduction

Many studies have been made of the removal of lignin from woody tissue,[1] and evidence has recently been submitted[2] indicating that as lignin is removed from gymnosperm woods using bisulfite–sulfurous acid solutions, relatively low molecular weight lignin sulfonates are first obtained in solution. Then, as the time of treatment is extended, the average molecular weight of the dissolved lignin sulfonates increases to a maximum, decreases to a minimum and finally begins to rise again. These changes are attributed to the effects of the following three processes which are thought to proceed simultaneously but at different rates: hydrolysis of hydrolyzable bonds in the lignin polymer, polycondensation of some lignin molecules with others and diffusion of soluble lignin sulfonates from the woody tissue into solution.

However, the usual delignification procedure which was used in our prior study comprised the heating of wood with aqueous bisulfite–sulfurous acid solutions in a closed autoclave or bomb. Under these batch conditions, the lignin sulfonates dissolved early in the period of reaction remain exposed to an acidic environment at elevated temperature for the remaining reaction time. In this situation hydrolysis and polycondensation reactions may be important. Thus the now-reported investigation was carried out using an "incremental" delignification method designed to minimize progress of these reactions during delignification. Experiments also have been conducted to establish

a basis for a study of the hydrolysis and polycondensation reactions in homogeneous solution.

Experimental

Incremental Delignification of Hemlock Wood.—Hemlock wood meal was prepared by passing hemlock wood shavings through a hammer mill. The resulting wood meal was exhaustively extracted with 2:1 ethanol–benzene followed by hot water and then air-dried and sieved to remove fines leaving a wood meal of mesh size 35 to 65. Analysis of this wood meal gave a methoxyl content of 4.62% OCH_3 on air-dried wood of 9.25% H_2O. Air-dried wood meal (12.8 g.) was used for the first delignification step, and each succeeding delignification was conducted on the wood residue from the preceding step. Delignification was carried out in sealed glass bombs at 130 ± 0.5° for 15 hr. except for the first step where an additional 2 hr. was used to slowly bring the temperature to 130°. The treating solution was prepared by passage of sulfur dioxide into an aqueous sodium hydroxide solution until the desired composition was attained as shown in Table I. The bombs were tumbled at about 25 r.p.m. in a stirred thermostated oil-bath.

Mol. wt.	1900	4800	7200	10500	13000

[a] Conditions for the delignification and hydrolysis reactions are given in the Experimental part. [b] Treatments to secure samples I, II, III, IV and V were conducted using aqueous solutions containing the following proportions of "free" and "combined" SO_2: 2.5, 2.5; 2.5, 2.5; 2.6, 2.4; 2.75, 2.25; and 3.25 and 1.75 g. of SO_2/liter, respectively.

After each delignification step the wood residue was separated from the solution product by filtration, washed thoroughly with water, air-dried and weighed and then subjected to the next delignification step. A portion of each wood residue was set aside for sulfur and methoxyl and moisture analyses which were carried out by previously described methods.[3] Solutions obtained from each step were analyzed for methoxyl and characterized by measurement of diffusion coefficient, D_A.[4] Molecular weights were estimated from the diffusion coefficients[5] and are average values, M_A, related to the molecular weights of the individual species, M_i, by the approximate expression

$$M_A = [\Sigma(w_i)(M_i)^{0.5a}]^{2/a} \cong [\Sigma(w_i)(M_i)^{1.5}]^{0.67}$$

where w_i = weight fraction of i-th species, and since $a \cong 3$.

Hydrolyses of the lignin sulfonates were conducted at 130° for 15 hr. in glass bombs. For sample I the hydrolyzing medium was adjusted to 2.25% "combined" SO_2 and 2.89% "free" SO_2 whereas for samples II, III, IV and V the composition was 1.75% "combined" SO_2 and 3.25% "free" SO_2. Diffusion coefficients of the lignin sulfonates were also measured after hydrolysis.

Sulfonation of Lignin Sulfonates.—The non-dialyzable lignin sulfonates used in this investigation were secured by continuous exhaustive dialysis of an industrial sulfite spent liquor made from a mixture of about 85% western hemlock and 15% white fir woods. Determinations of total sulfur, methoxyl, strong and weak acids, and diffusion coefficient on the sodium salt of the non-dialyzable lignin sulfonates were conducted. The treating solution was prepared by passing sulfur dioxide into cold water and then adding solid sodium bisulfite to attain the desired composition. Thirty cc. of the non-dialyzable sodium lignin sulfonate solution was combined with 45 cc. of the concentrated resulfonation solution to give a final combined "SO_2" content of 0.75% and free "SO_2" content of 4.7% and sodium lignin sulfonate concentration of 37.4 g./l. Reactions were conducted in sealed glass tubes with rotation at 25 r.p.m. in an oil-bath at 130 ± 0.5° for varying periods of time as shown in Table II. A separate sample was used for each reaction period.

The products from the reaction were prepared for analysis by the following sequence of steps: (a) filtration to remove free sulfur, (b) de-ashing and steam-distilling to remove sulfur dioxide and convert sulfates to sulfuric acid, (c) preparation of barium salts by slow addition of barium carbonate with stirring, (d) centrifuging to remove barium sulfate and excess barium carbonate and finally, (e) exhaustive dialysis through a Visking cellophane membrane tubing against distilled water.

Measurements for total solids and diffusion coefficient were made on each product before and after dialysis. Determinations of sulfur, methoxyl and strong and weak acids were conducted on the solutions after dialysis. Determination of strong and weak acids was conducted by titrating the free acids with standard 0.1 *N* carbonate-free NaOH and following the progress of neutralization with a Leeds and Northrup glass electrode *p*H electrometer.

Hydrolysis of Lignin Sulfonates.—Acidic hydrolysis was conducted on two non-dialyzable lignin sulfonate preparations, A and B, obtained by exhaustive dialysis of gymnosperm spent sulfite liquors obtained from two different industrial sources. Reactions were carried out in sealed glass tubes in 0.01 *N* HCl solutions using several conditions of time, temperature and sodium lignin sulfonate concentra-

[a] Hydrolysis reactions were conducted in 0.01 *N* HCl aqueous solutions at the indicated temperatures and sodium lignin sulfonate concentrations with preparation A or B. For Fig. 2, the samples are designated as, for example, A-40–131, which signifies preparation A treated at 40 g./liter and at 131°, etc.

Discussion

Hemlock wood has been delignified by successive treatments with five aqueous sodium bisulfite–sulfurous acid solutions of increasing acidity, *i.e.*, at *p*H 4.8, 4.8, 3.40, 2.51 and 2.09, respectively. After each treatment the solution was removed and the wood residue retreated with a fresh increment of bisulfite–sulfurous acid solution, and this procedure is somewhat similar to one followed by Freudenberg, Lautsch and Piazolo.[6]

Results of analyses of the several wood residues and solutions (Table I) show that about one-third of the lignin, as indicated by methoxyl groupings, can be removed from wood under weakly acidic conditions as previously observed by Abrahamson Lindgren and Hagglund.[7] Increasingly acidic solutions are required to remove the remaining lignin. The lignin sulfonates obtained in the first increment are found to be of relatively low average molecular weight, about 3000 as estimated by a diffusion method[4] calibrated by light scattering observations.[5a] The lignin sulfonates obtained in later increments proved to be of increasingly high average molecular weight up to about 30,000 for IV, but yet only about 20,000 for V.

Since it was thought that the disorderly molecular weight of V might have arisen as a result of progress of more extensive hydrolysis of lignin molecules in this increment compared with the others, further heating of each of the lignin sulfonate solutions in a more acidic environment was carried out. The average molecular weights of the lignin sulfonates were again estimated. They were now found to have decreased substantially as represented in Fig. 1 and, moreover, to increase progressively from the first to the last extracted increment.

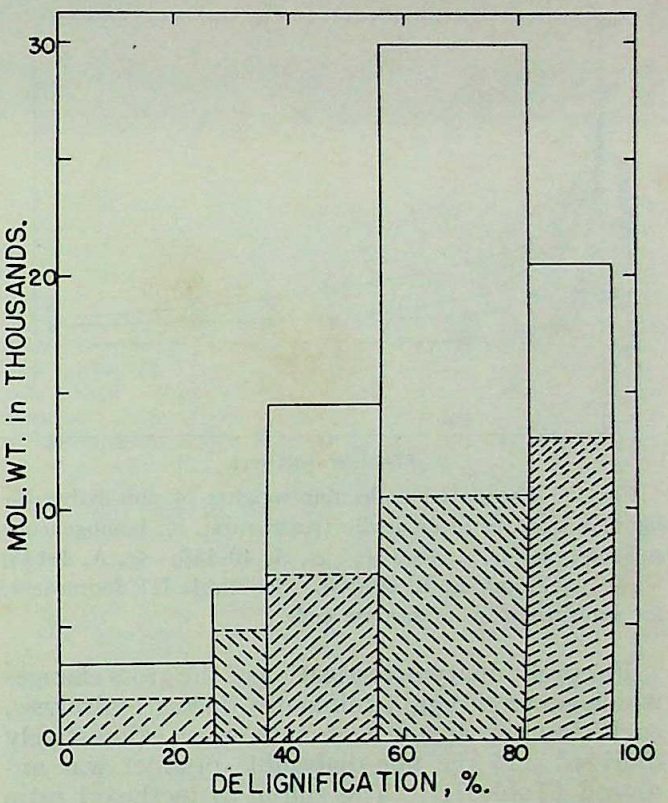

Fig. 1.—Estimated molecular weight of lignin sulfonates from incremental delignification and after hydrolysis (cross-hatched).

The weighted average molecular weight for the five lignin sulfonate preparations after hydrolysis, *i.e.*, for nearly the total lignin of the wood, is about 6000. After making allowances for the influences of the differences in types of molecular weight averages and also for the proportions of the total lignin examined, this value is believed to be in approximate agreement with a limiting value of about 3500 found by Gralen[8] and with the value of 3900 given by Loughborough and Stamm[9] and with quite a number of other average molecular weights of lignin preparations which have been reported in the literature.[1] However the molecular weights of these lignins are considerably higher than the values of around 1000 found in this Laboratory for the lignin sulfonates from maple wood,[2] and this difference may prove to be a characteristic distinction between gymnosperm and angiosperm lignins.

To observe the hydrolysis of lignin sulfonates in homogeneous aqueous solution in the substantial absence of sugars and other non-lignin substances, a non-dialyzable lignin sulfonate preparation was dissolved in sodium bisulfite–sulfurous acid solution adjusted to about *p*H 2 and then heated at 130° for various periods of time up to 48 hr. Average

molecular weights were estimated and were found to decrease progressively and to approach a limiting value of about 12,000 (Table II and Fig. 2). Lignins which have been hydrolyzed to this apparently limiting degree may be conveniently designated as "ω-lignins."

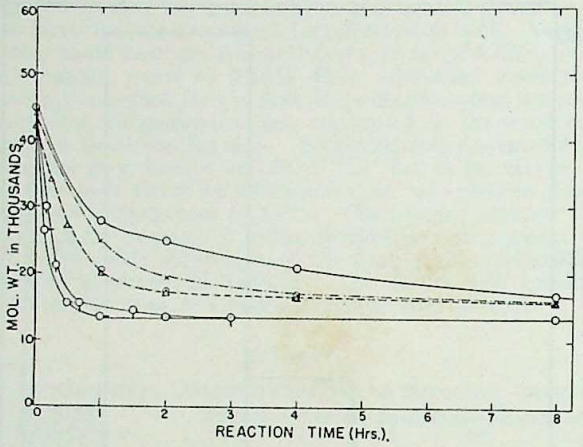

Fig. 2.—Estimated molecular weights of non-dialyzable lignin sulfonates after acidic treatments: ×, homogeneous sulfonation; O, A, 40–131; ♁, A, 40–146; ⊶, A, 4–145; ♀, 0.4–147; and △, B, 40–146. See Table III, footnote *a*, for interpretation of sample code.

For preliminary investigation of the gross changes which occur in lignin sulfonates during hydrolysis, each treated lignin sulfonate was exhaustively dialyzed and the non-dialyzable product was analyzed (Table II). The sulfur to methoxyl ratio increases from the initial value of 0.52 to a final value of 0.78 after 48 hr. Judging from the values found for "strong acid" groups, this increase occurs mostly as the result of increased sulfonation. The "weak acid" groups increase three- to sixfold, apparently because of formation of carboxylic or phenolic hydroxyl groups. From the estimated weight of the lignin sulfonates which passed through the membrane during dialysis, together with the average diffusion coefficients of the treated lignin sulfonates before and after dialysis, it is evident that the average molecular weights of these sulfonates which passed through the dialysis membrane must be small.

Preliminary hydrolysis experiments were also conducted under several conditions with aqueous solutions of hydrochloric acid, and average molecular weights and some other characteristics of the products were estimated (Table III and Fig. 3). With increasing reaction time, a decrease in average molecular weight is again found to occur and a limiting value is approached. For non-dialyzable lignin sulfonate preparations from two different sources, hydrolyses conducted at relatively high concentration (40 g./liter) gave rise to ω-lignin sulfonates with molecular weights in the range of 17,000 while hydrolyses at lower concentrations (4 and 0.4 g./liter) yielded products of substantially lower molecular weight, presumably because polycondensation reactions were minimized by dilution. An approximate fit to the present results can be obtained by assuming that the rate of hydrolysis is proportional to the concentration of unhydrolyzed hydrolyzable bonds. On this basis, values for reaction rate constants can be computed from the present data and correlated. However, for a serious treatment of the kinetics of the hydrolysis and condensation reactions of the lignin polymer, molecular weight distributions need to be known after various times of reactions under several different conditions. In this Laboratory such data are now being assembled and studied to provide a basis for a detailed statistical kinetic formulation.

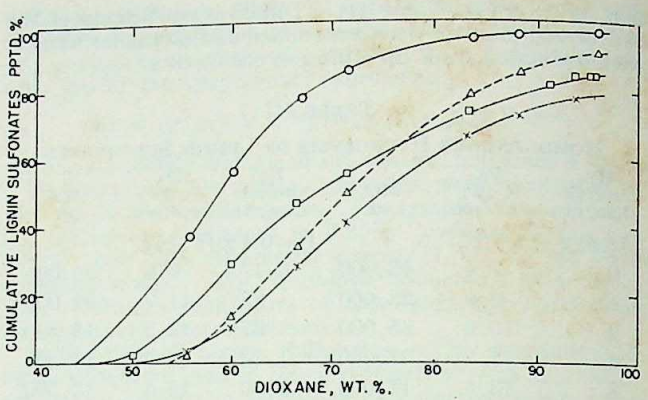

Fig. 3.—Precipitability of barium lignin sulfonate preparations in dioxane–water mixtures: whole sulfite spent liquor, □; dialyzable lignin sulfonate, ×; non-dialyzable lignin sulfonate, O; hydrolyzed lignin sulfonate (sample B, 40–146, 8 hr.), △.

The ultraviolet spectra of non-dialyzable lignin sulfonate preparation A and of its 8-hr. hydrolysis product (expt. A, 40–146) were ascertained. The spectra were very similar except that for the hydrolyzed sample the absorption minimum at about 2600 Å. was less pronounced and its absorptivity at 2800 Å. had increased by about 15%. For preparation B hydrolysis for 4 and 8 hr. (expt. B, 40–146) brought about increases of 70 and 86%, respectively, in the reducing substances calculated as glucose compared with the unhydrolyzed material. These changes may indicate formation of carbonyl end-groups as a result of the hydrolysis reaction, and the nature of the end-groups formed is now under study.

A non-dialyzable ω-lignin sulfonate (expt. B, 40–146, 8 hr.) was converted to a barium salt, dioxane was added in various proportions to aqueous solutions of the salt and the percentages of lignin precipitated were determined. Precipitation occurs over quite a wide range of dioxane concentrations (Fig. 3) which suggests that the preparation is rather polydisperse. Similar measurements were carried out with a non-dialyzable lignin sulfonate preparation which had not been hydrolyzed, and its precipitation at lower ranges of dioxane concentration may be a manifestation of the lower solubility of higher molecular weight lignin sulfonates in a less polar solvent medium. This interpretation is supported by the observation that precipitation of the relatively low molecular weight lignin sulfonates which had passed through a cellophane dialysis membrane took place only at the higher dioxane concentrations while the total lignin sulfonates in whole sulfite spent liquor were precipitated at intermediate concentrations of dioxane.

Isolation of a Cell-free Enzyme System from *Acetobacter xylinum* Capable of Cellulose Synthesis

BY GLENN A. GREATHOUSE

RECEIVED NOVEMBER 5, 1956

A cell-free enzyme system was isolated from the cellulose forming bacterium, *Acetobacter xylinum*. Cellulose-C^{14} was produced by this enzyme system from D-glucose-1-C^{14} and the position of the C^{14}-label determined in the D-glucose resulting from the hydrolysis of the cellulose formed. Ninety-six per cent. of the label was found to be in position one of the cellulose molecule.

Introduction

Previous publications[1-5] have been concerned with the biosynthesis of cellulose-C^{14} by *Acetobacter xylinum* from specifically C^{14}-labeled hexoses and trioses. We now report studies on the isolation of a cell-free enzyme or enzymes from the bacterium capable of synthesizing radioactive cellulose from D-glucose-1-C^{14}. Analyses reported include the distribution of the C^{14}-label in the purified D-glucose from the hydrolyzed enzyme cellulose-C^{14}.

Muhlethaler[6] by means of electron microscopic studies of *A. xylinum* presents evidence that the formation of cellulose by this bacterium probably does not take place within the cell or from its surface, but rather at some distance from the organism. This suggests that cellulose results from a possible enzymatically induced polymerization of the embedding slime that can accordingly be thought of as a kind of cellulose-precursor.

Schramm, Gromet and Hestrin[7,8] state that glucose, gluconate, dihydroxyacetone and glycerol in the presence of oxygen were rapidly converted to cellulose by the dry cell preparation of *A. xylinum*. They also state since aldolase was present in the cell extract, elongation and cleavage of the sugar carbon chain could have occurred by an action of this enzyme.

As far as we know this report describes the first experimental proof that a cell-free enzyme system capable of polymerization of hexose to cellulose has been studied.

Experimental

Culture Conditions.—The bacterium, *Acetobacter xylinum*, was grown on the following medium: 20 g. of yeast extract (Difco),[9] 10 g. of D-glucose, 1 g. of KH_2PO_4 and 10 ml. of ethyl alcohol per liter. This medium had a *p*H of 5.88. The inoculum was 1 ml. of a 24-hour liquid culture. The cultures were incubated for 48 hours at 30°. By this time membrane formation was evident.

Methods of Preparing Cell-free Enzymes from *A. xylinum*.—Muhlethaler's[6] study indicated that this organism produced cellulose by means of extracellular enzymes. It is realized that bacteria cells are particularly difficult to disrupt as well as produce cell-free enzyme systems. Thus, the degree of disruption was assessed by high power microscopic examination of stained preparations and making viable count to determine whether the enzyme product was cell-free. In addition, controls were made for each experiment and were left to incubate for 7 days and then examined microscopically for whole or living cells. In no case were cells found using the adopted method described. Hugo[8] discusses methods of preparing cell-free enzymes from microörganisms. The suggested methods of Hugo were evaluated and the one producing satisfactory results as to enzyme activity and being cell-free was selected.

The first experiments were performed utilizing a combination of standard methods for extracellular enzyme isolation. Later experiments used methods of disruption with abrasive particles, crushing without the use of abrasives, disintegration by agitation with small particles, disintegration by alternate freezing and thawing and by chemicals (surface active, dehydrating, etc.). An activity capable of producing cellulose in 15 to 18% yields from D-glucose was obtained with each of the methods studied at an optimum *p*H of 8.5. Consequently, the following method was adopted for this study. The contents (250 ml.) of ten flasks were poured into a chilled Waring Blendor vessel, and the blender was run for 15–30 seconds in order to break up completely the existing membranes. The crushed material (0.5 to 1 g. solids) was centrifuged at 3000 r.p.m. for 5 minutes to remove large particles and any abrasive material. The supernatant fluid was lyophilized. The resulting material was a light brown, hygroscopic powder. The freeze-drying required between 4 and 6 hours. The total solids were ether extracted to remove fats, etc., and then ground with 200-mesh powdered glass. The crude enzyme material was kept cold (−5 to 0°) until used in the experiments 1–2 hours later.

A 10% "enzyme" solution of the dry extracted material was made. Two and one-half ml. of this solution was added to 25 ml. of previously sterilized liquid medium consisting of 1% glucose, 2% yeast extract, 0.1% KH_2PO_4, and 0.5% ethyl alcohol plus 0.1% adenosine triphosphate (ATP). The enzyme system was incubated at 30°. The enzymatically synthesized cellulose was formed within 2–4 hours and no contamination occurred. A small quantity of ether was added to the surface of the cultures to delay or prevent possible contamination.

Preliminary experiments were conducted toward purification of the crude enzyme system. Of the purification methods tried, the glycerol (75%) extraction procedure gave the most promising results. Further research is required on this phase of the study.

Results and Discussion

The effect of varying *p*H values on the extent of cellulose produced by the cell-free enzyme systems is shown in Table I.

These data indicate the optimum *p*H for the enzyme systems is 8.5 to 9.0. Consequently all enzyme systems were adjusted to a *p*H of 8.5 for further studies.

Preliminary experiments indicated that the addition of adenosine triphosphate (ATP) to the other medium ingredients increased the cellulose yield. Thus experiments were designed to evaluate this factor. These data are presented in Table II.

TABLE I

OPTIMUM *p*H OF ENZYME SYSTEMS CAPABLE OF CELLULOSE FORMATION

*p*H	Cellulose yield, mg.	*p*H	Cellulose yield, mg.
5.0	0.40	8.0	34.30
5.5	0.82	8.5	48.04
6.0	4.71	9.0	47.35
6.5	12.34	9.5	32.50
7.0	19.85	10.0	0.25
7.5	25.22		

TABLE II

THE EFFECT OF ADDING ADENOSINE TRIPHOSPHATE TO THE MEDIUM ON CELLULOSE YIELD (30°, *p*H 8.5)

Amount of ATP added, g.	Cellulose yield, mg.	Amount of ATP added, g.	Cellulose yield, mg.
0	0.2	0.10	43.4
0.02	10.5	.20	45.1
.04	18.7	.40	44.8

Practically no cellulose was produced by this enzyme system without the addition of ATP. The yield was increased to 40 to 45 mg. by the addition of 0.1 to 0.4 g. of ATP. The energy for this possible direct polymerization of the glucose or glucose phosphate to cellulose by the cell-free enzyme system is likely phosphorylation, high energy phosphate bonds of ATP.

Production of Cellulose-C^{14} by the Isolated Cell-free Enzyme System.—The crude enzyme preparation was added to the medium containing D-glucose-1-C^{14} (50 microcuries) and 0.1% ATP along with the standard D-glucose, and other medium ingredients after adjusting to a *p*H of 8.5. Cellulose was produced as before, purified and the radioactivity determined. The yield based on the D-glucose-1-C^{14} was approximately 15%.

The cellulose was hydrolyzed and the resultant labeled D-glucose purified and crystallized. Paper chromatographic analysis of the cellulose hydrolyzate showed only one radioactive spot, being an R_f value identical with that of a D-glucose reference shot. An aniline hydrogen phthalate spray revealed only the same spot. The hydrolyzates were mixed with unlabeled D-glucose and purified by crystallization, to give D-glucose-C^{14} with the specific activity of 1.665 mc./m*M*. A 50-mg. sample of this radioactive glucose was oxidized by oxygen in aqueous potassium hydroxide to remove carbon 1.[10] The resulting potassium D-arabonate was separated and recrystallized and the percentage of C^{14}-activity determined. Calculations showed that 96.7% of the label was in the original position 1. Consequently, no other carbon positions were analyzed.

The radioactivity of the D-glucose was obtained with an α-β-γ proportional counter Model PC-1 and checked with a Vibrating Reed Electrometer. The proportional counter is a "P-gas (90% argon, 10% methane) windowless type counter." The geometry for small samples is 2π and the efficiency of a thin sample is 50% with this counter. Necessary precautions were taken to assure a precision of about 1% of the observed count rate. Counts were made of thin samples of $BaCO_3$ and D-glucose and the results were corrected in the standard way for the effects of background count, geometry and self-absorption.

The samples counted using the Vibrating Reed Electrometer were first combusted by the Van Slyke method and the CO_2 was collected in ionization chambers. The activity of the sample was then determined by the rate at which the condenser was charged or millivolts per second drift rate. The difference between this drift rate and the normal background of the reed gives the measure of the activity of the combusted sample. For this vibrating reed 0.1270 mv./sec. equalled one disintegration per second.

These data are most interesting, since they constitute strong evidence that glucose-1-C^{14} was synthesized to cellulose directly by the cell-free enzyme system.

Acknowledgment.—The author wishes to express his gratitude to the Office of Scientific Research of the Air Research Development Command, U. S. Air Force, for supporting the research, and to Wm. Borysewich, Jr., for his assistance with the radioactive analysis.

Biosynthesis of C^{14}-Labeled Cellulose by *Acetobacter xylinum*. IV. From D-Glucose-1-C^{14}, D-Glucose-6-C^{14} and Glycerol-1,3-C^{14}

BY GLENN A. GREATHOUSE[1]

RECEIVED NOVEMBER 5, 1956

The distribution of C^{14} in the D-glucose from the bacterial cellulose hydrolyzate produced from D-glucose-1-C^{14}, added 24 hours after inoculation as compared with that added initially was 10–12% higher in the original position 1. The hydrolyzate of cellulose-C^{14} produced from D-glucose-6-C^{14} indicated that approximately 82% of the label was in the original position 6 and had 9% in position 1, with smaller quantities in positions 2, 3, 4 and 5. The distribution of C^{14} in the D-glucose units of cellulose produced from glycerol-1,3-C^{14} was approximately 12% position 1; 4% position 2; 22% position 3; 29% position 4; 3% position 5; and 30% position 6.

Introduction

Preceding publications[2–5] have been made on the incorporation of labeled sugars into cellulose. Both *Acetobacter xylinum*[2–4] and wheat plants[6] appear to incorporate D-glucose directly. However, some of the original hexose units are cleaved prior to cellulose formation.

It would assist in determining the mechanism of cellulose formation, if the percentage of label could be changed in the original position by adding the labeled hexose after the growth of the bacteria had progressed and enzyme formed. Such experiments utilizing D-glucose-1-C^{14} are reported herein, along with the new data on the incorporation of D-glucose-6-C^{14} and glycerol-1,3-C^{14} into cellulose.

Procedures

Culture Conditions.—The culture conditions were identical with those described in the preceding paper of this series, unless designated as different.[4]

Counting Apparatus.—Counting rates were calculated from the results of counts obtained with an α-β-γ proportional counter Model PC-1 and in certain instances with a Vibrating Reed Electrometer. The proportional counter is a "P-gas (90% argon, 10% methane) windowless type counter." The geometry for small samples is 2π and the efficiency of a thin sample is 50% with this counter. Necessary precautions were taken to assure a precision of about 1% of the observed count rate. Counts were made of thin samples, as $BaCO_3$, glucose, etc. and the results were corrected in the standard way for the effects of background count, geometry and self-absorption.

The samples counted using the vibrating reed electrometer were first combusted by the Van Slyke method and the CO_2 was collected in ionization chambers. The activity of the sample was then determined by the rate at which the condenser was charged or millivolts per second drift rate. The difference between this drift rate and the normal background of the reed gives the measure of the activity of the combusted sample. For this vibrating reed 0.1270 mv./sec. equaled one disintegration per second.

Radioactivity Determinations of the Culture Products.—The procedure for the determination of C^{14} content in the CO_2, the C^{14} remaining in the culture media and the C^{14} activity of the cellulose were the same as those previously described.[2a]

Purification of the Cellulose Hydrolyzate D-Glucose.—The D-glucose-C^{14} resulting from the cellulose-C^{14} was purified by the method of Whistler and Durso[7] and by several recrystallizations before assay for C^{14}.

Methods Used for Location of C^{14} in Cellulose.—The distribution of C^{14} within the D-glucose units in the cellulose was determined by analysis of the D-glucose obtained by hydrolysis of the cellulose-C^{14}. Carrier D-glucose was added to the hydrolyzate to obtain the desired specific activity and increase the amount of C^{14}-glucose.

The activity at carbon 1 was obtained by the Frush and Isbell method.[8] Positions 2 and 3 were obtained by using the potassium D-arabonate from carbon 1-analysis and preparing its benzimidazole according to the method of Moore and Link.[9]

Carbon atoms 2 and 3 of D-glucose were then degraded stepwise by a method described by Roseman[10] by formation of benzimidazole carboxylic acid and carbon atom 2 by the benzimidazole. Position 2 was counted directly and position 3 was determined by difference of 2 and 3.

Activity at positions 4 and 5 were by difference of positions 1, 2, 3 and 6 or as described in previous publication.[2a]

Carbon atom 6 was made by the method of Reeves,[11] which involves oxidation with periodic acid of the C_6-carbon to CH_2O and its conversion to the dimedone derivative. Counts were made of this derivative, plated on aluminum pans from aqueous methanol or pyridine solutions.

Results

Cellulose-C^{14} Produced from D-Glucose-1-C^{14} Added Initially and 24 Hours after Inoculation.—The weight yields, as carbon content and the percentage of C^{14}-label in each of purified cellulose and carbon dioxide, are indicated in Table I. The table shows also, for comparison, the carbon and percentage of label in the D-glucose-1-C^{14} and ethanol that was supplied.

The original percentage activity per 1 mg. of D-glucose (100/80.5) is 1.24. The percentage activity per 1 mg. for the resultant cellulose when D-glucose-1-C^{14} was added initially (28.7/26.2) is 1.10; when D-glucose-1-C^{14} was added 24 hours after inoculation (33.6/28.4) is 1.18. Thus the activity was slightly lower than the original D-glucose-1-C^{14}.

The label in the cellulose-C^{14} was distributed over the six positions in the glucose units as shown in Table II. These experiments were performed at the same time and under identical conditions except the time of adding the D-glucose-1-C^{14}.

TABLE II

LOCATION OF LABEL IN D-GLUCOSE FROM BACTERIAL CELLULOSE

Structure position	D-Glucose-1-C^{14} Added 0 hr.	D-Glucose-1-C^{14} Added 24 hr. later
1	62.5	79.1
2	1.6	0.4
3	19.2	11.0
4	15.4	8.0
5	0.9	0.4
6	0.4	1.1
	100	100

Cellulose-C^{14} Produced by D-Glucose-6-C^{14}.—Radioactive cellulose was produced from D-glucose-6-C^{14} by use of *A. xylinum*. The procedure was similar to that described for the other labeled sugar and cellulose formation. The results of these experiments are summarized in Tables III and IV.

TABLE III

SUBSTRATES, YIELD OF PRODUCTS AND C^{14}-LABEL DISTRIBUTION

	Wt., mg. C	Label C^{14}, %
Substrates		
D-Glucose-6-C^{14}	80.5	100
Ethanol	79.3	None
Products		
Carbon dioxide	111.0	28.9
Cellulose	32.6	23.8

TABLE IV

LOCATION OF LABEL IN GLUCOSE FROM BACTERIAL CELLULOSE—FROM D-GLUCOSE-6-C^{14}

Structure position	%	Structure position	%
1	9.3	4	3.5
2	1.7	5	
3	3.9	6	81.6

The major portion (81.6%) of the label was located at position 6, corresponding to its position in the labeled substrate. Position 1 contained 9.3% and the remaining 9% was distributed at positions 3, 4 and 5 and 2 in descending order.

Cellulose-C^{14} Produced by Glycerol-1,3-C^{14}.—Cellulose-C^{14} was produced by *A. xylinum* using glycerol-1,3-C^{14} as the sole carbon label source. The procedures and analyses were the same as for the previously described radioactive sugar studies. These data are presented in Tables V and VI.

TABLE V

SUBSTRATES, YIELD OF PRODUCTS AND C^{14} LABEL DISTRIBUTION

	Wt., Mg. C	Label C^{14}, %
Substrates		
Glycerol-1,3-C^{14}	98.0	100
Ethanol	79.3	None
Products		
Carbon dioxide	87.4	6.1
Cellulose	11.8	5.7

TABLE VI

LOCATION OF LABEL IN GLUCOSE FROM BACTERIAL CELLULOSE FROM GLYCEROL-1,3-C^{14}

Structure position	%	Structure position	%
1	12.7	4	28.9
2	3.7	5	3.0
3	21.7	6	30.0

Smaller quantities of C^{14} were found in the CO_2 and cellulose with glycerol-1,3-C^{14} as the label source than with glucose-C^{14} during the 7 day incubation period. Most of the 87.4 mg. carbon as CO_2 must have come from the oxidation of the ethanol. The liquid products of the cultures contained a large portion of the label. *A. xylinum* is required to form cellulose from trioses in this case and it may be the time required for the bacteria or its enzyme system to produce sizable quantities of cellulose intermediate (hexoses, hexose phosphates, etc.) exceeds the 7-day period of the experiments. Experiments (to be reported elsewhere) concerned with the isolation of the cellulose intermediates between glycerol-1,3-C^{14} and cellulose formation bear out this reasoning.

The label in the cellulose was distributed over the six positions in the glucose units, with the smaller quantities being in position 2 and 5.

Discussion

This paper presents data for the first time on the biosynthesis of cellulose-C^{14} from D-glucose-1-C^{14} added 24 hours after inoculation as compared with that added initially. The delayed addition of D-glucose-1-C^{14} produced a 10–12% higher concentration of the label in the original position 1. These data indicate that polymerization of the D-glucose, as such, without prior cleavage is favored by adding the radioactive sugar after the bacteria have initiated growth. No previous data have been reported on the biosynthesis of cellulose-C^{14}, and the position of label, utilizing D-glucose-6-C^{14} or glycerol-1,3-C^{14}. The hydrolyzate of cellulose-C^{14} from D-glucose-6-C^{14} showed that approximately 82% of the label was in the original position 6. When glycerol-1,3-C^{14} was the sole carbon source, the label was 12% position 1, 4% position 2, 22% position 3, 29% position 4, 3% position 5 and 30% position 6.

In every case of cellulose biosynthesis studied, some of the original hexose units are cleaved prior to cellulose formation. The concentration of the label in the original position depends on which of

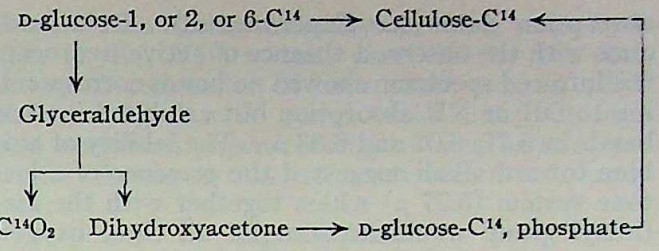
the six carbon atoms is labeled and on the time of adding the radioactive sugar. Thus, the mechanisms of cellulose polymerization is complex. At least two major mechanisms appear from these studies, (1) direct polymerization, possibly involving phosphorylation and (2) cleavage of the hexose and resynthesis of hexose phosphates from trioses such as glycerol. Hexose phosphates[12] have been isolated and identified as intermediates in the biosynthesis of cellulose from D-glucose, thus the reason for suggesting these products as possible energy sources in the major mechanism of polymerization.

To summarize the research, a schematic representation of the processes of cellulose formation may be shown as



A cell-free enzyme system has been isolated from *A. xylinum* capable of producing cellulose-C^{14}.[13] D-Glucose-1-C^{14} was polymerized to cellulose and the hydrolyzate (D-glucose) analyzed. Ninety-six per cent. of the label was found in position one of the cellulose molecule.

The Chemistry of Rosewood. Isolation and Structure of Anibine and 4-Methoxyparacotoin[1]

BY WALTER B. MORS,[2a,3] OTTO RICHARD GOTTLIEB[2b,3] AND CARL DJERASSI

RECEIVED APRIL 12, 1957

From the wood of the South American rosewood trees (genus *Aniba*) there has been isolated a new alkaloid, $C_{11}H_9NO_3$, which has been named anibine. By various degradations, in particular by alkaline cleavage, it was shown that anibine is 4-methoxy-6-(3′-pyridyl)-α-pyrone (IV). A neutral companion substance of anibine, when subjected to similar reactions, was proved to be 4-methoxy-6-piperonyl-α-pyrone (X) (4-methoxyparacotoin) and attention is called to the structural similarity with the constituents of the closely related *Coto* barks.

The South American rosewood trees belong to the *Lauraceae* family, and the derived essential oil has long been an article of commerce.[4] The botanical identification has been confusing, and the trees were once believed to belong to the genus *Ocotea*.[5] It is now accepted that the *bois de rose* from French Guiana and adjacent areas is *Aniba rosaeodora* Ducke and the Brazilian *páu rosa* from the lower Amazon basin *Aniba Duckei* Kostermans (*A. rosaeodora* var. *amazonica* Ducke).[6,7] The main constituent of the rosewood essential oil is linalool, but a ready differentiation of the two species is even possible on chemical grounds since the essential oil from French Guiana is strongly levorotatory while the Brazilian one is only slightly so or even dextrorotatory.[4]

Aside from the essential oil, no chemical work seems to have been done with these plants, and a detailed examination of the composition of these *Aniba* species was undertaken by one of us (O.R.G.) The Brazilian *Aniba Duckei* Kostermans represented commercial material from Manaus (State of Amazonas) while a sample of *Aniba rosaeodora* Ducke came from an isolated tree from the region of the Amaparí river (Territory of Amapá, Brazil).[8] A number of products were isolated, and the present paper is concerned with the alkaloid and one of the neutral constituents, which were found in both *Aniba* species.

Extraction of the rosewood sawdust with benzene followed by removal of basic material with hydrochloric acid and basification yielded a single, crystalline alkaloid, m.p. 179–180°, in *ca.* 2.6% yield. Its empirical formula, $C_{11}H_9NO_3$, immediately indicated that it must differ considerably from the few alkaloids (isoquinoline types) hitherto encountered among the *Lauraceae*,[5,9] and we have named the substance "anibine." Functional group analysis demonstrated the presence of one methoxyl group and the absence of N-methyl or C-methyl groups. Anibine contained no active hydrogen atom and was optically inactive over the range 700–400 mμ. The alkaloid, though forming a crystalline methiodide, hydrochloride and picrate, was weakly basic and in fact could be removed from hydrochloric acid solution by continuous extraction with chloroform. The nitrogen atom was, therefore, assumed to be part of a heterocyclic ring which was not inconsistent with the ultraviolet

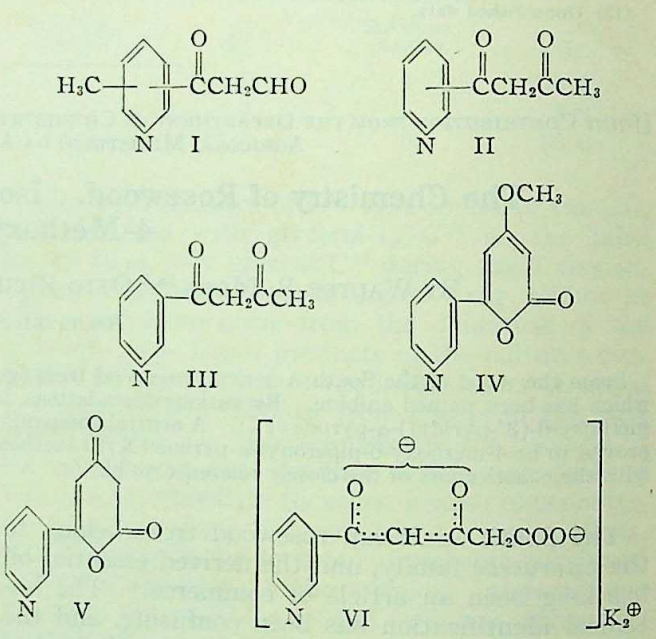
absorption data (see Experimental). In accordance with the observed absence of active hydrogen, the infrared spectrum showed no bands corresponding to OH or NH absorption but exhibited intense bands at 5.77, 6.02 and 6.33 μ. The lability of anibine toward alkali suggested the presence of a lactone system (5.77 μ) which together with the methoxyl group would account for all three oxygen atoms. The 6.02 μ band could be assigned to an enol ether and this was proved subsequently to be correct. Catalytic hydrogenation (platinum oxide in acetic acid) resulted in the uptake of 6 moles of hydrogen which indicated that hydrogenolysis must have occurred,[10] although no pure product could be isolated.

An ethanolic alkaline solution of anibine turns yellow immediately, but the spectrum (λ_{max}^{KOH} 252, 282 and 381 mμ) changes upon long standing (λ_{max}^{KOH} 334 mμ), and the color is virtually discharged. When this reaction was carried out on a preparative scale, there was isolated an insoluble dipotassium salt ($C_{10}H_7K_2NO_4 \cdot H_2O$), which in contrast to anibine itself did not contain any methoxyl group. Acidification of an aqueous solution of the potassium salt resulted in decarboxylation—indicating the presence of a β-keto acid—and the isolation of an amphoteric crystalline solid, $C_9H_9NO_2$. The latter also could be obtained in somewhat poorer yield by boiling anibine with acid. The absence of a methoxyl group already was noted in the potassium salt precursor, but it was now observed that the cleavage product contained one C-methyl group, which was not present in the parent alkaloid. Consequently, this new C-methyl group must represent the point of attachment of the potential carboxyl group of anibine which was lost by decarboxylation during the acid and alkaline cleavage reactions.

The infrared spectrum of the $C_9H_9NO_2$ cleavage product was very instructive since it showed no definite OH absorption or significant carbonyl absorption below 6 μ. Rather, it exhibited a broad band in the 6.2 μ region typical of carboxylate or enolate anions, and the above-mentioned chemical and analytical data were only compatible with the latter. Catalytic hydrogenation resulted in the uptake of 5 moles of hydrogen, and since only 6 units of unsaturation are permissible in $C_9H_9NO_2$, the substance can only contain one ring, from which it follows that the tertiary nitrogen atom in a heterocyclic ring present in anibine must be represented by a pyridine ring. A $C_9H_9NO_2$ formulation containing one C-methyl group, a pyridine ring and a β-diketone enolate moiety can only be incorporated in partial formulas I or II. Of these, the former is rather unlikely since model Kuhn–Roth oxidations with various methylated pyridines showed that virtually no acetic acid was produced while the cleavage product yielded slightly over 100% of volatile acid. All three possible isomers of II have been described in the literature, and it was shown by direct comparison with a synthetic specimen that the $C_9H_9NO_2$ cleavage product of anibine was identical with the known[11] 1-(3′-pyridyl)-butane-1,3-dione (β-acetoacetylpyridine)-(III).[12]

With this information at hand, anibine can only be represented by 4-methoxy-6-(3′-pyridyl)-α-pyrone (VI). As stated above, the absence of a C-methyl group in anibine requires that the carboxyl group of the lactone be attached to the end of the side chain of III. Since anibine clearly did not contain a β-lactone ring, lactonization must have involved the oxygen atom at the δ-position, leading to structure V. Anibine, however, contains one methoxyl group which can only be incorporated into V as an enol ether grouping, thus resulting in expression IV for anibine,[13] which appears to be the first alkaloid containing an α-pyrone ring.



Crystallization of the neutral benzene-soluble fraction of rosewood furnished a colorless solid, m.p. 221–224°, possessing the empirical formula $C_{13}H_{10}O_5$. The substance possessed one methoxyl and no C-methyl group, exhibited no hydroxyl absorption but showed general spectral similarities to anibine. When boiled with alkali, there was isolated piperonylic acid and 3,4-methylenedioxyacetophenone (VII). On the other hand, when the reaction was conducted at room temperature with ethanolic potassium hydroxide as was the case with anibine (IV), there was isolated an insoluble potassium salt. Acidification led to an unstable β-keto acid, m.p. 125–130°, shown to have structure VIII, since it was decarboxylated readily upon heating or attempted recrystallization to the previously unknown 1-piperonyl-butane-1,3-dione (IX). This compound was identified by comparison with a synthetic specimen prepared from methyl piperonylate and acetone. By employing precisely the same arguments outlined above for ani-

(10) The empirical formula of anibine permits eight double bonds or rings. The presence of a lactone ring and of a heterocyclic ring in the parent alkaloid would allow only for the uptake of 5 moles of hydrogen unless hydrogenolysis occurred as well.

(11) A. Ferenczy, *Monatsh.*, **18**, 673 (1897).

(12) Subsequently, nicotinic acid was isolated in poor yield in one alkaline cleavage reaction and by nitric acid oxidation of anibine.

(13) The loss of the methoxyl group in the alkaline cleavage presumably involves addition of hydroxide ion at the β-position followed by reverse Michael condensation with expulsion of methoxide. The initial product ($C_{10}H_7K_2NO_4 \cdot H_2O$), isolated in the alkaline cleavage of anibine, should then be represented by the hydrate of VI.

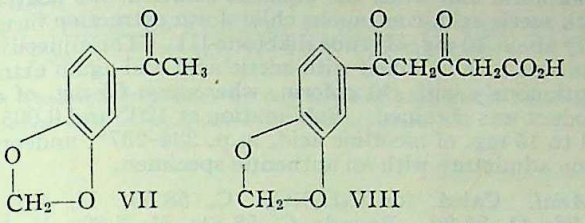
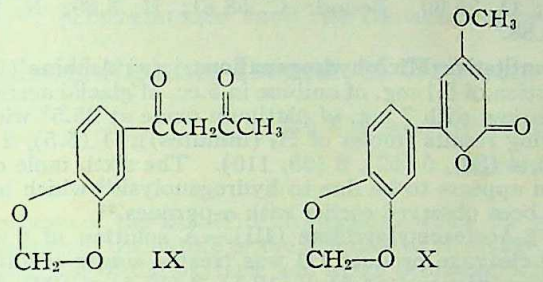
bine, the neutral product can only be 4-methoxy-6-piperonyl-α-pyrone (X).



VII VIII



IX X

Aside from the steroidal toad poisons and squill glycosides,[14] α-pyrones are quite rare in nature.[15] It is interesting to note that the only two closely related naturally occurring α-pyrones, phenylcoumalin (6-phenyl-α-pyrone) (XI) and paracotoin (6-piperonyl-α-pyrone) (XII), are found in *Coto* and *Paracoto* bark.[16] Although it was known that the Bolivian *Coto* bark was derived from a tree belonging to the *Lauraceae*, all of the early medicinal and chemical work[17] was carried out when the taxonomic problem was still very confused.[18] Only the comparatively recent botanical revision of the *Lauraceae*[7] has resulted in the classification of *Coto* as *Aniba coto* (Rusby) Kostermans (syn. *Nectandra coto* Rusby) and of *Paracoto* as *Aniba pseudo-coto* (Rusby) Kostermans (syn. *Ocotea*[19] *pseudo-coto* Rusby). The striking chemical relationship between these four, naturally-occurring α-pyrones (IV, X, XI, XII) is thus paralleled by the close botanical connection of their plant sources, all of them belonging to the genus *Aniba*, and would suggest a common biogenetic origin. Synthetic experiments relating to these structures are now in progress.

(19) It should be noted that rosewood itself was once assumed to belong to this genus (see ref. 5).

Experimental[20]

Extraction Procedure.—The rosewood[21] was reduced to sawdust and then extracted exhaustively with benzene in a Soxhlet apparatus. After concentration, the basic fraction was removed with dilute hydrochloric acid and the latter made alkaline with ammonia. Crude anibine (IV) was filtered and additional quantities could be recovered by chloroform extraction to raise the yield to 2.6%.

The benzene solution was next extracted several times with 3% sodium hydroxide solution, washed with water until neutral, dried and evaporated to yield a solid residue mixed with essential oil from which it could be separated by direct filtration. The solid (*ca.* 2%) was best purified by chromatography in order to remove an orange-colored contaminant and afforded 1.2% of 4-methoxyparacotoin (X).

Anibine (IV).—Crystallization from 95% ethanol and sublimation at 130° and 0.003 mm. provided colorless crystals, m.p. 179–180°, which showed no perceptible rotation in methanol solution (*c* 0.1) over the range 700–400 mμ and did not give any color with alcoholic ferric chloride solution. The infrared bands (Nujol or chloroform solution) were found at 5.77, 6.02 and 6.33 μ (no OH or NH absorption) and are thus somewhat shifted from those reported for steroidal bufadienolides.[22] The ultraviolet spectral data are listed in Table I.

TABLE I

Solvent	Max. mμ (log ε)	Shoulder mμ (log ε)	Min. mμ (log ε)
EtOH	228.5(4.32), 315(4.09)	254(3.70)	269(3.67)

Acid Cleavage of Anibine (IV).—A solution of 200 mg. of anibine in 50 cc. of 5% hydrochloric acid was heated under reflux for 6 hr. in a stream of nitrogen, decarboxylation occurring during this process as evidenced by the precipitation of barium carbonate (88% yield) in a barium hydroxide trap. The solution was cooled, extracted continuously with chloroform for 17 hr., and the chloroform layer was washed with water, dried and evaporated. The residual semi-solid (55 mg.) was crystallized from petroleum ether and then sublimed at 80° and 0.005 mm.; m.p. 84–86°, red color with ferric chloride, $\lambda_{max}^{CHCl_3}$ broad band at 6.1–6.25 μ and small band at 5.80 μ. The ultraviolt absorption data are listed in Table II.

TABLE II

Solvent	Max., mμ (log ϵ)	Min., mμ (log ϵ)
EtOH	236(3.88), 309(4.15)	256(3.57)
1 *N* HCl–EtOH	251.5(3.83), 315(4.07)	236(3.73), 268(3.69)
1 *N* KOH–EtOH	245(3.79), 330(4.17)	275(3.47)

Identity with a synthetic specimen[11] of β-acetoacetylpyridine (III) was established by mixture melting point determination and infrared spectral comparison.

Anal. Calcd. for $C_9H_9NO_2$: C, 66.24; H, 5.56; N, 8.58; O, 19.61; C–CH_3, 9.20; active H, 0.61; mol. wt., 163. Found: C, 66.32; H, 5.42; N, 8.66; O, 20.22; OCH_3, 0.00; C–CH_3,[23] 9.42, 9.64; active H, 0.69; neut. equiv. (perchloric acid titration), 162.

Alkaline Cleavage of Anibine.—A solution of 200 mg. of anibine dissolved in 40–50 cc. of 1 *N* ethanolic potassium hydroxide was kept at 20° in an atmosphere of nitrogen. After 2–3 hr. crystals started to appear and these were filtered after 15 hr. and washed well with absolute ethanol; yield 163 mg., m.p. 240–250° dec. This virtually colorless potassium salt (VI) was insoluble in organic solvents, highly soluble in water and gave a red color with ferric chloride solution. The analysis as well as the infrared spectrum (λ_{max}^{Nujol} 3.03, 6.08, 6.18 and 6.29 μ) indicated the presence of water, but this could not be removed even on attempted azeotropic distillation with toluene.

Anal. Calcd. for $C_{10}H_7K_2NO_4 \cdot H_2O$: C, 39.85; H, 3.01; N, 4.65; K, 26.54. Found: C, 39.96; H, 2.91; N, 4.39; K, 25.79; OCH_3, 0.00.

The potassium salt VI could be transformed into the corresponding silver salt by dissolving in water and adding 5% aqueous silver nitrate solution. The pale yellowish precipitate was dried in a desiccator before analysis.

Anal. Calcd. for $C_{10}H_7Ag_2NO_4 \cdot H_2O$: C, 27.36; H, 2.07; N, 3.19; Ag, 49.15. Found: C, 26.94; H, 1.85; N, 2.97; Ag, 50.33.

A solution of 511 mg. of the potassium salt VI in 50 cc. of water was acidified with a few drops of hydrochloric acid and then extracted continuously with chloroform for 30 hr. The extraction was accompanied by decarboxylation as demonstrated by the formation of barium carbonate in a barium hydroxide trap attached to the extraction apparatus. The chloroform solution was dried, evaporated to dryness and the crystalline residue was sublimed at 80° and 0.005 mm. to yield 316 mg. of pure β-acetoacetylpyridine (III), m.p. 84–86°. This is the preferred procedure since the over-all yield based on anibine is 50%. The cleavage product readily forms a 2:1 adduct with silver nitrate in water solution.

Anal. Calcd. for $C_{18}H_{18}N_2O_4 \cdot AgNO_3$: C, 43.57; H, 3.66; N, 8.46; Ag, 21.74. Found: C, 43.35; H, 3.32; N, 8.72; Ag, 21.73.

Isolation of Nicotinic Acid from Cleavage of Anibine (IV).—In one experiment, the ethanolic potassium hydroxide solution of 150 mg. of anibine was left for only 1 hr., most of the ethanol was removed at room temperature *in vacuo* and water was added. Nothing could be extracted by means of chloroform and when the aqueous solution was neutralized with acetic acid, continuous chloroform extraction furnished only about 10 mg. of crude diketone III. The aqueous solution was then acidified with acetic acid and again extracted continuously with chloroform, whereupon 65 mg. of crude product was obtained. Sublimation at 120° and 0.005 mm. led to 15 mg. of nicotinic acid, m.p. 234–237°, undepressed upon admixture with an authentic specimen.

Anal. Calcd. for $C_6H_5NO_2$: C, 58.53; H, 4.09; N, 11.38; O, 25.99. Found: C, 58.81; H, 3.89; N, 11.40; O, 25.88.

Quantitative Microhydrogenations. (a) **Anibine (IV).**—A solution of 6.1 mg. of anibine in 5 cc. of glacial acetic acid was shaken with 7 mg. of platinum oxide at 25.5° with the following results (moles of H_2 (minutes)): 1 (5.5), 2 (14), 3 (25), 4 (39), 5 (52), 6 (65, 110). The sixth mole of hydrogen appears to be due to hydrogenolysis[10] which has already been observed earlier with α-pyrones.[24]

(b) β-Acetoacetylpyridine (III).—A solution of 6.9 mg. of the cleavage product III was treated under exactly the same conditions: 1 (4.5), 2 (10.5), 3 (17.5), 4 (29), 5 (78, 94).

4-Methoxyparacotoin (4-Methoxy-6-piperonyl-α-pyrone) (X).—The crude product was purified by chromatography on alumina deactivated with 3% of 10% acetic acid and eluted with benzene. Recrystallization from ethanol yielded the analytical sample as colorless needles, m.p. 222–224°, $[\alpha]D \pm 0°$ ($CHCl_3$); λ_{max}^{Nujol} 5.75, 6.04, 6.12 and 6.38 μ; λ_{max}^{EtOH} 336 mμ (log ϵ 3.98), λ_{min}^{EtOH} 272 mμ (log ϵ 3.44).

Anal. Calcd. for $C_{13}H_{10}O_5$: C, 63.41; H, 4.09; O, 32.49; OCH_3, 12.59. Found: C, 63.30; H, 4.07; O, 32.68; OCH_3, 12.73; C–CH_3, 0.00.

Alkaline Cleavage of 4-Methoxyparacotoin (X). (a) **With Boiling Alkali.**—A solution of 201 mg. of 4-methoxyparacotoin (X) was heated under reflux for 3 hr. with 20 cc. of 0.5 *N* ethanolic potassium hydroxide. After dilution with water, the neutral material was extracted continuously with chloroform yielding 93 mg. of cream colored solid, m.p. 53–80°.

Recrystallization from water gave 45 mg. of small, colorless needles of **3,4-methylenedioxyacetophenone (VII)**, m.p. 87–88°, $\lambda_{max}^{CHCl_3}$ 6.2 μ (broad).

Anal. Calcd. for $C_9H_8O_3$: C, 65.85; H, 4.91. Found: C, 66.35; H, 4.59.

An authentic sample was not available, but the constants of the ketone and its phenylhydrazone (m.p. 112–114°) were in good agreement with those reported in the literature.[25] Furthermore, sodium hypobromite oxidation furnished piperonylic acid.

The original aqueous solution was separated into phenolic (less than 10 mg.) and acidic fractions. The latter (34 mg.) represented a yellowish solid which crystallized from ethanol as colorless needles, m.p. 231–233°, undepressed upon admixture with an authentic sample of **piperonylic acid** (m.p. 231–233°).

(b) **At Room Temperature.**—A solution of 100 mg. of 4-methoxyparacotoin (X) was left at room temperature in 50 cc. of 1 *N* ethanolic potassium hydroxide solution for 24 hr. in a current nitrogen. The potassium salt (59 mg., λ_{max}^{Nujol} 3.15 and 6.30 μ) was filtered, dissolved in water and acidified. The colorless precipitate (30 mg.) of the **β-keto acid VIII** was filtered and dried at room temperature for analysis; m.p. 125–130° (gas evolution), λ_{max}^{Nujol} 5.82, 6.08 and 6.2 μ. It could not be recrystallized without effecting decarboxylation.

Anal. Calcd. for $C_{12}H_{10}O_6$: C, 57.60; H, 4.03; O, 38.37. Found: C, 58.23; H, 4.30; O, 37.12.

The β-keto acid VIII was either decarboxylated by first heating above its melting point, cooling and then subliming or by recrystallization from boiling water containing a small amount of ethanol. In each case, there was obtained colorless crystals of **1-piperonyl-butane-1,3-dione (IX)**, m.p. 91–

(23) On the other hand, Mr. Alcino reported that under the same conditions of the Kuhn–Roth oxidation, α-, β- and γ-picoline as well as 2,6-lutidine yielded no titratable acetic acid. Up to 90% of acetic acid could be obtained when the pyridine ring was activated (*e.g.*, 2-amino-4-methylpyridine, pyridoxine).

(24) See A. Stoll, A. Hofmann and H. Helfenstein, *Helv. Chim. Acta*, **18**, 644 (1935); J. Fried and R. C. Elderfield, *J. Org. Chem.*, **6**, 566 (1941).

(25) G. Ciamician and P. Silber, *Ber.*, **24**, 2989 (1891), report m.p. 88° for the ketone and m.p. 114° for its phenylhydrazone.

92°; $\lambda_{max}^{CHCl_3}$ 5.80 (small) and broad, strong band at 6.2 μ; λ_{max}^{EtOH} 238.5 and 335 mμ, log ϵ 4.02 and 4.29; λ_{max}^{EtOH} 253 mμ, log ϵ 3.64.

Anal. Calcd. for $C_{11}H_{10}O_4$: C, 64.07; H, 4.89; C-CH_3, 7.29. Found: C, 63.60; H, 4.82; C-CH_3, 8.13.[26]

(26) The high value may be due to small amounts of piperonylic acid carried over in the Kuhn–Roth determination.

The substance proved to be identical by mixture melting point determination and infrared comparison with a synthetic specimen (m.p. 92–93°) prepared by condensation of methyl piperonylate and acetone in ether solution in the presence of sodium.

The Isoglutamine Isomer of Oxytocin: Its Synthesis and Comparison with Oxytocin[1]

BY CHARLOTTE RESSLER AND VINCENT DU VIGNEAUD

RECEIVED FEBRUARY 27, 1957

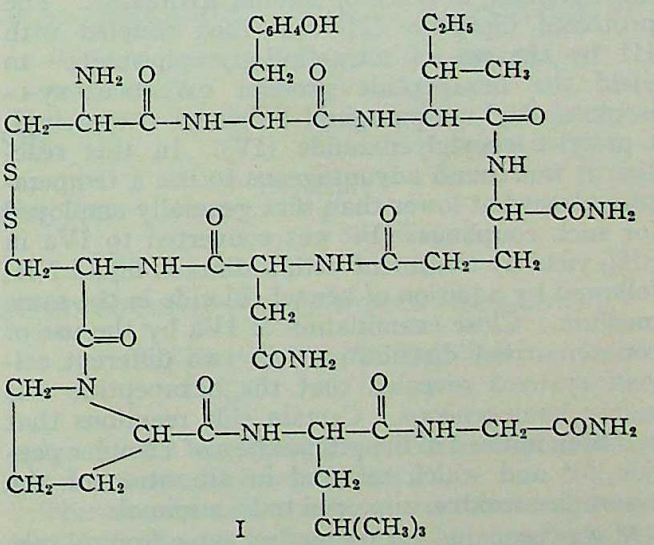
Synthesis of the isomer of oxytocin in which the glutamine residue has been substituted by isoglutamine is described. The change in the nature of the glutamic acid linkage with the consequent ring enlargement was found to result in virtually complete loss of the oxytocic and avian depressor activities of oxytocin. The *isoglutamine-oxytocin* differed from oxytocin also in some of its physical properties and exhibited a striking difference in optical rotation. However, several of the other properties of the two polypeptides were found to be indistinguishable.

The structure of oxytocin, the chief oxytocic principle of the posterior pituitary gland, has been established through its synthesis[2,3] as an octapeptide composed of a 20-membered cyclic disulfide ring branched by a tripeptide side chain, namely, the cyclic disulfide of L-cysteinyl-L-tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-L-cysteinyl-L-prolyl-L-leucylglycinamide.

It may be recalled that this synthesis was based on structural studies[4] in this Laboratory on natural oxytocin and, in addition, on certain assumptions regarding the position of two amide groups and the nature of the linkages of the aspartic acid and glutamic acid residues. In proposing the structure for oxytocin[4,5] it seemed reasonable to assign the position of two amide groups to the aspartic acid and glutamic acid residues and, furthermore, it was assumed that these were present as asparaginyl and glutaminyl residues rather than as the isomeric isoasparaginyl and isoglutaminyl residues. After this structure for oxytocin had been established through synthesis, further confirmatory evidence with respect to the assumptions made was obtained by the demonstration of the presence of glutamine and asparagine in enzymatic hydrolysates of oxytocin and vasopressin.[6]

It was of considerable interest to determine whether oxytocin could be distinguished from the octapeptides isomeric with it with respect to the glutamine and/or asparagine residues. Such isomers would allow observations on the effect of a small structural change on the physical and chemical properties of oxytocin, and these results might be of interest with respect to the characterization of polypeptides and proteins. Comparison of the biological activities of oxytocin with those of its isoglutamine and/or isoasparagine isomer would provide, in addition, information bearing on the relationship of structure to the biological activities of the oxytocic hormone.

These considerations have led us to undertake the synthesis of the isoglutamine isomer of oxytocin. In this polypeptide an isoglutamine residue replaces the glutamine residue of oxytocin. It may be noted that the ring moiety of this isomer is larger by two methylene units than that present in oxytocin, and thus, *isoglutamine-oxytocin* (I) possesses a 22-membered ring.



I

The synthesis of isoglutamine-oxytocin was approached *via* the nonapeptide intermediate N-carbobenzoxy-S-benzyl-L-cysteinyl-L-tyrosyl-L-isoleucyl-L-isoglutaminyl-L-asparaginyl-S-benzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (VI), which corresponds in structure to the key intermediate used in the synthesis of oxytocin, with isoglutamine replacing the glutamine of the oxytocin intermediate. In the synthesis of oxytocin, suitable reduction of the nonapeptide intermediate followed by oxidation led to the desired 20-membered cyclic disulfide hormone. The projected synthesis of isoglutamine-oxytocin through a similar route, *i.e.*, by oxidation of the appropriate sulfhydryl nonapeptide, involved the as-

sumption that ring closure to a 22-membered cyclic disulfide could be effected. Actually, the synthesis of the appropriate sulfhydryl nonapeptide afforded an excellent opportunity to determine whether oxidation would lead to a 22-membered cyclic disulfide. If closure to a ring of this size could not be effected, a larger disulfide ring might well be formed or a polymer might result. It was therefore vital, after oxidation of the isoglutamine sulfhydryl nonapeptide and isolation of the corresponding disulfide, to determine the molecular weight of the compound.

The synthetic reactions leading to isoglutamine-oxytocin are summarized in the accompanying diagram. Throughout the synthetic work described, the carbobenzoxy group was used to protect the amino group,[7] and the benzyl group served to protect the sulfhydryl group. The protective groups were removed by reductions with sodium in liquid ammonia.[8]

The preparation of VI was accomplished by coupling N-carbobenzoxy-S-benzyl-L-cysteinyl-L-tyrosyl-L-isoleucine (V) with the hexapeptide amide L-isoglutaminyl-L-asparaginyl-S-benzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (IVa), which had been prepared in turn from the coupling product of carbobenzoxy-L-isoglutaminyl-L-asparagine (II) and S-benzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (III).[9]

Carbobenzoxy-L-isoglutaminyl-L-asparagine (II) was prepared by the condensation of carbobenzoxy-L-isoglutamine with asparagine in aqueous solution by means of the mixed anhydride procedure with isobutyl chlorocarbonate,[10] modified by the use of triethylamine in place of sodium hydroxide. The protected dipeptide (II) was then coupled with III by the use of tetraethyl pyrophosphite[11] to yield the hexapeptide product carbobenzoxy-L-isoglutaminyl-L-asparaginyl-S-benzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (IV). In this reaction it was found advantageous to use a temperature somewhat lower than that generally employed for such couplings. IV was converted to IVa in 81% yield by treatment with sodium in liquid NH_3 followed by addition of benzyl chloride in the same medium. Close examination of IVa by the use of countercurrent distribution[12] in two different solvent systems revealed that the hexapeptide was highly homogeneous. Certain side reactions that had been noticed in the preparation of a similar peptide,[13,14] and which resulted in alteration of the asparagine residue, appeared to be minimal.

V was prepared *via* its methyl ester from N-carbobenzoxy-S-benzyl-L-cysteinyl-L-tyrosine and methyl L-isoleucinate by the N,N′-dicyclohexylcarbodiimide method.[15] Although some of the physical constants of both the ester and acid V differed from the values in the literature for these compounds obtained through several other methods, application here of one of the reported procedures[16] led to material which, after further purification, agreed closely in melting point and rotation with the methyl ester of V obtained here through the carbodiimide method.

V was coupled with IVa in aqueous tetrahydrofuran by the use of N,N′-dicyclohexylcarbodiimide and yielded the protected nonapeptide VI in 64% yield. All the protecting groups were then removed from VI by treatment with sodium in liquid NH_3, and the resulting material was oxidized to the disulfide form by aeration in aqueous solution at *p*H 6.9.

The final product was isolated by countercurrent distribution in 0.05% acetic acid–*sec*-butyl alcohol (K = 0.37) followed by distribution in 0.01 M NH_3–*sec*-butyl alcohol (K = 1.8). Only one product was found in contrast to the situation with the earlier syntheses of two other related polypeptides, namely oxytocin[3] and the cyclic disulfide of L-cysteinyl-L-tyrosyl-L-isoleucyl-L-glutaminyl-L-asparaginyl-L-cysteinamide.[13,14] Data obtained from the final distribution of the isoglutamine polypeptide indicated that the material possessed a high degree of purity.

That the compound actually possessed the desired monomeric octapeptide structure was shown by the value obtained for the molecular weight, which was within the expected range.

Isoglutamine-oxytocin was tested for some of the physiological activities associated with oxytocin. Oxytocic activity was measured on the isolated rat uterus according to the method of Burn[17] and the avian blood pressure effect was determined in the anaesthetized chicken by the method of Coon.[18] The U. S. P. Standard posterior lobe powder served as reference. Since it was desired to test the polypeptide also in its reduced form, a solution of the peptide was also assayed in the chicken soon after reduction without subsequent aeration. In addition, the reduction product was tested in the presence of added cysteine. The isoglutamine polypeptide was found to be essentially inert, any activity, if present, existing below the limits of detection of the assay procedures. Similar results were obtained with the reduced preparations. Based on the amounts of compound tested, the oxytocic activity was estimated to be below 0.01 unit per mg., and the avian vasodepressor activity below 0.05 unit per mg. In view of the high potencies of these biological effects in oxytocin (500 units per mg.) and the great sensitivity of the assay procedures,[19] the virtual absence of these activities in isoglutamine-oxytocin is striking and emphasizes the very high degree of biological specificity associated with those structural aspects of the oxytocic hormone under consideration. thermore, no pressor activity was detected when measured in the rat.[20]

The isoglutamine octapeptide was found to have the expected amino acid composition. Its distribution coefficient was essentially the same as that of oxytocin in the acetic acid–*sec*-butyl alcohol system, but in the ammonia–*sec*-butyl alcohol system the coefficient was somewhat higher than that of oxytocin. The physical constant that was found to differ most strikingly from oxytocin was the optical rotation. The specific rotation in water of the acetate of isoglutamine-oxytocin was approximately 59 degrees higher than that of oxytocin, as given in the Experimental section. No differences were detected in the infrared patterns of isoglutamine-oxytocin and oxytocin. Only small differences were observed when the two polypeptides were subjected to electrophoresis on paper at both *p*H 5.5 and *p*H 9.5.

These comparative data on oxytocin and its isoglutamine isomer demonstrate that small changes in the structure of a polypeptide of this degree of complexity may indeed be reflected in some of the properties. Thus, oxytocin and its isoglutamine isomer can be differentiated readily on the basis of certain differences in physical behavior as well as in biological properties, although a few of the properties of these two polypeptides are indistinguishable.

Experimental[21]

Methyl N-Carbobenzoxy-S-benzyl-L-cysteinyl-L-tyrosyl-L-isoleucinate.—Methyl L-isoleucinate hydrochloride was prepared as described[16] with the following modification.

(20) J. Dekanski, *Brit. J. Pharmacol.*, 7, 681 (1952).

(21) The reported melting points are corrected, capillary melting points.

The base obtained from the crude hydrochloride was not distilled but was converted to the hydrochloride by acidification of an ethereal solution with concd. HCl. The solution was evaporated to dryness, and the residue was recrystallized by dissolving it in ethyl acetate followed by the addition of ether. The hydrochloride melted at 100.5–101°; $[\alpha]^{23}D$ +26.6° (2% in water); reported[22] m.p. 98–100°; $[\alpha]^{21}D$ +26.6° (2% in water).

To a solution of 324 mg. of the hydrochloride in 2 cc. of tetrahydrofuran was added 0.25 cc. of triethylamine. The precipitated solid was removed by filtration, and the filtrate was added to a solution of 625 mg. of N-carbobenzoxy-S-benzyl-L-cysteinyl-L-tyrosine[23] in 3 cc. of tetrahydrofuran. Three hundred and forty mg. of N,N′-dicyclohexylcarbodiimide was then added, and the reaction mixture was allowed to stand at room temperature for 2.5 hours with occasional shaking. Following the addition of several drops of acetic acid, the solid was removed by filtration. The filtrate was concentrated *in vacuo*, and the residue was dissolved in 10 cc. of ethyl acetate. Removal of the solvent left a residue which started to crystallize. Precipitation was completed by the addition of ether and hexane, and the solid product was separated by filtration; wt. 0.7 g., m.p. 145.5–148°. The solid was then crystallized by stirring with warm nitromethane; wt. 0.52 g. (66%), m.p. 151–154°. A second crop of 104 mg., m.p. 146–151°, was obtained from the nitromethane liquor. When the reaction was conducted on 3 times this scale it yielded 1.5 g. melting at 154–156°.

For analysis, the methyl N-carbobenzoxy-S-benzyl-L-cysteinyl-L-tyrosyl-L-isoleucinate was recrystallized twice from nitromethane as clusters of needles, m.p. 159.5–160°; $[\alpha]^{23}D$ −34.8° (*c* 15 mg. in 1 cc. of methanol); reported[16] m.p. 135°; $[\alpha]^{19.5}D$ −32.3° (*c* 2.9, methanol).

Anal. Calcd. for $C_{34}H_{41}O_7N_3S$: C, 64.2; H, 6.50; N, 6.61. Found: C, 64.4; H, 6.59; N, 6.65.

This compound was also prepared by the mixed anhydride procedure.[16] In both methods an excess of methyl L-isoleucinate was used since this procedure yielded products which were easier to purify. The ester melted at 159–159.5° after several recrystallizations from ethyl acetate–hexane and a final crystallization from nitromethane; $[\alpha]^{24}D$ −34.2° (*c* 29 mg. in 1 cc. of methanol); $[\alpha]^{24}D$ −34.7° (*c* 13.6 mg. in 1 cc. of methanol).

N-Carbobenzoxy-S-benzyl-L-cysteinyl-L-tyrosyl-L-isoleucine (V).—The methyl ester (500 mg.), m.p. 156–157°, was hydrolyzed as described[16] with the exception that the reaction time was extended to 3.5 hours. The crude product obtained after acidification of the reaction mixture melted at 162–166°. However, after the product had been extracted from an ethyl acetate solution into 0.1 *N* $NaHCO_3$, acidification of the extract yielded material melting at 179–181°. After 2 recrystallizations from aqueous ethanol, 326 mg. (67%) of felty needles melting at 183–184° was obtained.

For analysis, a sample was further recrystallized, and it melted at 185–186°; $[\alpha]^{23.5}D$ −10.1° (*c* 39 mg. in 1 cc. of acetic acid); $[\alpha]^{23}D$ −31.2° (*c* 9.5 mg. in 1 cc. of acetone); reported m.p. 155°,[16] 161–163°,[24] 164–165°[25]; $[\alpha]^{23}D$ −11° ± 1 (*c* 3.84, acetic acid).[25]

Anal. Calcd. for $C_{33}H_{39}O_7N_3S$: C, 63.8; H, 6.32; N, 6.76. Found: C, 63.7; H, 6.51; N, 6.75.

Carbobenzoxy-L-isoglutaminyl-L-asparagine (II).—Carbobenzoxy-L-isoglutamine was prepared according to Bergmann and Zervas[7] by the addition of carbobenzoxy-L-glutamic acid anhydride[26] to a cooled solution of ammonia in chloroform. It was recrystallized from acetone–petroleum ether followed by ethanol–petroleum ether, after which the melting point was 172.5–173.5°; reported[7] m.p. 175°. A sample treated at room temperature with 1 *N* HBr in acetic acid for 2 hr. to remove the carbobenzoxy group was free of glutamine as determined by electrophoretic analysis on paper in borate buffer at *p*H 9.5.

A solution of 4.0 g. of carbobenzoxy-L-isoglutamine in 32 cc. of anhydrous tetrahydrofuran containing 2.0 cc. of triethylamine was cooled to −5° and 1.83 cc. of isobutylchlorocarbonate was added. The mixture was kept at this temperature for 5 minutes after which a suspension of 2.14 g. of asparagine hydrate in 16 cc. of water containing 2.0 cc. of triethylamine was added in two portions. The temperature of the reaction mixture rose to approximately 10°, and the mixture was allowed to warm spontaneously for ½ hour. It was then maintained at 25–30° for 1.5 hours. The clear solution was then decanted from a small amount of undissolved asparagine and was acidified to *p*H 3 with 1 *N* hydrochloric acid. Addition of 50 cc. of ether soon caused precipitation of the product as a white crystalline solid. The crude product weighed 2.9 g., m.p. 166–170°. It was then washed with warm absolute ethanol, and 2.6 g. of material melting at 178.5–180° remained. The material was recrystallized by dissolving it in a small volume of dimethylformamide followed by the addition of acetonitrile; wt. 2.3 g. (41%), m.p. 186.5–187.5°. A sample recrystallized for analysis melted at 187.5–188°; $[\alpha]^{21}D$ +7.28° (*c* 3.0 mg. in 1 cc. of dimethylformamide).

Anal. Calcd. for $C_{17}H_{22}O_7N_4$: C, 51.8; H, 5.62; N, 14.2; amide N, 7.10. Found: C, 52.0; H, 5.74; N, 14.3, 13.9; amide N, 7.27.

The corresponding glutaminyl compound carbobenzoxy-L-glutaminyl-L-asparagine[27] has been reported to melt at 206°.

Carbobenzoxy-L-isoglutaminyl-L-asparaginyl-S-benzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (IV).—Throughout this experiment anhydrous conditions were maintained. A solution of 239 mg. of S-benzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide[9] in 1 cc. of diethyl phosphite was warmed in an oil-bath at 78°, and 0.2 cc. of tetraethyl pyrophosphite was added. After the mixture had been heated for two minutes, 197 mg. of II was added in several portions followed by 0.5 cc. of diethyl phosphite and an additional 0.1 cc. of tetraethyl pyrophosphite. The mixture was stirred in a bath maintained at 70–72° for 1.5 hours. Sometime after the protected dipeptide had dissolved, precipitation of the product as a gel occurred. After the mixture had been cooled thoroughly, the gel was collected by filtration and washed with a small portion of diethyl phosphite. The material was then washed thoroughly with water followed by dilute sodium bicarbonate solution and water and then dried. The weight of the crude product was 317 mg., m.p. 202–206°. The dried material was freed of colored impurities by washing it twice with small portions of hot absolute methanol, and 228 mg. (54%) melting at 210–213° remained. Addition of water to the diethyl phosphite solution and washings yielded a small further crop of less pure material. Similar results were obtained when the experiment was conducted on six times this scale.

For analysis, a sample was dissolved in hot aqueous methanol and allowed to reprecipitate; m.p. 212–214°.

Anal. Calcd. for $C_{40}H_{55}O_{10}N_9S$: C, 56.3; H, 6.49; N, 14.8. Found: C, 55.9; H, 6.40; N, 14.8.

L-Isoglutaminyl-L-asparaginyl-S-benzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (IVa).—A solution of 200 mg. of the protected hexapeptide amide IV in 50 cc. of liquid ammonia was treated at −40° under anhydrous conditions with sodium until a deep blue color lasting approximately 30 seconds was obtained. A solution of 34 mg. of benzyl chloride in toluene was added, and the mixture was stirred for 1 hour, after which 146 mg. of ammonium chloride was added, and the ammonia was removed *in vacuo*. The water-soluble residue was extracted with ether and the insoluble portion was distributed for 105 transfers in the system 0.01 *M* NH_3–*sec*-butyl alcohol. The distribution of material was followed by determining the absorption in the ultraviolet at 260 mμ and the copper-Folin color[28] at 700 mμ. One main band, with a partition coefficient of 1.3, was obtained which agreed rather well with the theoretical curve. Concentration and lyophilization of the contents of the appropriate tubes yielded 114 mg. (68%).

For analysis, a sample was dried at 100° and 0.1 mm. to constant weight.

Anal. Calcd. for $C_{32}H_{49}O_8N_9S$: N, 17.5; amide N, 5.84. Found: N, 17.2; amide N, 5.60.

A small second band (K = 0.11) that was copper-Folin-positive and UV-negative was also obtained, and this presumably contained unbenzylated peptide.

When the reaction was carried out on a 2.0-g. scale using a 2 mole excess of benzyl chloride, the distribution yielded a single band with a total yield of 1.6 g. A portion of a large center fraction of this material, representing an 81% yield of IVa, was redistributed in 0.5% acetic acid–*sec*-butyl alcohol for 177 transfers. The material was recovered as the acetate almost quantitatively from a band (K = 0.34) which essentially coincided with the theoretical curve.

Carbobenzoxy-S-benzyl-L-cysteinyl-L-tyrosyl-L-isoleucyl-L-isoglutaminyl-L-asparaginyl-S-benzyl-L-cysteinyl-L-prolyl-L-leucylglycinamide (VI).—To a solution of 240 mg. of N-carbobenzoxy-S-benzyl-L-cysteinyl-L-tyrosyl-L-isoleucine and 250 mg. of IVa in 1.5 cc. of 75% tetrahydrofuran at +5° was added 90 mg. of N,N′-dicyclohexylcarbodiimide. The mixture was stored in the refrigerator for 19 hours. The solvent was then evaporated, and the residue was extracted with hot dimethylformamide. After the extracts had been cooled and filtered, the filtrate was evaporated under reduced pressure to a small volume and the product was precipitated with ether. The white solid was collected by filtration; wt. 400 mg., m.p. 229–231°. When washed three times with small volumes of warm methanol and dried, 296 mg. (64%) melting at 234.5–236.5° remained.

For analysis, the compound was dissolved in several drops of cold formic acid and was reprecipitated with cold water, m.p. 234.5–236.5°. The sample was dried at room temperature for 2 days at 0.2 mm. over P_2O_5, $[\alpha]^{21.7}D$ −44.1° (*c* 9.99 mg. in 1 cc. of dimethylformamide).

Anal. Calcd. for $C_{65}H_{86}O_{14}N_{12}S_2 \cdot H_2O$: C, 58.2; H, 6.62; N, 12.5; H_2O, 1.36. Found: C, 58.0; H, 6.58; N, 12.4; H_2O, 1.80.

Reduction of Protected Nonapeptide Amide (VI) and Oxidation of the Product.—Two batches VI of 200 mg. each were reduced with sodium in liquid ammonia and treated as described for the preparation of oxytocin from its corresponding nonapeptide derivative[3] with the following modifications. The dried reduced material was aerated in solution at a concentration of 0.4 mg. per cc. at *p*H 6.9 for approximately 3 hours. After standing in the ice-box overnight, the combined solutions were adjusted to *p*H 3.5 and were concentrated and lyophilized to a white powder.

Isolation of the Product.—The material was divided in the first 5 tubes of the all-glass automatic countercurrent apparatus[29] and was distributed in the system *sec*-butyl alcohol–0.05% acetic acid for 592 transfers. Determinations of weight, absorption in the ultraviolet, and copper-Folin color[28] all defined a single band traveling with a K of 0.37, which was irregularly shaped due probably to the emulsions which occurred in this area during the distribution. The material was then redistributed for 197 transfers in *sec*-butyl alcohol–0.01 M NH_3 in which the K was approximately 1.8. Spectrophotometric analysis at 275 mμ and at 700 mμ for the copper-Folin color, and comparison of the resulting curves with the theoretical curve indicated that the material had a purity estimated as over 90%. The contents of the peak were removed in fractions, and these were concentrated to a small volume. The solutions were acidified with acetic acid and finally were dried by lyophilization yielding a total of 152 mg. (50%) of a white fluffy powder; $[\alpha]^{21.5}D$ +33.0° (*c* 0.55, water), $[\alpha]^{24}D$ +24.2° (*c* 0.54, 1 N acetic acid). In comparison, oxytocin acetate possessed the negative rotations $[\alpha]^{22}D$ −26.2° (*c* 0.53, water)[3] and $[\alpha]^{22.5}D$ −23.1° (*c* 0.51, 1 N acetic acid).

A sample was hydrolyzed in 6 N HCl at 120° for 14 hours and was analyzed on the starch column by the method of Moore and Stein.[30] The following ratios were obtained: leucine, 1.0; isoleucine, 1.0; tyrosine, 0.9; proline, 0.9; glutamic acid, 1.0; aspartic acid, 1.1; glycine, 1.0; ammonia, 3.1; and cystine, 0.8.

Determination of the molecular weight of the isoglutamine polypeptide by the thermoelectric osmometer method[31] indicated a value of 852. This result corresponds with what would be expected of the cyclic octapeptide represented by Structure I, which has a calculated molecular weight of 1007.

Isoglutamine-oxytocin and oxytocin were applied separately to a doubled strip of Whatman No. 1 filter paper and subjected to electrophoretic analysis using 300 v. at 5°. Acetate buffer at *p*H 5.5 was used in one experiment which was run for 11 hours, and glycine buffer at *p*H 9.5 for 8 hours was used in another. The materials were stained with the brom phenol blue–mercuric chloride reagent.[32] The isoglutamine polypeptide traveled slightly faster than oxytocin in both buffers. However, when a mixture of the two peptides was run at *p*H 5.5 for 19 hours, separation was incomplete. A similar, small difference in mobility on paper was obtained when isoglutamine-oxytocin and oxytocin were subjected to chromatography on Whatman No. 1 filter paper for 16 hours in *n*-butyl alcohol–acetic acid–water (5:1:5).

Acknowledgments.—The authors wish to thank Mr. Joseph Albert for carrying out the microanalyses reported herein, Mr. Robert L. Tostevin and Mrs. Sylvia Kirsimagi White for the bioassays, and Mrs. Lorraine S. Abrash for her assistance. Appreciation is expressed to Dr. Julian R. Rachele for the critical molecular weight determination and to Mr. David A. De Peter and Dr. Rachele for the infrared analyses.

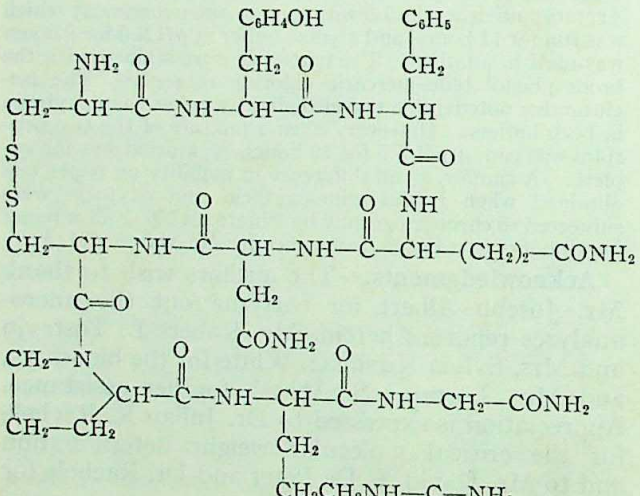
Synthetic Studies on Arginine-vasopressin: Condensation of S-Benzyl-N-carbobenzoxy-L-cysteinyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine and its O-Tosyl Derivative with S-Benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide[1]

BY PANAYOTIS G. KATSOYANNIS, DUANE T. GISH[2] AND VINCENT DU VIGNEAUD

RECEIVED MARCH 27, 1957

Two synthetic routes to arginine-vasopressin were investigated. The first approach involved the coupling of S-benzyl-N-carbobenzoxy-L-cysteinyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine with S-benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide monohydrobromide. Treatment of the product with sodium in liquid ammonia and subsequent oxidation of the sulfhydryl nonapeptide gave a biologically active product. Partial purification resulted in a product with a specific activity of 175 pressor units/mg. The synthetic product possessed biological properties associated with natural arginine-vasopressin and also many physical and chemical properties of the natural hormone. The second approach involved the coupling of S-benzyl-N-carbobenzoxy-L-cysteinyl-O-tosyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine with S-benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide monohydrobromide, routes to these intermediates differing from those used for the first approach. The resultant active product, after partial purification, assayed 220 pressor units/mg.

The isolation[3,4] in highly purified form of arginine-vasopressin, the pressor and antidiuretic hormone of the posterior pituitary gland of beef, followed by degradation studies[5-7] led to the postulation of structure I.[7,8] Synthetic studies were then undertaken. The ultimate objective of these synthetic studies was the preparation of a compound with the sequence L-cysteinyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparaginyl-L-cysteinyl-L-prolyl-L-arginylglycinamide, the sulfhydryl and free amino groups of which were covered by protective groups which could be removed by treatment with sodium in liquid ammonia. It was expected that subsequent oxidation of this compound by aeration in aqueous solution would lead to a product of structure I. This is analogous to the work on synthetic oxytocin.[9]



I

The first approach undertaken in this endeavor[10] was the coupling of the pentapeptide, S-benzyl-N-carbobenzoxy-L-cysteinyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine,[11] with the monohydrobromide of S-benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide,[12] by the tetraethyl pyrophosphite procedure.[13] The resultant crude product was isolated and treated with sodium in liquid ammonia. A dilute acetic acid solution of the reduction product was adjusted to *p*H 6.7 and aerated. Concentration on the flash evaporator[14] and lyophilization of the solutions from several runs gave material which on assay[15] showed a total of 58,000 units of pressor activity. After countercurrent distribution of this material in the solvent system 2-butanol–0.06 *M* *p*-toluenesulfonic acid, 520 mg. of a product with pressor activity of about 80 units/mg. was obtained. This material was purified further by electrophoresis at *p*H 4.0 in a pyridine–acetate buffer with a cellulose block[16] as the supporting medium. From the peak segments a solution was obtained which, after concentration and lyophilization, yielded a powder weighing 70 mg. which had a specific activity of about 175 pressor units/mg.

The distribution constant of this active material in 2-butanol–0.06 *M* *p*-toluenesulfonic acid (K = 0.84) was the same, within the limits of experimental duplication, as that for a highly purified sample of natural arginine-vasopressin[17] (K = 0.87). When equal quantities of the synthetic and natural products were mixed and chromatographed on an Amberlite IRC-50 (XE-64) ion-exchange column, a single peak was obtained. A com-

parison of the behavior of the natural and synthetic preparations on a partition column of Hyflo Super-Cel also showed that the synthetic pressor activity occupied the same position in the chromatogram as did the natural hormone.[18] When the synthetic and natural products were spotted separately on a single strip of paper and subjected to electrophoresis at *p*H 4.0 in a pyridine–acetate buffer the two spots were indistinguishable with relation to mobility, size and shape and both spots consisted of material of uniform mobility under these conditions.

In addition to the assays against the United States Pharmacopeia Standard Posterior Pituitary Powder for pressor activity, the product was assayed for antidiuretic and avian vasodepressor activities. The ratios between pressor, antidiuretic[19] and avian vasodepressor[20] activities were the same as those found for natural arginine-vasopressin (1:1:0.15).

It was obvious, however, due to the low specific activity, that our synthetic preparation was not homogeneous. It was also apparent, assuming that the active material represented arginine-vasopressin, that the chemical structure of the contaminant differed from that of the natural hormone in such a subtle way that its behavior in countercurrent distribution, ion-exchange and partition chromatography and electrophoresis, under the experimental conditions used, was identical to that of the active material. An amino acid analysis of a hydrolysate by starch column chromatography[21] showed the presence of the expected amino acids in approximately the calculated ratio. However, it was noted that the cystine peak had a larger spread than usually found and in one chromatogram it appeared that a second peak had actually started to separate from the cystine peak. This indicated the possible presence of another amino acid, such as a dibasic amino acid, which might appear at this point on the chromatogram. The identity of this ninhydrin-positive material was not established.

Several possibilities of the cause of the difficulty were considered. Among those initially considered were the possibilities of racemization, instability of one of the intermediates, structural changes during treatment with sodium in liquid ammonia of the protected nonapeptide and subsequent oxidation of the reduction product, and inactivation of the active material once it had been formed. The latter is known to take place in the case of the natural hormone[22] and a steady loss in total activity is incurred during handling of this unstable hormone. Any of the possibilities outlined above could lead to slight structural changes which, while altering only slightly the physical and chemical properties of the desired material, might lead to complete loss of biological activity. Rendering the problem yet more difficult was the sparing solubility in almost all solvents of the crude protected nonapeptide and the tendency of this mixture to form a gel in aqueous solvents. This fact caused the failure of attempts to purify this crude product before conversion of the nonapeptide to the active hormone.

Although at this time the root of the difficulty had not yet become apparent, a second approach to the synthesis of arginine-vasopressin was undertaken which we hoped might render the intermediates more stable and alter their solubility. O-Tosyl-N-carbobenzoxy-L-tyrosine was coupled by the mixed anhydride procedure,[23] with isobutyl chlorocarbonate in tetrahydrofuran solution, to L-phenylalanyl-L-glutaminyl-L-asparagine[24] in aqueous solution containing an equivalent of triethylamine. Conversion of the O-tosyl-N-carbobenzoxy-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine to O-tosyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine by treatment with HBr in acetic acid[25] and coupling of this tetrapeptide with S-benzyl-N-carbobenzoxy-L-cysteine by the mixed anhydride procedure, as described for the preparation of the tetrapeptide, gave S-benzyl-N-carbobenzoxy-L-cysteinyl-O-tosyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine.

S-Benzyl-N-carbobenzoxy-L-cysteinyl-L-prolyl-L-arginylglycinamide hydrobromide was prepared by a procedure analogous to that used for the preparation of the *p*-nitrobenzyloxycarbonyl derivative.[12] Treatment with sodium in liquid ammonia, rebenzylation and purification of the product by countercurrent distribution gave S-benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide dihydrohalide.[26] The tetrapeptide was then converted to the monohydrohalide and coupled with S-benzyl-N-carbobenzoxy-L-cysteinyl-O-tosyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine by the tetraethyl pyrophosphite method. The unreacted tetrapeptide was removed from the crude product by trituration with water. Treatment of the resulting product with sodium in liquid ammonia, followed by aeration in aqueous solution, gave 57,000 units of pressor activity. The solvent was removed by concentration and lyophilization and most of the inorganic salts were removed by an extraction procedure. The crude peptide material, which assayed 41,000 units, was distributed in the system 2-butanol–0.1% acetic acid. The material recovered from the active peak weighed 400 mg. and assayed 70 units/mg. Electrophoresis of 195 mg. of this material on a cellulose block at *p*H 4.0 in a pyridine–acetate buffer gave, as the most active fraction, 63 mg. of material which assayed 150 units/mg. This active material was then redistributed in the system 2-butanol–0.1% acetic acid. The most active fraction recovered was 23 mg. of a product which had a specific pressor activity of 220 units/mg.

It seemed to us that the activity obtained repre-

sents unquestionably arginine-vasopressin because of all the biological and physical properties encountered with it. In view of the data on the authenticity of the protected pentapeptides and the tetrapeptide, it appeared that something had occurred during the condensation between the protected pentapeptides and the tetrapeptide yielding a by-product or by-products which we were unable to separate from arginine-vasopressin by the techniques available. Therefore, reactions leading to the formation of the peptide bond through the carboxyl group of asparagine have been subjected to closer scrutiny. As reported recently, evidence has now been derived that in the formation of asparaginyl peptides a mixture of products is obtained.[27] Means of avoiding the formation of by-products have been investigated and these results will be reported subsequently.

Experimental[28]

Coupling of S-Benzyl-N-carbobenzoxy-L-cysteinyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine with S-Benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide Monohydrobromide and Conversion of the Product to Active Material.—S-Benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide dihydrobromide[12] was dissolved in about 4 parts of dimethylformamide and about a 10% excess of triethylamine was added with stirring. Chloroform was then added, dropwise at first, to redissolve the precipitate of triethylamine hydrobromide and to precipitate the tetrapeptide monohydrobromide as a semi-solid. The monohydrobromide was collected by filtration, washed with chloroform and then redissolved in dimethylformamide. Two or three drops of triethylamine was added and the material was again precipitated with chloroform, washed, and dried *in vacuo* over P_2O_5 and NaOH. The yield of the monohydrobromide was nearly quantitative.

In a typical experiment, S-benzyl-N-carbobenzoxy-L-cysteinyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine[11] (114 mg., 0.16 millimole), S-benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide monohydrobromide (75 mg., 0.13 millimole), tetraethyl pyrophosphite[13] (0.09 g., 0.35 millimole) and diethyl phosphite (0.45 ml.) were heated at about 95° for 50 minutes. Ether was added to the cooled reaction mixture to precipitate the crude product which was collected by filtration, washed with ether and dried over P_2O_5 *in vacuo*. The crude product was treated with sodium in liquid ammonia.[9] The residue, after evaporation of the ammonia, was dissolved in 200 ml. of 0.1% acetic acid, the *p*H was adjusted to 6.7 with NH_4OH and the solution was aerated with a slow stream of air for one hour. Solutions from a number of runs were combined and a total activity of 66,000 pressor units[29] was obtained. The solution was concentrated in the rotary evaporator[14] (bath temperature 25°) and lyophilized to give about 4 g. of a mixture of peptide material and inorganic salt which assayed 58,000 units of pressor activity. This material was subjected to countercurrent distribution in the solvent system 2-butanol–0.06 *M* *p*-toluenesulfonic acid. The material was placed in the first 5 tubes of the all-glass countercurrent distribution machine.[30] The distribution was followed by developing the Folin color[31] and the Sakaguchi color,[32] and by pressor assays, on aliquots of selected tubes. After 690 transfers the solvent from the tubes containing the active peak was pooled and the two phases separated. The organic phase was extracted several times with water and the aqueous extract was combined with the aqueous phase. This solution was passed through a column of Amberlite IR-45 in the acetate form to remove the *p*-toluenesulfonic acid. The solution, which assayed 45,000 pressor units, was concentrated on the rotary evaporator and lyophilized to yield a powder, wt. 520 mg.

Electrophoresis on a Cellulose-supported Medium.—Essentially the procedure described by Kunkel[16] was followed. The supporting medium was a cellulose product, Solka-Floc, of Brown Co. of New York. The buffer used was a pyridine–acetic acid buffer of *p*H 4.0 prepared by diluting 24 ml. of pyridine and 91 ml. of acetic acid to 4 liters with distilled water. The above partially purified material (490 mg.) was dissolved in 3 ml. of the buffer and placed on the block along with two 0.25-ml. washes. The electrophoresis was carried out for 40 hours at 5° with a potential gradient of 9 volts/cm. The Folin color was developed on aliquots of the solutions from the various segments and pressor assays were obtained. The solutions from the three segments which exhibited the highest activity was lyophilized to give about 70 mg. of a powder which assayed 175 units/mg. of pressor activity. When a sample of this material was dissolved and the solution assayed for pressor, antidiuretic[19] and avian vasodepressor[20] activities, the ratio found was 1:1:0.15, the ratio found for natural arginine-vasopressin.[4]

Ion-exchange Chromatography.—The procedure described by Taylor,[33] which employed the resin Amberlite IRC-50 (XE-64) and a 0.2 *M* sodium phosphate buffer of *p*H 6.95, was followed. The preparation of the resin and operation of the column was carried out according to the procedures of Hirs, Moore and Stein[34] and Tallan and Stein.[35] One mg. each of the synthetic product and natural arginine-vasopressin[17] were mixed and chromatographed. A single peak was obtained and there was no evidence of any separation whatever.

Paper Electrophoresis.—The buffer used was the *p*H 4.0 pyridine–acetic acid buffer already described. Solutions of the synthetic product and of natural arginine-vasopressin[17] (0.1 ml. of a solution containing about 0.85 mg./ml.) were spotted, side by side, on Whatman No. 1 paper previously wet with the buffer, and the electrophoresis was carried out, with glass plates as described by Kunkel and Tiselius,[36] for 18 hours with a potential gradient of 9 volts/cm. and at a temperature of 5°. The material was stained on the paper with brom phenol blue as described by Durrum.[37] The spots were identical in appearance, each containing material of uniform mobility in this buffer, and the mobility of the synthetic product was the same as that of natural arginine-vasopressin.

Amino Acid Analysis.—Amino acid analysis by the starch column chromatographic method of Moore and Stein[21] of the synthetic material after hydrolysis showed the following molar ratios: phenylalanine, 1.2; tyrosine, 1.2; proline, 0.8; glutamic acid, 1.3; aspartic acid, 0.85; glycine, 1.0; ammonia, 3.7; arginine, 1.1; cystine, 0.85; unknown, 0.5.[38] The value for ammonia was somewhat high but is uncorrected for the liberation of ammonia due to the destruction of amino acids. In the example cited, sufficient separation of the unidentified peak, which emerged just following cystine, was obtained to permit its approximate quantification. In other chromatograms only partial separation of these two peaks was obtained.

O-Tosyl-L-tyrosine.[39]—To a solution of 18 g. (0.1 mole) of L-tyrosine in 200 ml. (0.2 mole) of *N* NaOH was added a solution of 12.5 g. (0.05 mole) of $CuSO_4 \cdot 5H_2O$ in 50 ml. of water. The mixture was stirred until solution was complete and then was added a solution of 19 g. (0.1 mole) of *p*-toluenesulfonyl chloride in 40 ml. of ether. The reaction mixture was shaken for 3.5 hours and the precipitated copper complex was isolated by filtration, washed with water and finally dissolved in 200 ml. of concd. HCl. After several

hours cooling the precipitated crystalline hydrochloride of the product was collected by filtration, dissolved in 1 l. of water and the *p*H of the solution was adjusted to 6 with NH_4OH. After cooling, the precipitated crystalline product was filtered, washed with water and dried, wt. 15 g. Recrystallization from 1.5 l. of boiling water gave 12.5 g. (37%) m.p. 215–217°, $[\alpha]^{22}D$ +9.0° (*c* 3.0, *N* HCl); reported in literature[40] m.p. 213–214° uncor. and $[\alpha]^{20}D$ +9.5° (*c* 3.16, *N* HCl).

O-Tosyl-N-carbobenzoxy-L-tyrosine.—A mixture of 3.35 g. (0.01 mole) of O-tosyl-L-tyrosine, 10 ml. of *N* NaOH, 15 ml. of *N* Na_2CO_3 and 80 ml. of *N* $NaHCO_3$ (*p*H 9) was warmed for a few minutes and then cooled to 0°. To this suspension 2 g. (0.016 mole) of carbobenzoxy chloride was added in portions over a period of one hour with vigorous stirring and cooling. After the final addition the reaction mixture was stirred for a further 30 minutes, acidified with HCl and stirred for 15 minutes. The precipitated product was isolated by filtration, washed with water and dried. For purification it was dissolved in ethyl acetate and precipitated with hexane; wt. 3.8 g. (83%), m.p. 124–126°, $[\alpha]^{25}D$ −27° (*c* 1, dimethylformamide).

Anal. Calcd. for $C_{24}H_{23}O_7NS$: C, 61.4; H, 4.93; N, 2.98. Found: C, 61.3; H, 4.97; N, 3.05.

O-Tosyl-L-tyrosine from HBr–Acetic Acid Cleavage of N-Carbobenzoxy-O-tosyl-L-tyrosine.—Tosyl-N-carbobenzoxy-L-tyrosine (0.7 g., 0.0015 mole) was suspended in 15 ml. of acetic acid saturated with HBr and the mixture was allowed to stand at 25° for one hour with occasional stirring. The solution was concentrated *in vacuo* to dryness, the residue was mixed with 50 ml. of water and the *p*H of the mixture was adjusted to 6.0 with NH_4OH. The precipitated crystalline O-tosyl-L-tyrosine was filtered off, washed with water and dried; wt. 0.45 g. (90%), m.p. 214–216°.

O-Tosyl-N-carbobenzoxy-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine.—A solution of 1.88 g. (0.004 mole) of O-tosyl-N-carbobenzoxy-L-tyrosine and 0.4 g. (0.004 mole) of triethylamine in 12 ml. of tetrahydrofuran was cooled to −10° and 0.55 g. (0.004 mole) of isobutyl chlorocarbonate was added with stirring. After 10 minutes at −10° a cooled solution of 1.7 g. (5% excess) of L-phenylalanyl-L-glutaminyl-L-asparagine[24] and 0.43 g. of triethylamine in 9 ml. of water was added. The mixture was then allowed to come to room temperature over a period of 25 minutes and the triethylamine salt of the tetrapeptide was precipitated with ether. The product was then collected by filtration, washed with ether, suspended in 100 ml. of water and acidified with HCl. The tetrapeptide thus obtained was separated by filtration, washed with water, dried and triturated with ethyl acetate; wt. 2.7 g. (78.7%), m.p. 214–216°. A sample for analysis was precipitated from 50% acetic acid; m.p. 218–220°, $[\alpha]^{25}D$ −16.6° (*c* 1, dimethylformamide).

Anal. Calcd. for $C_{42}H_{46}O_{12}N_6S$: N, 9.78; S, 3.73. Found: N, 9.62; S, 3.62.

S-Benzyl-N-carbobenzoxy-L-cysteinyl-O-tosyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine.—O-Tosyl-N-carbobenzoxy-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine (2.55 g.) was suspended in 50 ml. of 2 *N* HBr in acetic acid and the mixture was allowed to stand at 25° for one hour. The hydrobromide of the O-tosyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine was precipitated from the reaction mixture with ether, collected by filtration, washed with ether and reprecipitated twice from methanol–ether; wt. 1.92 g. (82%). The product (2.4 millimoles) was dissolved in 5 ml. of water plus 4.8 ml. (4.8 millimoles) of *N* NaOH and the mixture was cooled and added to the anhydride of S-benzyl-N-carbobenzoxy-L-cysteine and isobutylcarbonic acid, prepared according to the procedure described in the preceding section from 7.6 g. (2.34 millimoles) of S-benzyl-N-carbobenzoxy-L-cysteine[41] in 12 ml. of tetrahydrofuran, 0.24 g. (2.34 millimoles) of triethylamine and 0.32 g. (2.34 millimoles) of isobutyl chlorocarbonate. The sodium salt of the pentapeptide was precipitated from the reaction mixture with ether, separated by filtration, suspended in 200 ml. of water and acidified with HCl. The precipitated S-benzyl-N-carbobenzoxy-L-cysteinyl-O-tosyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine was filtered off, washed with water, dried and triturated with ethyl acetate; wt. 1.92 g. (83%), m.p. 214–216°. For analysis a sample was precipitated from 70% acetic acid; m.p. 217–219°, $[\alpha]^{25}D$ −33.5° (*c* 1, dimethylformamide).

Anal. Calcd. for $C_{52}H_{57}O_{13}N_7S_2$: C, 59.3; H, 5.46; N, 9.31. Found: C, 59.2; H, 5.56; N, 9.16.

S-Benzyl-N-carbobenzoxy-L-cysteinyl-L-prolyl-L-arginylglycinamide Hydrobromide.—S-Benzyl-N-carbobenzoxy-L-cysteinyl-L-proline was prepared through the methyl ester as described for the *p*-nitrobenzyloxycarbonyl derivative.[12] The yields of the methyl ester and of the saponification product, neither of which could be crystallized, were 70 and 85%, respectively. The protected dipeptide (2.92 g., 0.0066 mole), L-arginylglycinamide monohydrobromide[12] (1.86 g., 0.003 mole), tetraethyl pyrophosphite (3.10 g., 0.006 mole) and diethyl phosphite (10 ml.) were heated at 100° for 30 minutes. The reaction mixture was cooled and the product, along with unreacted L-arginylglycinamide, was precipitated with ethyl acetate. The material was collected by filtration, washed with ethyl acetate and dried over P_2O_5 and NaOH. This crude product was purified by countercurrent distribution in the solvent system 2 butanol–1% acetic acid; 120 transfers were sufficient to separate the tetrapeptide (K = 1.2) from the dipeptide (K = 0.23). The Sakaguchi color reaction was used for the preparation of the distribution curve. The solvent from the tubes containing the tetrapeptide was concentrated and lyophilized to give 3.0 g. (68%) of an hygroscopic amorphous powder.

S-Benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide Dihydrohalide.[26]—S-Benzyl-N-carbobenzoxy-L-cysteinyl-L-prolyl-L-arginylglycinamide hydrobromide (2.87 g., 0.0039 mole) was treated with sodium (0.47 g.) in liquid ammonia (300 ml.). The sodium was added in small pieces until a permanent blue color persisted. Ammonium chloride was then added in an amount just sufficient to discharge the blue color, and benzyl chloride (0.5 ml., 10% excess) was added and the mixture was stirred for 30 minutes. Ammonium chloride (1.09 g.) was then added and the ammonia was allowed to evaporate and the last traces then removed *in vacuo*. The residue was extracted with 30 ml. of glacial acetic acid in 3 portions, the solution filtered, and the product was precipitated by addition of 400 ml. of ether. This material was reprecipitated from 70 ml. of acetic acid with ether. The amorphous peptide material was collected, washed with ether and dried *in vacuo* over P_2O_5 and NaOH. This material was purified by countercurrent distribution in the solvent system 2-butanol–0.1% acetic acid, 520 transfers being sufficient for the separation of the tetrapeptide (K = 0.18)[42] from a small peak which possessed a very low distribution constant. The Folin color reaction was used for preparation of the distribution curve. Concentration and lyophilization of the solvent from the tubes containing the tetrapeptide gave 1.9 g. (82%) of an amorphous hygroscopic powder. An analysis of this material indicated that it was a mixture of the hydrochloride and hydrobromide salt, that is, part of the acid bound was HBr and part was HCl. This fact rendered it difficult to interpret the analytical results, but the behavior of this tetrapeptide in countercurrent distribution indicated it to consist of a single component.

Preparation and Isolation of Active Material.—The coupling of the pentapeptide S-benzyl-N-carbobenzoxy-L-cysteinyl-O-tosyl-L-tyrosyl-L-phenylalanyl-L-glutaminyl-L-asparagine with the tetrapeptide S-benzyl-L-cysteinyl-L-prolyl-L-arginylglycinamide monohydrohalide by the tetraethyl pyrophosphite method was carried out as described above for the coupling without the presence of the O-tosyl group. In a typical experiment 1.05 g. (1 millimole) of pentapeptide, 0.56 g. (0.93 millimole) of tetrapeptide monohydrohalide, 4 ml. of diethyl phosphite and 0.56 g. (2.2 millimoles) of tetraethyl pyrophosphite was used. The reaction product was precipitated with water, filtered off and again triturated with water to remove the unreacted tetrapeptide, and dried. The treatment with sodium in liquid ammonia of this material and subsequent oxidation, in the manner described above, gave a solution which possessed an activity of 22,000 pressor units when assayed in the rat.[15] Solution from a number of runs with a total activity of 57,000 pressor units were combined, concentrated on the rotary evaporator and lyophilized to give about 6 g. of a mixture of peptide material and inorganic salt. This mixture was extracted with 50 ml. of glacial acetic acid, the

solution was filtered and the peptide material was precipitated with 200 ml. of absolute, peroxide-free ether and collected immediately by filtration before crystallization of sodium acetate hydrate occurred. The peptide material thus obtained weighed 1.95 g. and had a specific activity of 21 pressor units/mg. For purification this material was placed in the first 8 tubes of the all-glass automatic countercurrent distribution apparatus and distributed in the system 2-butanol–0.1% acetic acid for 1100 transfers. The activity was concentrated in a single peak. The solvent from the tubes containing the active peak was pooled and the solution, which assayed 28,000 pressor units, was concentrated and lyophilized to give 400 mg. of a product which had a specific activity of about 70 units/mg. A portion of this material (195 mg.) was subjected to electrophoresis on a cellulose block at *p*H 4.0 in a pyridine–acetate buffer and yielded, as the most active fraction, 63 mg. of material which assayed 150 units/mg. This material was redistributed in the system 2-butanol–0.1% acetic acid for 2000 transfers to give as the most active fraction 23 mg. of a product which possessed a specific activity of 220 units/mg.

Bottromycin. I. A New Sulfur-containing Antibiotic

BY J. M. WAISVISZ, M. G. VAN DER HOEVEN, J. VAN PEPPEN AND W. C. M. ZWENNIS

RECEIVED DECEMBER 21, 1956

A new antibiotic bottromycin[1] has been isolated from fermentation broth by solvent extraction and purified either by chromatography on Florisil or by means of its salts with organic acids. On the basis of analysis of bottromycin and its crystalline derivatives, the antibiotic has been assigned an empirical formula $C_{38}H_{57-61}N_7O_{7-8}S$.

The antibiotic activity present in the fermentation broths of a soil actinomycete *Streptomyces bottropensis*[2] was found to be extractable at neutral or alkaline *p*H by a variety of organic solvents, such as diethyl ether, ethyl acetate and butyl acetate and at acid *p*H by chloroform.

Paper chromatographic methods gave evidence that two antibiotic substances were present in the culture broth, one of which was present in only minor quantities. This one was discarded during the isolation of bottromycin.

The main antibiotic was extracted from the filtered culture broth with butyl acetate. The extracts were concentrated to a small volume by distillation of the azeotropic mixture and thereafter re-extracted with phosphate buffer at *p*H 2. When the aqueous layer was adjusted to *p*H 9 with dilute sodium hydroxide, the crude bottromycin precipitated as an amorphous white product. This crude antibiotic produced a red color with concentrated mineral acids. The crude product was purified by chromatography on Florisil or by precipitation from its solutions in ether or butyl acetate with organic acids, such as salicylic, acetylsalicylic, *p*-aminosalicylic, 3,5-dinitrosalicylic, 3,5-dibromosalicylic, 3,5-dibromo-4-aminosalicylic, benzoic, *p*-aminobenzoic, 3,5-dinitrobenzoic, acetic, phenylacetic, picric, anthranilic acids and benzylpenicillin. Several of the amorphous salts thus obtained could be crystallized from ethyl acetate.

The water-soluble phosphate as well as the relatively insoluble sulfate and hydrochloride also have been prepared. The free bottromycin base could be obtained from its salts by suspending these salts in water–diethyl ether, adjusting the *p*H with dilute sodium hydroxide to 9 followed by repeated extraction of the alkaline water layer with ether. Evaporation of the dried ether extracts yielded the antibiotic as a glittering white amorphous powder. The purified product, thus obtained, no longer produces a red color with concentrated mineral acids.

As to whether bottromycin is a chemically pure entity the following comments may be made. When highly purified bottromycin preparations derived from different production batches were compared, identical elementary analyses were always obtained. Also, the biological activities per mg. bottromycin, determined microbiologically, were identical and the value obtained could not be increased by further purification.

On the other hand some of these seemingly pure products gave a definite red coloration when treated with concentrated sulfuric acid whereas others did not. Such batches, after further purification, usually yielded products which no longer gave a positive test.

The molecular weight determined by the isothermic distillation method[3] was found to be about 743 ± 36. On the basis of analyses of bottromycin as well as of its crystalline salts, the antibiotic has been assigned the empirical formula $C_{38}H_{57-61}N_7O_{7-8}S$. The antibiotic is a very weak base (pK'_a = *ca.* 6.5); it is readily soluble in most organic solvents but is virtually insoluble in hexane, cyclohexane and petroleum ether. In ice-water it is more soluble (2.3 mg./ml.) than in water of about 30° (1.3 mg./ml.). The compound is optically active, $[\alpha]^{25}D$ −14.2° (*c* 0.5, in 96% ethanol).

Bottromycin is not adsorbed on alumina or cellulose but is completely adsorbed on activated carbon from which it can be recovered in part (*ca.* 65%) by elution with acetone containing 3% concentrated hydrochloric acid. "Magnesol" also adsorbs the antibiotic. In this case it can be eluted with benzene containing 5% of methyl alcohol.

Amorphous bottromycin or its crystalline salts are fully stable when stored for several months in the refrigerator. Aqueous solutions of the new antibiotic at *p*H 7 show no loss in microbiological activity after 8 days at 0°. However, a solution at *p*H 2 loses 50% of its activity when exposed for 1.5 hours at 100°. Alkaline solutions of *p*H 9 are completely inactivated when kept for the same

(1) Bottromycin is the generic name given to an antibiotic isolated from a culture of *Streptomyces bottropensis* n.sp.

(2) Dutch patent no. 79,749 (16-10-1955); Belgian patent no. 537,

Digitized by Arya Samaj Foundation Chennai and eGangotri

period of time at 100°. When dissolved in organic solvents bottromycin is relatively stable even at elevated temperatures.

The ultraviolet absorption spectrum of the free base in 96% ethanol solution shows a strong absorption peak at 203 mμ and a weak shoulder at 240 mμ.

The infrared spectrum (KBr) shows bands at: 3.01 μ (3322 cm.$^{-1}$), 3.23 (3086), 3.31 (3021), 5.73 (1745), 5.90 (1695), 6.05 (1653), 6.48 (1543), 6.68 (1497), 7.32 (1366), 7.65 (1307), 7.94 (1295), 8.53 (1172), 8.74 (1144), 8.93 (1120), 9.23 (1083), 9.45 (1058), 10.01 (999), 10.28 (973), 11.07 (903), 11.75 (851) and 13.17 μ (760 cm.$^{-1}$).

Further studies on the degradation and structure of bottromycin will be reported in two other papers.[4,5]

Experimental

Isolation of Crude Bottromycin.—The filtrate from 3000 l. of bottromycin fermentation broth (9000 γ/l.) was extracted in a Podbielniak extractor with 4,100 l. of butyl acetate. After azeotropic concentration of this extract to 16 l. (1.35 g./l.), the concentrate was washed three times with 5 l. of 5% sodium bicarbonate solution and two times with 5 l. of distilled water. The antibiotic was then re-extracted from the butyl acetate with 5 l. of phosphate buffer of *p*H 2. The aqueous extract was then washed with ether to remove dissolved butyl acetate. After evaporation of dissolved ether the crude bottromycin could be precipitated from the aqueous extract by adjusting the *p*H to 9, with 4 *N* sodium hydroxide. The amorphous white product was filtered and dried *in vacuo* (17.4 g.); yield 64.5%. Microbiological assays were carried out by a plate assay method using *B. subtilis* (A.T.C.C. 6633) as test organism.

Purification of Bottromycin. (a) By Florisil Chromatography.—Commercial Florisil was purified by suspending in 4 *N* hydrochloric acid. After 24 hours the adsorbent was filtered and washed with distilled water until free of acid and then air dried. A solution of crude bottromycin (144 g.) in chloroform (800 ml.) was added to a column previously packed with purified Florisil (1500 g.) in chloroform (column-size: 950/63 mm.). The column was developed by gravity with chloroform containing 7.5% of ethyl alcohol. Fractions of 1.5 l. (1), 1.8 l. (2), 200 ml. (3), 100 ml. (4), 100 ml. (5), 1 l. (6), 60 ml. (7), 660 ml. (8), and finally 3 l. (9) were collected. To each fraction was added an equal volume of 0.1 *N* sulfuric acid after which the organic solvent was removed by evaporation under reduced pressure. Bottromycin was precipitated as an amorphous white product from the various aqueous solutions by adjusting the *p*H to 9 with 4 *N* sodium hydroxide. Fractions 5 and 6 both yielded pure bottromycin (3.6 and 48.5 g.). On addition of concentrated mineral acids no red color appeared. Fractions 4, 7 and 8 and 9 on the other hand, yielded impure products, namely, 2.1, 4.7, 24 and 6.5 g. (red color with mineral acids). However, pure bottromycin could be isolated from these fractions by subjecting them to a second chromatographic procedure.

(b) By Means of its Salts with Organic Acids.—The crude antibiotic (26.8 g.) was dissolved in 1 l. of phosphate buffer *p*H 2. To this solution was added 3 l. of ether whereupon the *p*H was adjusted to 9 with 4 *N* sodium hydroxide. The alkaline aqueous layer was extracted repeatedly with ether. The combined ether extracts (6.7 l.) were dried with anhydrous sodium sulfate and after filtration were concentrated to a volume of 3 l.

Under vigorous stirring a solution of 25 g. of salicylic acid in 150 ml. of ether was added. The salicylate of bottromycin precipitated at once as an amorphous yellowish powder. After storing for three hours in the refrigerator the product was filtered and dried in the desiccator (21.35 g.). This product still gave a red color upon addition of concentrated mineral acids.

A suspension of the crude salicylate was stirred in cold ethyl acetate (100 ml.). After filtration, the washed product was recrystallized from ethyl acetate (150 ml.) to yield 15.05 g. of crystalline bottromycin salicylate; m.p. 161–162° dec. This product gave no red color upon addition of concentrated mineral acids.

Anal. Calcd. for $C_{38}H_{60}N_7O_7S \cdot C_7H_6O_3$: C, 60.27; H, 7.37; N, 10.94; S, 3.57. Found: C, 59.95; H, 7.30; N, 11.17; S, 3.49.

Recovery of Free Bottromycin Base.—The crystalline salicylate (10.05 g.) was dissolved in acetone (220 ml.). To this solution was added successively distilled water (650 ml.), ether (400 ml.) and 1 *N* sodium hydroxide (10 ml.). After shaking, followed by addition of solid sodium chloride in order to break emulsions, the ether layer was separated whereupon the alkaline water layer again was extracted with two 400-ml. portions of ether.

The combined ether extracts were dried over anhydrous sodium sulfate, filtered, concentrated under reduced pressure to a volume of 150 ml., then allowed to evaporate to dryness at room temperature. Glittering white amorphous bottromycin was obtained (8.20 g.); yield 96.5%. The substance melted at 143–147° dec.

Anal. Calcd. for $C_{38}H_{59}N_7O_8S$: C, 58.99; H, 7.63; N, 12.68; S, 4.14. Found: C, 58.94; H, 7.78; N, 12.53; S, 3.88.

Salts of Bottromycin. (1) The *p*-Aminosalicylate.—The *p*-aminosalicylate of bottromycin was prepared by the same method as described for the salicylate. It may be recrystallized from ethyl or butyl acetate. The crystalline salt had a m.p. of 175–180° dec.

Anal. Calcd. for $C_{38}H_{57}N_7O_7S \cdot C_7H_7NO_3$: C, 59.47; H, 7.05; N, 12.33; S, 3.52. Found: C, 59.77; H, 7.11; N, 12.25; S, 3.64.

(2) The Benzylpenicillinate.—Benzylpenicillin sodium salt (712 mg.) was dissolved in a few ml. of distilled water. Butyl acetate (10 ml.) was added followed by 2 *N* phosphoric acid (4 ml.). After shaking, the organic layer was separated, washed twice with water and dried over anhydrous sodium sulfate. After filtration, a solution of purified bottromycin (1.48 g.) in butyl acetate (4 ml.) was added.

The white precipitate formed was filtered off, washed with ether and dried. The crude amorphous penicillinate was dissolved in 50 ml. of cold ethyl acetate, filtered, then concentrated, at 10° under reduced pressure, to a small volume. The penicillinate crystallized after remaining in the refrigerator; 1.57 g. of the pure penicillinate was obtained, m.p. 157–159° dec.

Anal. Calcd. for $C_{38}H_{58}N_7O_8S \cdot C_{16}H_{18}N_2O_4S$: C, 58.59; H, 6.87; N, 11.39; S, 5.79. Found: C, 59.05; H, 6.95; N, 11.26; S, 5.72.

(3) The Sulfate.—Bottromycin (1.48 g.) was dissolved in butyl acetate (4 ml.). To this solution was added ether (40 ml.) and a few drops of concentrated sulfuric acid.

The sulfate, which precipitated at once, was filtered. The hygroscopic salt was dissolved in 20 ml. of alcohol, the solution was filtered and the salt was precipitated by the addition of ether. This purification procedure was repeated and yielded 1.02 g. of amorphous bottromycin sulfate, m.p. 189–196° dec. The product is readily soluble in water.

Anal. Calcd. for $C_{38}H_{60}N_7O_7S \cdot 2H_2O_4S \cdot 3H_2O$: C, 45.23; H, 6.95; N, 9.72; S, 9.53. Found: C, 45.22; H, 6.96; N, 9.60; S, 9.60.

Acknowledgments.—The authors wish to thank Mr. P. J. Hubers and Mr. M. Van Leeuwen for microanalysis, Miss V. Roest and Drs. L. M. Rientsma for infrared absorption determinations, Miss Dra. I. Hoette for bio-assay and Professor W. Berends of Delft, Dr. A. P. Struyk and Dr. G. Drost for many helpful discussions.

Bottromycin. II. Preliminary Degradation Studies

BY J. M. WAISVISZ, M. G. VAN DER HOEVEN, J. F. HÖLSCHER AND B. TE NIJENHUIS

RECEIVED DECEMBER 21, 1956

Bottromycin, $C_{38}H_{57-61}N_7O_{7-8}S$, is cleaved by vigorous acid hydrolysis into six ninhydrin-positive substances, two of which have been identified as glycine and valine. Two of the four unidentified fragments have been isolated and shown to have the formulas $C_6H_8N_2O_2S$ and $C_{10}H_{13}NO_2$. Acetylation of the antibiotic yielded two crystalline ninhydrin-negative compounds $C_{19}H_{23}N_3O_4S$ and probably $C_{21}H_{34}N_4O_4$.

In a previous publication Waisvisz and coworkers[1] have reported the isolation, purification and some of the properties of a new sulfur-containing antibiotic, bottromycin.

Analyses and molecular weight determinations[1] indicated a probable molecular formula for bottromycin as $C_{38}H_{57-61}N_7O_{7-8}S$.

Although bottromycin gives a negative ninhydrin test, a Van Slyke nitrogen test indicates the presence of one primary amino group.

Ready decolorization of bromine suggests the unsaturated character of the antibiotic. A Friederich N-alkyl determination and an acetyl determination on the intact antibiotic proved that no such groups are present. The reaction of Kuhn-Roth revealed the presence of two or three C-methyl groups. A Zeisel determination indicated the presence of one methoxyl group.

Desulfurization of the antibiotic with Raney nickel and precipitation of the reaction product with salicylic acid yielded an amorphous sulfur-free degradation product.

Refluxing a solution of bottromycin in 20% aqueous or alcoholic potassium hydroxide resulted in extensive degradation and only tarry or oily products could be isolated.

Hydrolysis of the antibiotic with concentrated hydrochloric acid at 110° for 72 hours yielded a hydrolyzate containing several compounds which gave a positive ninhydrin reaction.

By paper chromatographic methods we were able to demonstrate the presence of seven ninhydrin-positive compounds in this hydrolyzate (compounds no. I/VII, numbers according to the position of the fragments on paper chromatograms).

CHART I

Bottromycin, $C_{38}H_{57-61}N_7O_{7-8}S$

Vigorous acid hydrolysis | "Acetylation"

7 ninhydrin-positive reacting compd.		$C_{19}H_{23}N_3O_4S$ (VIII)	$C_{21}H_{34}N_4O_4$? (IX)
Glycine	(I)	↓ vigorous acid hydrolysis	↓ vigorous acid hydrolysis
Degradation product of III	(II)		
$C_6H_8N_2O_2S$	(III)	$C_6H_8N_2O_2S$ (III)	Glycine (I)
Unidentified	(IV)	$C_{10}H_{13}NO_2$ (VII)	Unidentified (IV)
Valine	(V)		Valine (V)
Unidentified	(VI)		Unidentified (VI)
$C_{10}H_{13}NO_2$	(VII)		

No. I, V, VI and VII developed a purple color on spraying with ninhydrin, II and IV produced faint yellow colors, whereas III showed a brown spot turning purple on exposure to daylight. Up to the present two compounds (I and V) have been identified as glycine (I) and valine (V).

Fractionation of the acid hydrolyzate on an Amberlite IR-4B resin column resulted in the isolation of VII as a pure crystalline compound (m.p. 176–177°) and the isolation of an unidentified ninhydrin-negative substance (m.p. 218° after sublimation). Compound VII crystallizes from 96% alcohol as a monohydrate. Molecular weight determination by the method of Rast indicated that this compound has a molecular weight of about 187. It is optically active. On the basis of analysis of VII and its dinitrophenyl, acetyl- and tosyl-derivatives we have assigned to it the empirical formula $C_{10}H_{13}NO_2$.

Acetylation of bottromycin with boiling acetic anhydride yielded, in addition to tarry and amorphous products, two crystalline degradation products VIII and IX. Compound VIII, recrystallized from ethyl acetate, diisopropyl ether or benzene, contains sulfur and melts at 215–216° (after sublimation). The molecular weight of VIII, determined in camphor, is approximately 408 ± 20. Analysis disclosed that this ninhydrin-negative product has the molecular formula $C_{19}H_{23}N_3O_4S$. According to group analyses, compound VIII contains one acetyl-, one methoxyl- and also one C-methyl group. Kunz-hydrolysis[2] of VIII showed that one molecule utilizes one molecule of sodium hydroxide under the conditions of the reaction, which means that one group of the molecule is subjected to saponification.

By paper chromatographic methods it was shown that mild hydrolysis of compound VIII produced three ninhydrin-positive compounds, namely, the above-mentioned III and VII, and in addition a product with a rather high R_f-value (VIIIa). VIIIa which could be isolated from the hydrolyzate and recrystallized from alcohol or water. The melting point of this sulfur-containing degradation product was 203–206°. Analyses indicated a probable molecular formula $C_{16}H_{19}N_3O_3S.{}^1/_2H_2O$. The same product (VIIIa) could be isolated from a mild acid hydrolyzate of the antibiotic.

Vigorous hydrolysis (72 hours with concentrated hydrochloric acid at 110°) of VIII or VIIIa yielded mainly the two products III and VII. Both products were isolated from these hydrolyzates either by fractional crystallization of their hydrochlorides or by

column chromatography on Amberlite IR-4B. III, recrystallized from alcohol, melts at 197.5–201.5° dec. and has the molecular formula $C_6H_8N_2O_2S$. A mono-dinitrophenyl derivative of III was prepared.

A third unidentified product (IIIa), which showed a salmon-pink spot on the paper chromatograms, was isolated from the above-mentioned hydrolyzates as its crystalline hydrochloride. Continued vigorous acid hydrolysis of IIIa yielded III. The other crystalline product IX obtained by acetylation of the antibiotic with boiling acetic anhydride could be recrystallized from ethyl acetate and melted at 165–170°. This ninhydrin-negative compound contained no sulfur. Its composition is best represented by the formula $C_{21}H_{34}N_4O_4$.

A Friederich determination on IX disclosed the presence of one or two N-alkyl groups. However, the same determination on bottromycin failed to demonstrate the presence of N-alkyl groups in the intact antibiotic.

A Kuhn-Roth determination showed the presence of two C-methyl groups. Vigorous hydrolysis of IX with concentrated hydrochloric acid yielded a hydrolyzate which contained the ninhydrin-positive reacting compounds I (= glycine), IV, V (= valine) and VI. A crystalline mixture of the four substances was isolated. Further work on the purification and structure of these compounds will be reported later.

It has been found that alkaline hydrolysis or oxidation of III results in the formation of II, in other words, II is a degradation product of III.

Taking into account the above-mentioned facts, it seems likely that bottromycin has a peptide-like structure.

Experimental

Acid Hydrolysis of Bottromycin.—Purified bottromycin (2 g.) was heated for 72 hr. in a Carius tube with concentrated hydrochloric acid (10 ml.) at 100–110°. Paper chromatograms (run in butanol–acetic acid–water 100:12:100) showed the presence of seven ninhydrin-positive compounds in this hydrolyzate.

Fractionation of the Acid Hydrolyzate of Bottromycin on an Amberlite IR-4B Resin Column (Isolation of VII).—The acid hydrolyzate was evaporated *in vacuo* and redissolved in water (50 ml.). This solution was added to an Amberlite IR-4B (OH-form) resin column (310 × 28 mm.). The column was at first developed by gravity with distilled water (205 fractions of 12.5 ml. were collected) followed by 0.5 *N* hydrochloric acid (65 fractions of 12.5 ml. and one of 600 ml.). Although the paper chromatograms (run in butanol–acetic acid–water 100:12:100) disclosed that a poor elution and separation had been achieved, nevertheless we could isolate by freeze-drying (1) from the water fractions (no. 1/10) an amorphous ninhydrin-negative compound. This product was crystallized from ethyl acetate–acetone and melted at 218° (after sublimation in needles at 184°).

(2) The water fractions (no. 33/60) contained, according to the paper chromatograms, a single ninhydrin-positive compound VII. After freeze-drying and several recrystallizations from alcohol we obtained 18 mg. of pure VII melting at 176–177°. The mother liquors yielded another 11 mg. (m.p. 173°) of the same compound. The hydrochloric acid fractions contained the impure III together with VI.

Anal. Calcd. for $C_{10}H_{13}NO_2 \cdot H_2O$: C, 60.91; H, 7.61; N, 7.11. Found: C, 60.91; H, 7.64; N, 7.17.

Acetylation of Bottromycin (Isolation of VIII and IX).—A solution of bottromycin (50 g.) in acetic anhydride (500 ml.) was heated for 3 hours on a steam-bath. The solution was then concentrated *in vacuo* to a small volume (100 ml.) and cooled in the refrigerator, whereupon spontaneous crystallization took place. The snow-white crystals were filtered off, washed with acetic anhydride (20 ml.) and dried. The crude product (14.2 g.) was recrystallized from ethyl acetate (800 ml.) and yielded VIII (11.4 g.) melting at 215–216° (after sublimation in needles).

From the recrystallization mother liquor we isolated another crop of VIII (2.3 g.) melting at 209–211°.

Anal. Calcd. for $C_{19}H_{23}N_3O_4S$: C, 58.61; H, 5.91; N, 10.80; S, 8.23; CH_3CO, 11.05; OCH_3, 7.97; mol. wt., 392. Found: C, 58.52; H, 6.05; N, 10.62; S, 8.29; CH_3CO, 11.57; OCH_3, 8.14; mol. wt. (Rast), 408.

The reaction mother liquor was evaporated to dryness and the tarry residue dissolved in acetone (20 ml.). Crystallization occurred very slowly. After one week the crystals were collected, washed with a small quantity of cold acetone and dried.

Recrystallization from ethyl acetate (100 ml.) yielded 3.8 g. of IX melting at 165–170°.

Anal. Calcd. for $C_{12}H_{34}N_4O_4$: C, 62.04; H, 8.43; N, 13.78. Found: C, 61.86; H, 8.35; N, 13.67.

Hydrolysis of VIII with 6 *N* Hydrochloric Acid. a. Isolation of VIIIa.—Compound VIII (120 mg.) was dissolved in 6 *N* (11 ml.) hydrochloric acid and heated on a steam-bath for 4.5 hours. The hydrolyzate was evaporated to dryness, redissolved in water and concentrated. Finally the concentrate was dissolved in water (2 ml.) and extracted several times with a 5% solution of methyldioctylamine in chloroform until the *p*H of the water layer was about 6. The remaining water layer was evaporated to dryness and the solid residue recrystallized from ethanol (1 ml.). VIIIa (21 mg.), m.p. at 203–206°, was obtained.

Anal. Calcd. for $C_{16}H_{19}N_3O_3S \cdot 1/2H_2O$: C, 56.11; H, 5.85; N, 12.28; S, 9.38. Found: C, 55.89; H, 5.87; N, 12.03; S, 9.72.

Hydrolysis of VIII with Concentrated Hydrochloric Acid. a. Isolation of III and VII by Fractionation on an Amberlite IR-4B Resin Column.—Compound VIII (3.21 g.) was heated with concentrated hydrochloric acid (16 ml.) in a Carius tube at 110° for 72 hours. Paper chromatograms (run in butanol–acetic acid–water 100:12:100) showed that mainly two ninhydrin-positive compounds III and VII were present in this hydrolyzate. The acid solution was evaporated to dryness, dissolved in water (50 ml.) and added to a previously packed IR-4B (OH-form) resin column (430 × 42 mm.). The column was successively developed with water (135 fractions of 50 ml. and one of 300 ml.) and 0.5 *N* hydrochloric acid (17 fractions of 50 ml., one of 850 ml. and 3 fractions of 100 ml.). According to the paper chromatograms the water fractions 1–24 contained mainly compound III, the fractions 25–110 contained substance VII, whereas the hydrochloric acid fractions contained both III and VII. After evaporation and several recrystallizations from alcohol, the water fractions 1–24 yielded 68 mg. of III melting at 197–201.5°. From the water fractions 25–100 we obtained by evaporation and recrystallization from alcohol 500 mg. of VII melting at 176–177°.

Anal. Calcd. for $C_6H_8N_2O_2S$: C, 41.86; H, 4.66; N, 16.28; S, 18.60. Found: C, 41.86; H, 4.71; N, 15.91; S, 17.95.

b. Isolation of the Hydrochlorides of III and VII by Fractional Crystallization.—Compound VIII (10 g.) was heated with concentrated hydrochloric acid (50 ml.) in a Carius tube at 110° for 72 hr. The hydrolyzate crystallized when stored in the refrigerator. The white crystals were collected, washed with two small portions of cold concentrated hydrochloric acid, and dried to yield 2.88 g. of solid K_1. The mother and wash liquors were combined and concentrated *in vacuo* to half their volume. A second crop of crystals (1.15 g.) K_2 was isolated. After concentration of the filtrate to a still smaller volume another 0.5 g. of solid product K_3 was obtained.

The remaining mother liquor was evaporated to dryness and the resulting brown gum was dissolved in a small quantity of cold alcohol. Spontaneous crystallization set in. After storing in the ice-box for a few hours, the yellowish product was collected, washed with two small portions of cold alcohol and dried to give K_4 (4.1 g.), as a crystalline solid.

Paper chromatographic methods showed that K_1 and K_2 were both the pure hydrochloride of VII, $[\alpha]^{25}D$ −10.6 (*c*

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

5%, water). K_3 was a mixture of III and VII, whereas K_4 proved to be the pure hydrochloride of III.

Preparation of Derivatives of III and VII. a. The 2,4-Dinitrophenyl Derivative of III.—According to the method of Sanger[3] the dinitrophenyl derivative of III was prepared by treating the hydrochloride of III (239 mg.) with 2,4-dinitrofluorobenzene (0.56 ml.). After three recrystallizations from 60% methyl alcohol, the yellow, acicular crystalline derivative (223 mg.) was obtained, m.p. 148–151°.

Anal. Calcd. for $C_{12}H_{10}N_4O_6S$: C, 42.61; H, 2.98; N, 16.57; S, 9.46. Found: C, 42.47; H, 2.91; N, 16.49; S, 9.34.

b. The 2,4-dinitrophenyl derivative of VII was prepared from the hydrochloride (283 mg.) and 2,4-dinitrofluorobenzene (0.28 ml.). After three recrystallizations from 60% methanol we obtained the yellow derivative (254 mg.), m.p. 175–179°.

Anal. Calcd. for $C_{16}H_{15}N_3O_6$: C, 55.65; H, 4.38; N, 12.17. Found: C, 55.62; H, 4.37; N, 12.27.

c. The Tosyl Derivative of VII.—The hydrochloride of VII (500 mg.) was dissolved in 1 *N* sodium hydroxide (10 ml.). A solution of *p*-toluenesulfonyl chloride (1 g.) in ether (12.5 ml.) was added and the mixture was shaken mechanically for 4 hr. The ether layer was discarded and the water layer acidified with 4 *N* hydrochloric acid. A white precipitate formed, which was recrystallized several times from 60% alcohol. The acicular, white crystals (414 mg.) melted at 169–171°.

Anal. Calcd. for $C_{17}H_{19}NO_4S$: C, 61.25; H, 5.75; N, 4.20; S, 9.60. Found: C, 61.23; H, 5.79; N, 4.25; S, 9.73.

d. The Acetyl Derivative of VII.—A solution of the hydrochloride of VII (5 g.) in 1 *N* sodium hydroxide (50 ml.) was cooled in an ice-bath. Acetic anhydride (3 ml.) and 1 *N* sodium hydroxide (25 ml.) were added simultaneously and gradually under stirring over a period of 15 minutes. The mixture was stirred for an additional 30 minutes, whereupon another portion of acetic anhydride (3 ml.) and sodium hydroxide (65 ml.) were added in 13 minutes. After another 30 minutes the solution was filtered, acidified with concentrated hydrochloric acid and cooled; the precipitated solid was filtered off, washed with water and dried.

The product was recrystallized from 20% alcohol. A white, acetyl derivative (3.4 g.), m.p. 177–185°, $[\alpha]^{25}D$ +35.0° (*c* 2%, 96% ethyl alcohol), was obtained.

(3) F. Sanger, *Biochem. J.*, **39**, 507 (1945).

Anal. Calcd. for $C_{12}H_{15}NO_3$: C, 65.14; H, 6.79; N, 6.33. Found: C, 64.84; H, 6.79; N, 6.42.

Kunz-hydrolysis of VIII.—Compound VIII (197.9 mg.) was dissolved in purified acetone (25 ml.). To this solution was added 0.1011 *N* sodium hydroxide (25 ml.). After 2.5 hours in the refrigerator, titration with 0.0906 *N* hydrochloric acid showed that 0.98 milliequivalent of alkali had been consumed per milliequivalent of VIII.

Identification of Valine and Glycine in the Acid Hydrolyzate of Bottromycin by Means of Paper Chromatography.—A hydrolyzate of bottromycin with concentrated hydrochloric acid (72 hr. hydrolysis) was compared with known amino acids by means of paper chromatographic methods. The one-dimensional descending method was used (Whatman no. 1 paper). The following eluent systems were used: *n*-propanol–water (70:30), *n*-propanol–water–diethylamine (85:15:3), *n*-butanol–acetic acid–water (100:12:100), isobutyl alcohol–formic acid–water (70:15:13), phenol–water–NH_3–NaCN, pyridine–isoamyl alcohol–water (35:35:30). In all six systems spots I and V coincided with the spots of glycine and valine, respectively. Identity was demonstrated also as follows. The hydrolyzate was evaporated to dryness under vacuum and treated with 2,4-dinitrofluorobenzene, according to the method of Levy.[4] This yielded a mixture of dinitrophenyl derivatives. By paper chromatographic technique this mixture was compared with the dinitrophenyl derivatives of glycine and valine. The following systems were used: 1, the Blackburn system[5] (phthalate buffered paper strips of *p*H 6.0 and as eluent: (a) phthalate buffer–saturated *n*-propanol–petroleum ether 3:7); (b) phthalate buffer saturated amyl alcohol; 2, the Biserte system[6] (toluene–pyridine–ethylene chlorhydrin–0.8 *N* ammonia, 5:1:3:3). In all cases the spots of dinitrophenylvaline and dinitrophenylglycine coincided with two spots of dinitrophenyl derivatives obtained with bottromycin hydrolyzate.

Acknowledgments.—The authors wish to thank Mr. P. J. Hubers and Mr. M. Van Leeuwen for microanalyses, Miss V. Roest and Dr. L. M. Rientsma for infrared absorption determinations and Professor W. Berends of Delft for many helpful discussions.

The Structure of the Sulfur-containing Moiety of Bottromycin

BY J. M. WAISVISZ, M. G. VAN DER HOEVEN AND B. TE NIJENHUIS

RECEIVED DECEMBER 21, 1956

The degradation of the antibiotic bottromycin by means of boiling acetic anhydride yielded two crystalline acetyl products $C_{19}H_{23}N_3O_4S$ and probably $C_{21}H_{34}N_4O_4$. The sulfur-containing moiety proved to be the methyl ester of a N-acetyl dipeptide. The two components of this peptide are two new naturally occurring amino acids, α-amino-β-phenylbutyric acid and β-(2-thiazole)-β-alanine.

Previously[1] it was reported that treatment of bottromycin with boiling acetic anhydride yields two crystalline acetyl-degradation products: $C_{19}H_{23}N_3O_4S$ (VIII) and a compound with the probable formula $C_{21}H_{34}N_4O_4$ (IX).

This paper deals with the elucidation of the structure of the sulfur-containing moiety. It has already[1] been reported that VIII contains one acetyl, one methoxyl and, in addition, one C-methyl group. Furthermore on Kunz hydrolysis one group of the molecule is split off, whereas mild acid hydrolysis yields a crystalline substance $C_{16}H_{19}N_3O_3S$ (VIIIa). Finally, vigorous hydrolysis of VIII or VIIIa yields two ninhydrin-positive compounds $C_{10}H_{13}NO_2$ (VII) and $C_6H_8N_2O_2S$ (III).

The ultraviolet spectrum of VII showed the typical absorption maxima of the phenyl nucleus (252.5–258 and 264 mμ).

By paper electrophoretic methods it could be demonstrated that VII has basic properties whereas the hydroxamic acid test[2] proved that, in addition, a carboxyl group was present in the molecule.

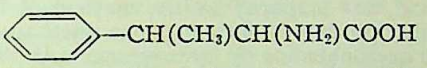
The fact that crystalline acetyl, 2,4-dinitrophenyl and tosyl derivatives of VII[1] could be prepared indicated the presence of an amino grouping. Potentiometric titrations suggested the presence of an amino acid grouping.

Oxidation of VII with potassium permanganate at room temperature yields acetophenone, which was isolated and identified as its *p*-nitrophenyl- and 2,4-dinitrophenylhydrazones. This indicated a branched side chain and proved the presence of the expected phenyl nucleus. Ultraviolet spectra of VII at alkaline and acid *p*H indicated that no dissociable grouping was attached to the phenyl nucleus.

Decarboxylation and deamination of VII with ninhydrin according to the method of Van Slyke[3] yielded hydratropic aldehyde which was isolated and identified as its 2,4-dinitrophenylhydrazone.

All these data left open only this possibility



VII, α-amino-β-phenylbutyric acid

Apart from the question of the optical activity the validity of these structural deductions was confirmed by synthesis of this amino acid according to E. Fischer.[4] Fischer reported the synthesis of α-amino-γ-phenylbutyric acid, but because of the work of F. Knoop,[4] later agreed[4] that the substance was not the γ-isomer but in fact was α-amino-β-phenylbutyric acid. Although two isomers are possible, DL- and DL-allo, synthetic α-amino-β-phenylbutyric acid proved to be identical with the natural product isolated from bottromycin in respect to analyses, melting range, mixed melting range, melting and mixed melting ranges of the tosyl-, acetyl- and dinitrophenyl derivatives, R_f values on paper chromatograms, ultraviolet and infrared spectra.

The other ninhydrin-positive, optically inactive hydrolytic degradation product of VIII is $C_6H_8N_2O_2S$ (III). This water-soluble compound also is unsaturated. Its ultraviolet spectrum showed maxima at 210 and 242.5 mμ. Paper electrophoretic methods demonstrated the acid properties of III. The presence of a single amino group was shown by the facts that it was possible to prepare only a mono-dinitrophenyl derivative, and that the hydrochloride salt, isolated from an acid hydrolysate, proved to be a monohydrochloride.[1]

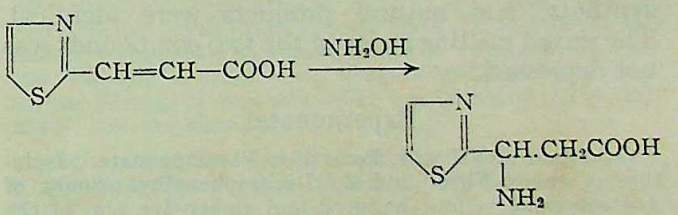
These facts suggested the presence of a heterocyclic nucleus containing sulfur and nitrogen in III. This supposition was supported by the infrared spectrum.

A literature study revealed that R. G. Jones, *et al.*,[5] synthesized a compound which has the same molecular formula and melting point as III, namely, 2-thiazolealanine. A comparative study of the two compounds revealed that they are very similar but not identical. For instance, the mixed melting point had a depression of 5°.

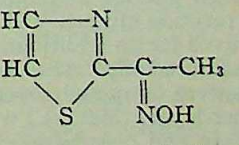
Paper chromatographic methods showed that in one of the four development solvents employed there was a slight difference in R_f value and that the spot produced by compound III turned from brown to purple on exposure to daylight, whereas the spot of 2-thiazolealanine remained brown.

There were only minor differences in the ultraviolet and infrared spectra of the two compounds, the latter indicating that III possibly could have a β-amino acid structure. Paper electrophoresis, on the other hand, showed marked differences: at *p*H 8.5 compound III moved in the direction of the anode, whereas 2-thiazolealanine did not move at all. There was also a marked difference in the melting points of the dinitrophenyl derivatives, that of III melting at 148–151° dec. and that of 2-thiazolealanine at 203.5–210° dec.

Paper chromatographic studies using the method of Crumpler[6] with the aid of copper carbonate were indecisive. Desulfurization of III with Raney nickel catalyst proved unsatisfactory. Oxidation with potassium permanganate, however, yielded a crystalline compound $C_4H_4N_2OS$. This compound proved to be 2-thiazolecarbonamide.[7] This established the presence of a thiazole nucleus substituted in the 2-position. This fact and the infrared spectrum indicated III to be β-(2-thiazole)-β-alanine. We succeeded in synthesizing this compound by the following route. 2-Methylthiazole,[8] prepared from chloroacetaldehyde and thioacetamide,[9] was converted to β-2-thiazoleacrylic acid by the method of Jones, *et al*.[8,10] Condensation with hydroxylamine gave β-(2-thiazole)-β-alanine, m.p. 199–202° dec.



A by-product (m.p. 163–165.5°) was also obtained. It is thought to be methyl 2-thiazolyl ketoxime



Apart from the question of the optical activity the synthetic β-amino acid (m.p. 199–202° dec.) was identical with the natural product as is evidenced by analysis, identical melting points and mixed melting point, identical melting points and mixed melting point of the dinitrophenyl derivatives, same ultraviolet and infrared spectra, same

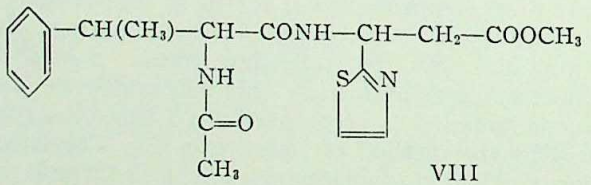
R_f values on paper chromatograms, and identical behavior on paper electrophoresis.

The structure elucidation of the two amino acids III and VII being completed, there remained the question of the structure of the acetyl degradation compound of bottromycin, $C_{19}H_{23}N_3O_4S$ (VIII) from which these two amino acids were derived. Group analyses showed that VIII contained one acetyl and one methoxyl group.[1] Since neither of the two degradation products of VIII possessed a hydroxyl group, it is very likely that the acetyl group was linked to a nitrogen atom and that the methoxyl group possibly was a methyl ester grouping. The last supposition was supported by Kunz hydrolysis of VIII and by the fact that we were able to prepare a benzylamide derivative of the acetyl compound by reaction with benzylamine.

By lithium aluminum hydride reduction of VIII and acid hydrolysis of the reaction product followed by paper chromatographic study of the products formed we could establish that β-(2-thiazole)-β-alanine was the C-terminal amino acid. By synthesis of the dipeptide from the natural N-acetyl-α-amino-β-phenylbutyric acid[1] and β-(2-thiazole)-β-alanine methyl ester, by the method of Sheehan,[11] we could prove that apart from the question of the optical activity the structure of the acetyl degradation product VIII is



VIII

Analyses, ultraviolet and infrared spectra of the synthetic and natural products were identical. The mixed melting range of the two compounds was not depressed.

Experimental

Oxidation of VII with Potassium Permanganate. Isolation of the *p*-Nitro- and 2,4-Dinitrophenylhydrazones of Acetophenone.—Four hundred and eighty-five mg. of the hydrochloride of VII was dissolved in 27.5 ml. of water. To this solution was added gradually with stirring and external cooling a solution of 553 mg. of potassium permanganate in 27.5 ml. of water, the addition being completed in 55 minutes. After stirring at room temperature for another 50 min. the reaction mixture was heated to a temperature of 50° and stirred for an additional 30 min. The manganese dioxide was filtered off, washed with hot water and the combined filtrates were extracted several times with ether. The combined ether layers (300 ml.) were dried over anhydrous sodium sulfate and concentrated *in vacuo*. The residual oily product (67 mg.) was dissolved in 1 ml. of ethanol and heated on a steam-bath for five minutes with 1 ml. of a solution of *p*-nitrophenylhydrazine (1 g. of *p*-nitrophenylhydrazine dissolved in 2 ml. of 4 *N* hydrochloric acid and 10 ml. of water). After cooling, the orange-colored derivative was filtered off, washed with water and dried. Fifty-one and a half mg. of the *p*-nitrophenylhydrazone was obtained (m.p. 160–178°). After two recrystallizations from 70% ethanol the derivative melted at 177–184° (with sublimation).

The mixed melting point with synthetic material was not depressed. The ultraviolet spectra of both compounds were identical.

Repetition with 485 mg. of VII gave a similar oily product. After heating with 5 ml. of a solution of 2,4-dinitrophenylhydrazine (according to Shriner and Fuson[12]) an orange-colored 2,4-dinitrophenylhydrazone was obtained. Recrystallized twice from ethanol 56 mg. of pure product was obtained which had a m.p. of 243–246° (with sublimation), undepressed on mixture with an authentic sample. The ultraviolet spectra of both compounds were also identical.

Decarboxylation and Deamination of VII with Ninhydrin. Isolation of Hydratropicaldehyde 2,4-Dinitrophenylhydrazone.—To a solution of 234 mg. of the hydrochloride of VII 42 g. of sodium chloride and 28 g. of primary potassium phosphate in 280 ml. of water was added 56 ml. of a 1% ninhydrin solution in water. Over a period of 30 minutes the reaction mixture was heated to its boiling point, then steam distilled. To the distillate (80 ml.) was added 10 ml. of a 2,4-dinitrophenylhydrazine solution and the solution was heated briefly on a steam-bath. After cooling the yellow crystals were collected, washed with water and recrystallized from 4 ml. of ethanol. Recrystallized once more 25 mg. of pure 2,4-dinitrophenylhydrazone (m.p. 133–136°) was obtained, not depressed on mixture with an authentic sample. The ultraviolet spectra of both products also proved to be identical.

The Synthesis of α-Amino-β-phenylbutyric Acid.—This α-amino acid was prepared by the method of E. Fischer.[4] The starting product, 1-bromo-1-phenylethane, was prepared from acetophenone by hydrogenation.[13] This yielded phenylmethylcarbinol, which was brominated according to the method of J. B. Conant, *et al.*[14] The amino acid obtained was recrystallized from water as a monohydrate and melted at 162–166°. After drying *in vacuo* for four hours at 110° the product had lost its water content and melted at 234° dec.

Anal. Calcd. for $C_{10}H_{13}NO_2$: C, 67.02; H, 7.31; N, 7.82. Found: C, 67.00; H, 7.24; N, 7.75.

Preparation of Derivatives of α-Amino-β-phenylbutyric Acid. a.—The 2,4-dinitrophenyl derivative was prepared from 239 mg. of its monohydrate and 0.28 ml. of 2,4-dinitrofluorobenzene according to the method of Sanger.[15] After two recrystallizations from 68% methanol it showed a melting range of 185–213° dec.

b.—**The tosyl derivative** of synthetic α-amino-β-phenylbutyric acid was prepared according to the method described in the previous paper.[1] The product melted at 147–152.5°.

c.—**The acetyl derivative** of the synthetic α-amino-β-phenylbutyric acid was prepared according to the method described in the previous paper.[1] The derivative melted at 185–190°.

Oxidation of III with Potassium Permanganate. Isolation of 2-Thiazole-carbonamide.—Four hundred and ninety-one mg. of the hydrochloride of III was dissolved in 27.5 ml. of water. The *p*H of the solution was adjusted to 8 by addition of concentrated sodium hydroxide solution. Gradually with stirring and external cooling (with running water) a solution of 1.24 g. of potassium permanganate in 40 ml. of water was added over a period of 45 min. The reaction mixture was heated to 50° and stirred for an additional 15 min. After cooling the manganese dioxide was filtered off, washed with hot water and the combined filtrates extracted continually with ether. The ether extract was dried over anhydrous sodium sulfate and concentrated *in vacuo*. The residual crystalline product (122 mg.) melting at 116–118° was recrystallized from 75 ml. of heptane; obtained, 95 mg. of the acicular crystalline product, melting at 117–118°. A molecular weight determination (Rast-camphor) gave a value of approximately 124.

Anal. Calcd. for $C_4H_4N_2OS$: C, 37.51; H, 3.15; N, 21.87; S, 25.00. Found: C, 37.61; H, 3.13; N, 21.66; S, 27.39.

Synthesis of β-(2-Thiazole)-β-alanine.—Chloroacetaldehyde was prepared by direct chlorination of paraldehyde according to the method of H. Guinot[16] (yield 46%). Thio-

acetamide was obtained by treating acetamide with phosphorus pentasulfide[9] (average yield 30%). 2-Methylthiazole was prepared from above-mentioned components by the method of Erlenmeyer[8] (average yield 45%). 2-(β-Oxy-γ-trichloro)-*n*-propylthiazole and 2-thiazoleacrylic acid were prepared from 2-methylthiazole and trichloroacetaldehyde by the method of Jones.[10] Yields obtained were in agreement with those given by the authors. β-(2-Thiazole)-β-alanine was prepared as follows: 0.46 g. of sodium was dissolved in 16 ml. of absolute ethanol. To this solution was added a hot solution of 1.39 g. of hydroxylamine hydrochloride in 1 ml. of water. After cooling in an ice-bath the precipitated sodium chloride was filtered with suction and the filtercake washed with three portions of 1 ml. each of absolute ethanol. To the combined filtrates was added under shaking 1.55 g. of 2-thiazoleacrylic acid. The solution obtained was heated under reflux for 9 hours on a steam-bath, followed by an additional 14 hours at room temperature. On concentration *in vacuo* to a small volume crystallization occurred. The crystals were collected, washed with small quantities of alcohol and hexane, respectively; obtained, 600 mg. of a cream-colored product (m.p. 195–200°). After recrystallization from 280 ml. of 96% ethyl alcohol 475 mg. of the acicular crystalline compound was isolated (m.p. 199–202° dec.).

Anal. Calcd. for $C_6H_8N_2O_2S$: C, 41.86; H, 4.68; N, 16.28; S, 18.59. Found: C, 41.73; H, 4.68; N, 16.12; S, 18.60.

A second crop of crystals (155 mg.) was obtained from the mother liquors by concentration. The melting point of this fraction was 155–162° (under sublimation). After recrystallization from water 80 mg. of a white product was isolated melting at 163–165.5°. Supposedly this compound is methyl 2-thiazolyl ketoxime.

Anal. Calcd. for $C_5H_6N_2OS$: C, 42.25; H, 4.26; N, 19.71; S, 22.52. Found: C, 42.24; H, 4.30; N, 19.58; S, 22.56.

The Dinitrophenyl Derivative of β-(2-Thiazole)-β-alanine.—Similarly as described for this derivative of III[1] we prepared the 2,4-dinitrophenyl-β-(2-thiazole)-β-alanine from 260 mg. of synthetic β-amino acid and 0.84 mg. of 2,4-dinitrofluorobenzene. After two recrystallizations from 60% methanol 300 mg. of a yellow derivative was obtained. The melting point was 148–151°.

Anal. Calcd. for $C_{12}H_{10}N_4O_6S$: C, 42.61; H, 2.98; N, 16.57; S, 9.46. Found: C, 42.51; H, 3.06; N, 16.44; S, 9.52.

Synthesis of the Benzylamide of VIII.—A hundred and ninety-nine mg. of VIII was dissolved in 1 ml. of benzylamine on a steam-bath. After an additional 18 hr. at room temperature crystallization occurred. The reaction mixture was heated for another 2 hr. under reflux on a steam-bath and stored for an additional 24 hr. at room temperature. To the crystalline mass was added a mixture of 10 ml. of ethyl acetate and 2 ml. of alcohol, whereupon the suspension was heated to the boiling point, then filtered with suction while still hot; obtained, 117 mg. of a white solid of melting point 286° (dec. after sublimation). After recrystallization from 200 ml. of ethanol 80 mg. of the crystalline compound was isolated. The melting point was 290–291° (dec. under sublimation).

Anal. Calcd. for $C_{25}H_{28}N_4O_3S$: C, 64.64; H, 6.08; N, 12.06; S, 6.89. Found: C, 64.36; H, 6.13; N, 12.14; S, 7.41.

Lithium Aluminum Hydride Reduction of VIII.—A finely divided suspension of 97 mg. of lithium aluminum hydride in 25 ml. of dry ether was treated with 66 mg. of VIII introduced by extraction (7 hours) from an extraction thimble. After the thimble was removed the heating was continued for another 30 min. and the reaction mixture thereafter kept at room temperature for 16 hours. The excess of lithium aluminum hydride was destroyed by careful addition of 1 ml. of water. The precipitated hydroxides were filtered off and extracted several times with small portions of boiling alcohol. The combined ethereal alcoholic filtrates were evaporated to dryness and the residual oily product was hydrolyzed in a Carius tube for 72 hr. with 2 ml. of concentrated hydrochloric acid at 100–110°. Paper chromatograms run in butanol–acetic acid–water (100:12:100) showed that only the unchanged VII was present in this hydrolyzate, while the spot due to III was no longer observed.

Methyl Ester of III.—Two grams of the hydrochloride of III was suspended in 75 ml. of absolute methanol. The suspension was saturated with a stream of dry hydrogen chloride whereupon the compound dissolved. The reaction mixture was heated under reflux for 2.5 hours, then kept for 15 hours in the refrigerator. After evaporation to dryness the residual crystalline mass was dissolved in 10 ml. of ice-water, the solution adjusted to a *p*H of 8.5 by careful addition of a saturated solution of potassium carbonate and extracted several times with ether (180 ml.). The combined extracts were dried over anhydrous sodium sulfate, filtered, then evaporated to dryness; obtained, 1.27 g. yellow colored, oily methyl ester of III.

Synthesis of VIII.—One and a half g. of the methyl ester of III, 1.89 g. of the N-acetyl compound of VII[1] and 2.05 g. dicyclohexyl carbodiimide[17] were suspended in 25 ml. of purified tetrahydrofuran. The reaction mixture was shaken occasionally and kept at room temperature for 4 hr. The precipitate (1.9 g., dicyclohexyl carbamide) was removed by filtration and washed with a small quantity of tetrahydrofuran. After addition of a few drops of glacial acetic acid the filtrates were evaporated *in vacuo*, and the tarry residue dissolved in 25 ml. of boiling ethyl acetate. This solution was decolorized with active carbon. After cooling another crop (129 mg.) of dicyclohexyl carbamide was obtained. This was removed by filtration. The filtrate was extracted with three portions of 5 ml. each of 1 *N* hydrochloric acid. The *p*H of the combined extracts was adjusted to 5 by addition of a few drops of 33% potassium hydroxide solution. The resulting solution was re-extracted twice with 10-ml. portions of ethyl acetate. The extracts were dried and concentrated *in vacuo* to a small volume. After cooling crystallization took place. The product was filtered with suction and dried (96 mg.). The melting point was 195–202°. After two recrystallizations from ethyl acetate 34 mg. of synthetic VIII was obtained (m.p. 202–208.5° with sublimation).

Anal. Calcd. for $C_{19}H_{23}N_3O_4S$: C, 58.61; H, 5.91; N, 10.80; S, 8.23. Found: C, 58.65; H, 5.85; N, 10.63; S, 8.13.

Acknowledgments.—The authors wish to thank Mr. P. J. Hubers and Mr. M. Van Leeuwen for microanalyses, Miss V. Roest and Dr. L. M. Rientsma for infrared absorption determinations, and Professor W. Berends of Delft for many helpful discussions. We are also indebted to the Eli Lilly Research Labs. for a gift of 2- and 4-thiazolealanine, and to Mr. A. K. J. Mulder for the synthesis of α-amino-β-phenylbutyric acid.

The Cross-linking of Gelatin Using a Water-soluble Carbodiimide

BY JOHN C. SHEEHAN AND JOSEPH J. HLAVKA[1]

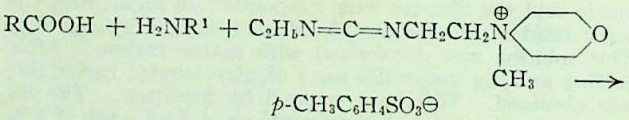
RECEIVED MARCH 30, 1957

Treatment of an aqueous gelatin solution with a water-soluble carbodiimide (III) resulted in very rapid gelation, shown to be due to amide bond formation.

Recently[2] we reported that water-soluble carbodiimides may be used to form peptide bonds in fully aqueous solution. It is of obvious interest to study the effect of these unusual reagents on proteins.

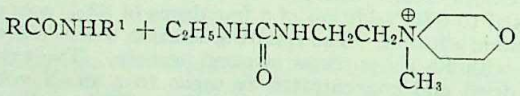
Gelatin may be regarded as a partially degraded protein, being derived from collagen by acidic or basic hydrolysis. In addition to amino and carboxy terminal groups, the peptides possess side-chains, some of which end in carboxy groups (due principally to glutamic and aspartic acid residues) and others bear free amino functions (accounted for chiefly by lysine).

We have found that treatment of an aqueous solution of gelatin with a water-soluble carbodiimide [1-ethyl-3-(2-morpholinyl-(4)-ethyl)-carbodiimide metho-*p*-toluenesulfonate (III)] results in very rapid (30 seconds) gelation, presumably due to cross-linking by amide bond formation.



p-$CH_3C_6H_4SO_3\ominus$

III



p-$CH_3C_6H_4SO_3\ominus$

IV

Previously, known methods for denaturing, insolubilizing, hardening or tanning protein-type materials with chemical agents, such as aldehydes (formaldehyde or glyoxal) or metallic ions (chrome-alum), are slower acting, leave a residue in the treated material, and operate by complex and poorly understood mechanisms. The carbodiimides II and III are especially useful for amide and peptide bond formation in high yield,[2] by virtue of their accessibility from commercially available intermediates and favorable physical properties.

The normal gelation of gelatin is considered generally to involve hydrogen bond formation through amide groups.[3] It is of interest to demonstrate that the carbodiimide reagent is operating by a different mechanism, namely, formation of new amide bonds. The following experiments convincingly demonstrate this latter mechanism.

Gelatin will not gel in a 2 *M* urea solution at 25° (considered to be due to efficiency of urea in the disruption of hydrogen bonds), but the addition of III causes immediate gelation. Benzoyl gelatin,[4] which contains essentially no free amino groups, gels reversibly as a 5% solution in 10–15 minutes at 25° with or without added III.

Treatment of gelatin with a high ratio (equal weight dry basis) of water-soluble carbodiimide leads to very rapid gelation, but after 10–16 hours storage at 25°, the mixture liquefied. However, if the gelled solution of gelatin and carbodiimide is heated immediately on a steam-cone for 10 minutes, the mixture remains solid at the elevated temperature and on storage for five days at 25°.

At ratios of 10–25% by weight of carbodiimide to a 5% gelatin solution, the rate of gelation is less. The melting point of the treated gelatin is increased to 50–90° and no liquefaction was observed on storage.

In a separate experiment a 5% gelatin solution was freeze-dried immediately after gelation with a nearly equal weight of III. The resulting powder was washed free of water-soluble components and divided into three portions. The first portion (a control) was suspended in water corresponding to a 5% solution and stored three days at 25°, but the mixture did not become homogeneous. A second portion, suspended in water containing the urea IV, likewise did not dissolve on storage. The third portion, treated with an additional quantity of III, did dissolve on storage, thereby establishing excess III as the factor producing liquefaction.

On storing the gelatin–carbodiimide mixture, the rate of disappearance of carboxyl groups (Sörensen titration[5]) paralleled the loss of free amino functions (Van Slyke determination), further evidence that amide bond formation was taking place. Immediately after gelation the carboxy value dropped to 25% of the original gelatin figure and after reliquefaction only 10% of the amino and carboxyl groups remained. Liquefaction is considered to be associated with phase-separation, and the phenomenon is being investigated further.

Experimental[6]

1-Ethyl-3-(2-morpholinyl-(4)-ethyl)-thiourea (I).—To a solution of 10 g. (0.077 mole) of N-(2-aminoethyl)-morpholine in 100 ml. of ether was added slowly 6.7 g. (0.077 mole) of ethyl isothiocyanate. After ebullition had ceased, the reaction solution was stored overnight at 0°. The crystalline product I amounted to 14.0 g. (84%), m.p. 94–96°.

Anal. Calcd. for $C_9H_{19}N_3OS$: C, 49.75; H, 8.81; N, 19.34. Found: C, 49.80; H, 8.83; N, 19.35.

1-Ethyl-3-(2-morpholinyl-(4)-ethyl)-carbodiimide (II).—A solution of 5.0 g. (0.023 mole) of 1-ethyl-3-(2-morpholinyl-(4)-ethyl)-thiourea in 100 ml. of dry acetone was stirred at room temperature with 7.0 g. of mercuric oxide (Merck Yellow) for 5 hours. The precipitated mercuric sulfide was

removed by filtration and the filtrate was again stirred 12 hours with 7.0 g. of mercuric oxide. After filtration the acetone was distilled under reduced pressure and the residue was purified by distillation at 80° (0.05 mm.), yield 3.5 g. (76%).

Anal. Calcd. for $C_9H_{17}N_3O$: C, 58.98; H, 9.35; N, 22.93. Found: C, 59.11; H, 9.34; N, 23.10.

1-Ethyl-3-(2-morpholinyl-(4)-ethyl)-carbodiimide Metho-*p*-toluenesulfonate (III).—A mixture of 2.0 g. (0.011 mole) of methyl *p*-toluenesulfonate and 2.0 g. (0.11 mole) of carbodiimide II was heated on a steam-bath for 10 minutes. On trituration with benzene the mixture crystallized; 3.6 g. (90%), m.p. 86–88°. Recrystallization from an acetone–benzene mixture raised the m.p. to 91–93°.

Anal. Calcd. for $C_{17}H_{27}N_3O_4S$: C, 55.27; H, 7.37; N, 11.38. Found: C, 55.41; H, 7.50; N, 11.50.

Reaction of Gelatin[7] with an Excess of 1-Ethyl-3-(2-morpholinyl-(4)-ethyl)-carbodiimide Metho-*p*-toluenesulfonate (III). Experiment 1.—To a solution of 2.0 g. of gelatin[7] in 25.0 ml. of water was added 1.5 g. of III. The solution gelled almost immediately (30 seconds), but liquefied on storage at room temperature for 16 hours. The resulting solution was dialyzed (using $^8/_{32}''$ cellulose casing) for 4 days. The solution was freeze-dried to a white powder; weight 2.0 g. A Sorensen titration[5] on 0.4 g. required 0.25 ml. of 0.103 *N* sodium hydroxide. An untreated gelatin sample (0.4 g.) required 2.6 ml. A Van Slyke analysis yielded 0.19% nitrogen, while untreated gelatin yielded 0.64% nitrogen.

Experiment 2.—A solution of gelatin in 50.0 ml. of water was gelled with 2.25 g. of carbodiimide III. The gel was immediately freeze-dried, followed by trituration with 500 ml. of water. The resulting material after drying weighed 3.0 g. The wash water on evaporation yielded 2.3 g. of urea IV.

A 0.5-g. sample of the above-treated gelatin was dissolved in 20 ml. of a 50% calcium chloride solution by heating on a steam-bath for 1 hour. A Sorensen titration[5] required 0.65 ml. of 0.103 *N* sodium hydroxide.

When 0.1 g. of the gelatin prepared above was suspended in 2.0 ml. of water containing 75 mg. of urea IV, no liquefaction occurred even after 9 days. If, however, carbodiimide was substituted for IV, liquefaction occurred.

When conductometric amino titrations[8] were carried out on the gelatins prepared in both runs 1 and 2, a decrease in amino content as compared to untreated gelatin was observed.

Experiment 3.—A solution of 0.2 g. of gelatin, 0.45 g. of urea and 0.15 g. of carbodiimide III in 4.0 ml. of water gelled after 20 seconds. On storage overnight the reaction mixture liquefied.

Reaction of Carbodiimide III and Benzoyl Gelatin.[4]—To a solution of 0.1 g. of benzoyl gelatin[4] in 2 ml. of water was added 0.1 g. of III. On stirring no sudden gelation occurred as with the control gelatin.

(7) The gelatin was obtained from the Atlantic Gelatin Co., Division of General Foods, Lot #6200-X.

The Biogenesis of Nicotine. III. Further Observations on the Incorporation of Ornithine into the Pyrrolidine Ring[1]

BY EDWARD LEETE AND KENNETH J. SIEGFRIED

RECEIVED MARCH 6, 1957

Radioactive nicotine was isolated from two groups of *Nicotiana tabacum* plants, which were harvested one and three weeks after the administration of equal counts of ornithine-2-C^{14}. The nicotine from the two experiments had almost the same specific activity, indicating that little or no metabolic breakdown of nicotine had occurred during the last two weeks of the second experiment. The nicotine from both experiments was degraded unambiguously and all the activity in the alkaloid was shown to be equally divided between the two α-carbons of the pyrrolidine ring.

Introduction

It has been shown that radioactive nicotine is obtained when ornithine-2-C^{14} is fed intact *N. tabacum*[1a] or *N. rustica*[2] plants, or to sterile roots[3] of the former species. Degradation of the radioactive nicotine[1a,2] indicated that half the activity was located on C-2 of the nicotine molecule I. This result could be explained by postulating that ornithine was metabolized to a symmetrical compound before incorporation into nicotine. In the biogenetic scheme suggested by the author,[1b] the mesomeric anion of Δ^1-pyrroline functioned as the symmetrical intermediate. Putrescine (1,4-diaminobutane) is another plausible intermediate, which would result from ornithine on decarboxylation. However the feeding of radioactive putrescine to *Datura stramonium* plants did not yield radioactive hyoscyamine,[4] whereas radioactive ornithine was incorporated into the pyrrolidine ring of the hyoscyamine.[5] Furthermore in other biological systems the pyrrolidine ring has been shown to arise from ornithine *via* glutamic-γ-aldehyde, putrescine not being an intermediate.[6]

It was considered of interest to investigate changes in the activity of the nicotine after feeding ornithine-2-C^{14} for varying lengths of time. In the present work radioactive ornithine was administered to two groups of *N. tabacum* plants growing in inorganic nutrient solution. The first group was harvested after 7 days and the second after 21 days. The degradative steps which were used to locate the positions of activity in the radioactive nicotine are shown in Fig. 1. Treatment of nicotine with hydrogen iodide yielded methyl iodide which was absorbed in triethylamine affording methyltriethylammonium iodide (II). Oxidation of nicotine with concentrated nitric acid yielded

nicotinic acid (III) and 3-nitro-5-(3′-pyridyl)-pyrazole (V). This pyrazole derivative was first isolated by Gough and King[7] who suggested that it was 4-nitro-5-(3′-pyridyl)-pyrazole. The assigned position of the nitro group was shown to be incorrect by Lund[8] and shown to be actually on the 3-position by Clemo and Holmes.[9] The mechanism of the formation of the pyrazole is being inves-

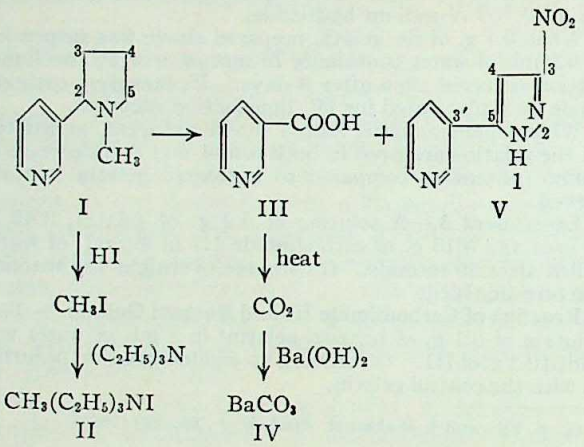

Fig. 1.—Degradation of radioactive nicotine.

tigated. It is only obtained in about 5% yield from nicotine, but it is separated readily from nicotinic acid by adjustment of the *p*H of the oxidation mixture. The pyrazole derivative contains all the carbons of nicotine except C-5 and the N-methyl group. The nicotinic acid was decarboxylated in boiling quinoline, the evolved carbon dioxide being absorbed in barium hydroxide.

Experimental[10]

Administration of the Ornithine-2-C^{14} to the Tobacco Plants and Isolation of the Nicotine.—The *N. tabacum* (variety Turkish Samsun) was grown as previously described[1b] in soil and then in inorganic nutrient. When they were about 4 months old, eight healthy plants (about 30 inches tall) were selected and ornithine-2-C^{14} monohydrochloride[11] (490 mg.) with an activity of 7.56×10^7 c.p.m./m*M*[12] (total activity, 2.22×10^8) was divided equally between their nutrient solutions. After 7 days four of the plants were harvested. The method of isolation of the nicotine was identical with that used for the isolation of anabasine from *N. glauca*,[1b] and was less tedious than the method previously used. In brief, the method involved digestion of the fresh macerated plant with chloroform and aqueous ammonia. The chloroform was extracted with 2 *N* sulfuric acid, which was then made basic with ammonia and again extracted with chloroform yielding crude nicotine after drying and evaporation. The crude alkaloid[13] was distilled *in vacuo* and converted to the diperchlorate. After 21 days the other four plants were harvested and the nicotine similarly isolated. Activity and weights of plant material from the two experiments are shown in Table I.

TABLE I

TOTAL ACTIVITIES IN C.P.M.

	7 day	21 day
Fresh wt. of plants at time of harvesting, g.	810	860
Dried wt. of plant after extraction with $CHCl_3$ and NH_3, g.	41	51
Wt. of distilled nicotine, mg.	96	115
Activity of:		
Chloroform extract	1.0×10^6	1.1×10^6
Ammoniacal sap	1.5×10^6	0.8×10^6
Dried residue[14]	7.1×10^6	4.2×10^6
Crude nicotine (not distilled)	0.6×10^6	0.7×10^6

Degradation of the Nicotine. (a) Activity in the N-Methyl Group.—About 70 mg. of the undiluted nicotine diperchlorate was dissolved in water, made alkaline with sodium hydroxide and the solution extracted with ether. The dried ether solution water evaporated and the residue distilled *in vacuo* (120° (0.01 mm.)). The distilled nicotine was demethylated according to the procedure of Brown and Byerrum.[15]

(b) Oxidation with Nitric Acid.—The active nicotine diperchlorate (100 mg.) was diluted with inactive perchlorate (1.900 g.) and recrystallized from ethanol. Diluted nicotine diperchlorate (1.50 g.) was dissolved in 20 ml. of concentrated nitric acid and heated at 100° for 18 hours. The solution was then evaporated to dryness *in vacuo* and the residue redissolved in 10 ml. of water. The pale yellow solution was brought to *p*H 5 by the addition of 10% sodium hydroxide. At this *p*H a yellow crystalline precipitate of 3-nitro-5-(3′-pyridyl)-pyrazole (V) (32.6 mg., 4.1%) separated out. It was sublimed (200° (0.001 mm.)) and recrystallized from glacial acetic yielding long colorless needles, m.p. 277–278°.

Anal. Calcd. for $C_8H_6N_4O_2$: C, 50.53; H, 3.18. Found: C, 50.76; H, 2.98.

The filtrate obtained after removal of the pyrazole derivative contained nicotinic acid which was isolated as its cupric salt and degraded as previously described.[1b] The activities of nicotine and its degradation products from the two feeding experiments are shown in Table II. The activities are for carrier free material.

TABLE II

	Specific activities (c.p.m./m*M*) 7 day expt.	21 day expt.
Ornithine-2-C^{14} fed	7.56×10^7	7.56×10^7
Nicotine diperchlorate	9.0×10^5	8.4×10^5
Nicotine dipicrate	8.9×10^5	8.2×10^5
3-Nitro-5-(3′-pyridyl)-pyrazole (V)	4.6×10^5	4.4×10^5
Nicotinic acid (III)	4.3×10^5	4.1×10^5
Nicotinic acid hydrochloride	4.4×10^5	4.0×10^5
Methyltriethylammonium iodide (II)	0	0
Barium carbonate (IV)	4.2×10^5	3.9×10^5

Discussion

An examination of Table I shows that the loss of activity from the plants was surprisingly large. Thus after 7 days only 9% (9.6×10^6 c.p.m.) of the radioactive carbon administered in the form of ornithine remained in the plant. After 21 days the activity in the plant had been reduced to 5% (6.1×10^6). The radioactive carbon was presumably ex-

pired as carbon dioxide since the activity of the nutrient solution was negligible. Although the total activity of the plants in the 21 day experiment was less than in the 7 day experiment, the activity of the crude alkaloid fraction had increased slightly.

It is considered that there was an initial rapid uptake of radioactive ornithine which was incorporated into proteins and a certain fraction into nicotine. Inactive ornithine was then synthesized by normal routes from inactive precursors. This inactive ornithine apparently exchanged with combined radioactive ornithine in proteins or other non-alkaloid plant components reducing the activity in the residual plant material. Some of the released radioactive ornithine would be incorporated into nicotine and some would be oxidized to carbon dioxide which on expiration would reduce the over-all activity in the plant. Since the nicotine fraction had a slightly higher activity after 21 days it appears that nicotine does not re-enter the general metabolic pool of the plant once it has been formed. Work is proceeding to see whether the nicotine remains indefinitely in the plant without undergoing metabolic change.

The activities of nicotine and its degradation products in the two experiments are almost identical and they can be discussed together. No activity was found in the N-methyl group. This result is in agreement with that previously obtained.[1a] Dewey, *et al.*,[2] detected a small amount of activity in the N-methyl group after feeding ornithine-2-C^{14} to tobacco plants. The plants used by these workers were younger than ours and possibly had not as large a photosynthetic capacity. Thus the plants were possibly deficient in carbon and would utilize some of the breakdown products of ornithine for the synthesis of N-methyl groups, albeit inefficiently. Our plants were grown in a strong draught, expired radioactive carbon dioxide being rapidly swept away. It has been reported[16] that excised tobacco leaves utilize carbon dioxide for the synthesis of the N-methyl group of nicotine.

The activity of the barium carbonate represents the activity of C-2 of nicotine. Since the activity of the nicotinic acid and its hydrochloride are almost identical with this, there must be negligible activity in the pyridine ring. Since no activity was found in the N-methyl group, the difference in the activity of the nicotine and the pyrazole (V) represents the activity of C-5. The difference in the activity of the pyrazole and nicotinic acid represents the activity of C-3 and C-4. This is negligible, thus all the activity in the nicotine is located on C-2 and C-5 and is equally divided between them. This confirms our previous hypothesis[1a] that ornithine is metabolized to a symmetrical four carbon compound before incorporation into the nicotine molecule.

Acknowledgment.—The authors are indebted to Dr. S. G. Wildman and Dr. A. Lang of the Department of Botany of this University for help in the cultivation of the tobacco plants.

The Veratrum Alkaloids. XLI.[1] The Position of the Second Hydroxyl in Rubijervine and the Identity of Certain Dehydrogenation Products

BY S. WILLIAM PELLETIER AND DAVID M. LOCKE

RECEIVED MARCH 22, 1957

The second hydroxyl of rubijervine is shown to be at position 12 by infrared and optical rotatory dispersion studies on rubijervone-12. Reduction of this ketone with sodium-in-propanol gives 12-epirubijervine (IIIa), showing that the 12-hydroxyl in rubijervine (Ia) is axial. Molecular rotation data for rubijervine and 12-epirubijervine derivatives are also in agreement with assignment of the 12α- and 12β-configurations, respectively, to these compounds. The hydrocarbon $C_{18}H_{16}$ from the dehydrogenation of rubijervine is shown to be 1′-methyl-1,2-cyclopentenophenanthrene (VIII). The phenol $C_{18}H_{16}O$ obtained in the same dehydrogenation has been converted to 1′-methyl-1,2-cyclopentenophenanthrene (VIII) by reduction of its diethyl phosphate ester with sodium in liquid ammonia. Its infrared spectrum leads to the conclusion that it is 1′-methyl-1,2-cyclopentenophenanthrol-3 (X).

The various species of *Veratrum* elaborate a series of complex alkaloids, some of which have found use in combatting hypertensive disorders. The alkaloids fall into two broad classes.[2,3] The first includes a series of highly oxygenated alkamines of the formula $C_{27}H_{43}NO_{7-9}$, which occur in nature as esters of relatively simple organic acids. The second comprises a group of C_{27}-bases of low oxygen content which occur free or as glycosides. Rubijervine,[3,4] an example of the latter class, was first discovered by Wright and Luff[5] in *Veratrum album*[6] and has since been found in *Veratrum viride*.[7,8] Studies by Jacobs and Craig showed this alkaloid to have the molecular formula $C_{27}H_{43}NO_2$[9] and to be a hexacyclic tertiary steroidal base containing a 3β-hydroxy-Δ^5-stenol system and a second hydroxy

group.[10] Dehydrogenation of rubijervine with selenium afforded 2-ethyl-5-methylpyridine and a methylcyclopentenophenanthrene[9] and a phenanthrol, $C_{18}H_{16}O$,[9,11] both of uncertain identity. Rubijervine was subsequently shown to be a hydroxysolanidine by Sato and Jacobs who oxidized rubijervine monobenzoate to a ketone which was reduced by the Wolff–Kishner method to solanidine.[11] These workers also reduced diketodihydrorubijervine to solanidan-3β-ol. An assignment of the second hydroxyl group of rubijervine was made on the basis of the following argument. Since it is this hydroxyl which appears in the $C_{18}H_{16}O$ phenanthrol (no phenol was isolated from solanidine under the same conditions),[12] its position is thereby restricted to the A, B or C ring. The available data exclude all of these positions except carbon-12. Thus, rubijervine is stable to periodate; dihydrorubijervine gives a diketone which is stable to alkali, forms a disemicarbazone, fails to form a pyridazine with hydrazine and shows no interaction of the chromophores in the ultraviolet; rubijervone-12 shows no α,β-unsaturation in the ultraviolet.[11] In addition, the molecular rotation difference between diketodihydrorubijervine and solanidan-3-one is in agreement with that recorded for a 12-keto steroid.[13] The second hydroxyl in rubijervine was tentatively assigned the α-configuration by Sato and Jacobs[11] who noted that the molecular rotation difference between dihydrorubijervine and solanidan-3β-ol is comparable to that recorded for a 12α-hydroxy steroid.[13]

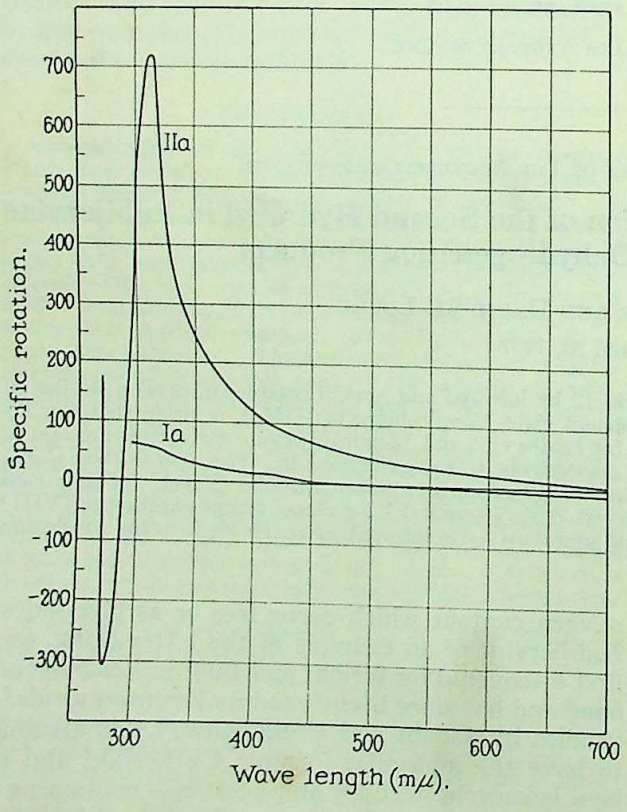

Fig. 1.—Rotatory dispersion curves[16] of: rubijervine (Ia) and rubijervone-12 (IIa) in dioxane.

Data have now been accumulated which demonstrate that rubijervine is indeed Δ^5-solanidene-3β,12α-diol. It is the purpose of this paper to present the details of this work and to discuss the identity of the hydrocarbon $C_{18}H_{16}$[9] and phenol $C_{18}H_{16}O$[9,11] obtained from the dehydrogenation of rubijervine.

The structure proposed requires that rubijervone-12 benzoate (IIb), produced by chromic acid oxidation of rubijervine 3-benzoate (Ib), should show absorption in the infrared for an unconjugated ketone in a six-membered ring. This compound shows, in fact, only single carbonyl absorption at 1708 cm.$^{-1}$, due to both the benzoyl and the keto groups.[14] Its hydrolysis product, rubijervone-12 (IIa), shows carbonyl absorption at 1706 cm.$^{-1}$.[15] More striking confirmation of the position of this carbonyl function is available from a comparison of the optical rotatory dispersion curves of rubijervine and rubijervone-12 (IIa) (Fig. 1),[16] which were determined in the laboratory of Professor Carl Djerassi. The curve of the ketone with a "maximum" of 720° at 313 mμ may be compared with those of a series of 12-keto bile acids which show "maxima" of 772–887° at 305–307 mμ[17] and with those of 12-ketosapogenins which show "maxima" of 424°, 783° and 802° at 312.5–315 mμ.[18] In the case of the bile acids the maxima are more positive than for rubijervone-12 because of the higher background rotation of the bile acid system. The curve is perfectly compatible with that expected for a 12-ketone, while an 11-ketone may be definitely excluded.

The configuration of the second hydroxyl in rubijervine was established by two lines of evidence, the first chemical and the second based on molecular rotation differences.

Thus, reduction of rubijervone-12 (IIa) by sodium-in-alcohol (a reaction which is known to be the equivalent of equilibration[19]) should in theory produce the epimer with a 12-equatorial hydroxyl,[20] *viz.*, Δ^5-solanidene-3β,12β-diol (IIIa). In practise, this reaction afforded in 79% yield, not rubijervine (see Fig. 2 for infrared spectra), but an isomer of m.p. 231–233°, $[\alpha]^{27}D$ −18°. The benzoate of the above ketone, Δ^5-solanidene-3β-ol-12-one benzoate (IIb), was similarly reduced to the same isomer IIIa. Catalytic reduction of IIIa over plat-

(10) W. A. Jacobs and L. C. Craig, (a) *J. Biol. Chem.*, **152**, 641 (1944); (b) **159**, 617 (1945).

(14) L. J. Bellamy, "The Infrared Spectra of Complex Molecules," John Wiley and Sons, Inc., New York, N. Y., 1954, pp. 114, 152.

(15) It should be noted that even if the position of the hydroxy is not restricted to the A, B or C ring, the 15-position is excluded by the infrared data. In addition, the 26-position is excluded since oxidation at this position should produce a lactam and not a ketone. It seems unlikely that a hydroxyl group would occur on the 23- or 24-position because of the isolation from the dehydrogenation mixture of 2-ethyl-5-methylpyridine and the failure to isolate a hydroxypyridine. Both jervine and veratramine contain oxygen functions at carbon-24 and give rise to hydroxypyridines on dehydrogenation. By this alternative argument, all positions in the D, E and F rings may be excluded as possible locations for the hydroxyl.

(16) We wish to express our grateful appreciation to Professor Carl Djerassi for supplying the rotatory dispersion curves presented in this paper and also for his advice in interpreting them.

inum oxide gave in 84% yield a dihydro compound, solanidane-3β-12β-diol (IV), m.p. 220–221°, $[\alpha]^{26}D$ 27°, different from dihydrorubijervine, but furnishing on oxidation with chromic acid the known diketodihydrorubijervine (V).[11] This series of reactions (together with those reported below) demonstrates that the product of sodium-in-alcohol is in fact 12-epirubijervine (IIIa) and possesses a hydroxyl with the 12β-configuration (equatorial).

lated in small yield rubijervine monobenzoate (Ib) and in slightly greater yield its 12-epimer, 12-epirubijervine 3-benzoate (IIIb), m.p. 230.5–231.5°, $[\alpha]^{26}D$ −4°. The structure of the latter was shown by its hydrolysis to 12-epirubijervine (IIIa).

It has been pointed out that the molecular rotation difference between dihydrorubijervine and solanidane-3β-ol is close to that recorded for a

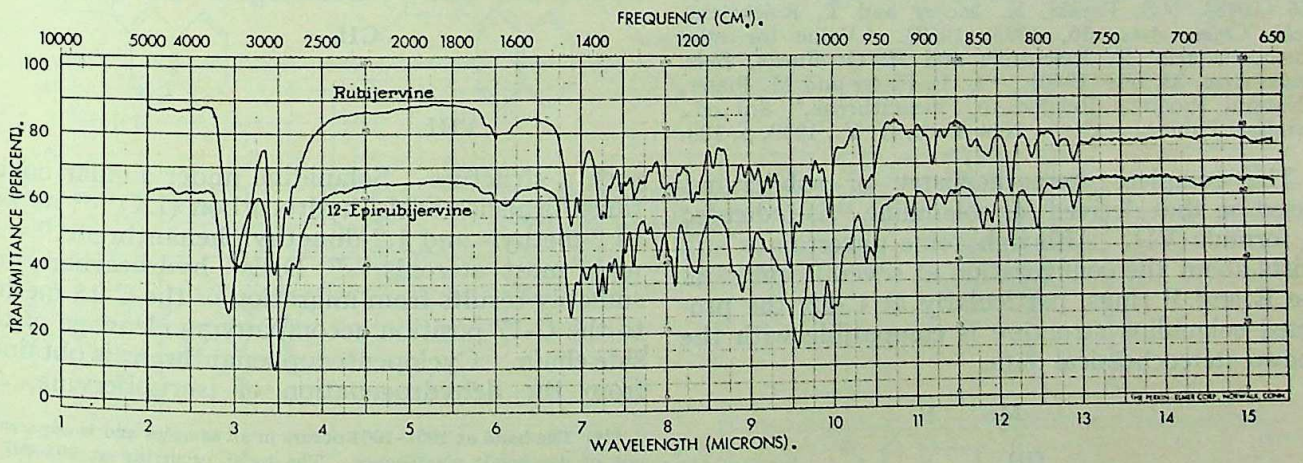

Fig. 2.—Infrared absorption spectra in KBr.

It is a general rule that lithium aluminum hydride or sodium borohydride reduces a highly hindered ketone to an axial hydroxyl and an unhindered ketone to an equatorial hydroxyl.[20,21] The 12-position in steroids is a moderately hindered one, and it is therefore not surprising that rockogenin, a 12-ketosapogenin, gives on lithium aluminum hydride reduction a mixture of epimeric 12-diols.[22] In agreement with these results, sodium borohydride reduction of rubijervone-12 benzoate (IIb) produced a mixture of epimers from which was isolated in small yield rubijervine monobenzoate (Ib) and in slightly greater yield its 12-epimer, 12-epirubijervine 3-benzoate (IIIb), m.p. 230.5–231.5°, $[\alpha]^{26}D$ −4°. The structure of the latter was shown by its hydrolysis to 12-epirubijervine (IIIa).

It has been pointed out that the molecular rotation difference between dihydrorubijervine and solanidane-3β-ol is close to that recorded for a 12α-hydroxy steroid. With a series of rubijervine derivatives which are epimeric at C-12 now available, the molecular rotation differences of both configurations may be compared with those of related compounds whose configuration at carbon-12 is known. In Table I are included a series of rubijervine and 12-epirubijervine derivatives together with appropriate steroids, sapogenins and bile acids. It will be noted that in a given epimeric pair, the molecular rotation difference for the 12α-epimer is always more strongly positive than for the 12β-isomer. Thus the molecular rotation differences support the assignment of the 12α-configuration to compounds of the rubijervine series and the 12β configuration to those of the 12-epirubijervine series.

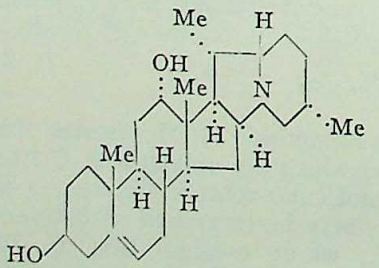
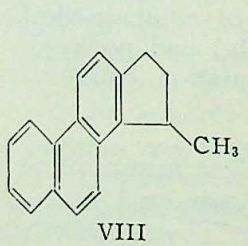
The complete stereochemistry of rubijervine, based on that derived for solanidine,[23] is indicated in formula VII. Although some uncertainty still exists about the configuration at several centers in the E and F rings, particularly at C-22, the proposed solanidine structure is compatible with the known stereochemical data.



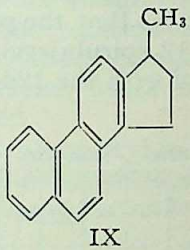
VII, rubijervine

Since the configurations of the hydroxyls in rubijervine and its derivatives now appear well established, it is interesting to consider the assignment of infrared absorption bands in the C–O stretching region to the different types of hydroxyls. The appropriate bands are given in Table II. Solanidine, epirubijervine and rubijervine contain the Δ^5-3β-hydroxy system which appears to be responsible for the absorption at 1048–1047 and 1018–1016 cm.$^{-1}$ [24] (Δ^5-3β-hydroxy steroids, 1052–1050 cm.$^{-1}$).[25] In dihydrorubijervine the 3β-hydroxy allo system absorbs at 1037 cm.$^{-1}$ (3β-hydroxy allo steroids, 1040–1037 cm.$^{-1}$).[25,26] Epirubijervine contains, in addition to the Δ^5-3β-hydroxy system, a 12β (equatorial) hydroxyl which apparently absorbs at 1052 cm.$^{-1}$, although its absorption may coincide with that of the equatorial hydroxyl at C-3. The absorption of rubijervine and dihydrorubijervine at 1028–1026 cm.$^{-1}$ may be assigned to the 12α (axial) hydroxyl. If these assignments are correct, the 12-equatorial hydroxyl absorbs at a higher frequency than the 12-axial epimer. This situation parallels that found for the 2-, 3- and 4-positions in the steroids,[25,27] but the reverse is true for the 3-position in the triterpenes.[28]

In the course of a study of the dehydrogenation products of rubijervine, Jacobs and Craig isolated a hydrocarbon $C_{18}H_{16}$ having an ultraviolet absorption spectrum similar to that of cyclopentenophenanthrene.[9] Its melting point and that of its TNB adduct were very close to the corresponding constants reported for 1′-methyl-1,2-cyclopentenophenanthrene.[29] It is difficult to rationalize the formation from rubijervine of a hydrocarbon of



VIII



IX

such a structure. Solanidine under similar conditions furnishes Diels' hydrocarbon (IX)[12,30] as well as 2-methyl- and 1,2-dimethylphenanthrene.[12] As with most steroids,[31,32] Diels' hydrocarbon presumably results from migration of the C-18 methyl to the C-17 position accompanying cleavage of the side chain. Cyclopentenophenanthrene is obtained from the dehydrogenation of isorubijervine, Δ^5-

TABLE II

POSITION OF THE C–OH STRETCHING BANDS OF RUBIJERVINE AND RELATED COMPOUNDS

Compound	Substitution type	Frequency,[a] cm.$^{-1}$					
Solanidine (VI)	Δ^5,3β-OH(e)		1047s		1018m	1003w	
Epirubijervine (IIIa)	Δ^5,3β-OH(e); 12β-OH(e)	1052m	1047s		1018m	1004m	997m
Rubijervine (Ia)	Δ^5,3β-OH(e); 12α-OH(a)		1048s	1028m	1016m	1003m	
Dihydrorubijervine	5α-H,3β-OH(e); 12α-OH(a)		1037s	1026m		1001m	995m

[a] 5% solutions in CS_2 in 2-mm. cell; s = strong, m = medium, w = weak.

solanidene-3β,18-diol.[10b] In this case, it is presumed that the C_{18}-hydroxyl interferes with the expected migration of this group to the 17-position during the dehydrogenation. However, with rubijervine there seems to be no simple explanation for the presumed appearance of a methyl group at the 1′-position of cyclopentenophenanthrene. Several different structural features may lead to methyl migrations during dehydrogenation. For example, in addition to the methyl group migration in the production of Diels' hydrocarbon there are instances where a methyl migrates to an unsubstituted position on the aromatic nucleus.[33] Cases are also known in which a methyl group migrates to a position occupied by a hydroxyl, presumably by a retropinacol rearrangement, prior to the dehydrogenation proper.[34] The unique feature of the dehydrogenation of rubijervine is the apparent methyl migration to an unsubstituted methylene on the non-aromatic portion of the molecule, two carbon atoms removed from its original site.

These considerations seemed to warrant a further study of the identity of this hydrocarbon. Accordingly, a sample of the hydrocarbon from the original dehydrogenation,[9] which was placed at our disposal by Drs. Jacobs and Craig, was purified by repeated chromatography and crystallization to give material melting at 78–80° cor. and with an ultraviolet absorption spectrum almost identical with Diels' hydrocarbon[35] IX and with cyclopentenophenanthrene.[36] A new analysis confirmed its formula as $C_{18}H_{16}$. Synthetic 1′-methyl-1,2-cyclopentenophenanthrene[29] was unavailable for direct comparison, but 3-methyl-1,2-cyclopentenophenanthrene,[37,38] m.p. 86–87°, and 5-methyl-1,2-cyclopentenophenanthrene,[38,39] m.p. 75–76°, both showed melting point depressions with the hydrocarbon from rubijervine. The infrared spectrum of the hydrocarbon from rubijervine is included in Fig. 3. It is appreciably different from all of the recorded spectra[40] for the methyl-1,2-cyclopentenophenanthrenes, which include all but the 1′-, 2′- and 7-isomers. Since the melting points[29,41] of the last two isomers and/or of their derivatives are different from those of the hydrocarbon from rubijervine, only 1′-methylcyclopentenophenanthrene remained as a possibility. Accordingly, the synthesis of this compound by the method of Ruzicka, *et al.*,[29] was repeated (with minor modification)[42] to give material of m.p. 79–81°, mixture m.p. with the hydrocarbon from rubijervine, 78–80°. The ultraviolet and infrared absorption spectra (Fig. 3) of the latter were identical with those of the synthetic sample. In addition, the picrates and trinitrobenzene adducts of each hydrocarbon showed no melting point depression on admixture. Thus, the identity of the $C_{18}H_{16}$ hydrocarbon from rubijervine with 1′-methyl-

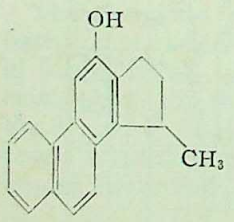
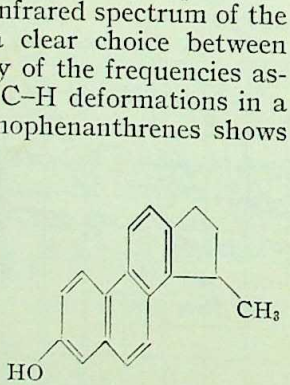
1,2-cyclopentenophenanthrene is established.

A related question concerns the formation of the phenanthrol $C_{18}H_{16}O$, m.p. 136–138°, obtained in the same dehydrogenation.[9] In order to provide more information concerning this phenol, which was kindly supplied by Drs. Jacobs and Craig, several attempts were made to convert it to the corresponding hydrocarbon by heating with zinc dust. At temperatures high enough to effect reduction, rearrangement occurred since only a high melting hydrocarbon fraction could be obtained which had the ultraviolet spectrum of chrysene. Recently Kenner and Williams[43] have reported a mild method for the conversion of phenols to aromatic hydrocarbons, which involves reduction of the aryl diethyl phosphate with sodium in liquid ammonia. Since the method had been tested only with benzene and naphthalene derivatives, its application to phenols of higher molecular weight was first explored by reduction of 3-phenanthrol,[44] chosen as a suitable model for the phenol from rubijervine. The reduction proceeded smoothly to give phenanthrene in 30% yield. Reduction of the phenol from rubijervine by this method gave in 36% yield, 1′-methyl-1,2-cyclopentenophenanthrene, identified by mixture melting point, infrared (Fig. 3) and ultraviolet absorption spectra. The hydroxyl of this phenol has been assumed (*vide supra*) to be derived from the second hydroxyl (position-12) of rubijervine. If so, the phenol can be assigned the structure 1′-methyl-1,2-cyclopentenophenanthrol-3 (X). If, however, the hydroxyl is derived from the 3-hydroxyl of rubijervine, the structure should be 1′-methyl-1,2-cyclopentenophenanthrol-7 (XI). The infrared spectrum of the $C_{18}H_{16}O$ phenol provides a clear choice between these alternatives. A study of the frequencies associated with the aromatic C–H deformations in a series of fifteen cyclopentenophenanthrenes shows



X



XI

that without exception compounds having four adjacent ring hydrogens (*i.e.*, an unsubstituted A-ring) show strong absorption at 741–762 cm.$^{-1}$ [40]. The only other situation which causes strong absorption in this region is the presence of three adjacent ring hydrogens,[45] and these occur in neither X nor XI. Since the phenol from rubijervine shows strong absorption at 748 cm.$^{-1}$ [46] it appears that the A-ring is unsubstituted and that the phenol therefore has structure X. Regardless of the precise structure of the phenol, the fact that it is a derivative of 1′-methylcyclopentenophenanthrene demonstrates that the methyl group is able to migrate without prior, or simultaneous, loss of the hydroxyl from the molecule. On the other hand, the hydroxyl seems to be implicated in this migration in some fashion since solanidine (VI), in which this hydroxyl is absent, gives Diels' hydrocarbon. Thus the precise mode of formation of the dehydrogenation products from rubijervine remains to be explained.

Acknowledgment.—We wish to express our appreciation to The Lilly Research Laboratories, Eli Lilly and Co., for a generous grant in support of this work. We also wish to thank Dr. Walter A. Jacobs who kindly read the manuscript and who placed his collection of samples at our disposal. Analyses are by Mr. D. Rigakos of this Laboratory. The technical assistance of Miss Vera Bohan is gratefully acknowledged.

Experimental

General Experimental Procedures.—Boiling points are uncorrected. Melting points are corrected and were taken on a hot-stage equipped with a polarizer. Finely powdered samples were placed on the stage about 15° below the melting point and the temperature raised rapidly to within 5° of the melting point. The temperature was then raised 2°/min.

Petroleum ether refers to a light petroleum fraction of b.p. 30–60°. Ligroin refers to a light petroleum fraction of b.p. 60–70°.

The removal of solvents *in vacuo* was accomplished with a rotating flash evaporator at about 15 mm. and with a heating bath operated usually at about 35–40°.

Infrared spectra were determined from 2 to 15 μ without compensation on a Perkin–Elmer model 21 double beam spectrometer with sodium chloride optics, set at resolution 927, response 2, gain 6, suppression 2 and a scanning speed of 0.3 μ/minute on a chart scale of 5 cm. for 1 μ. Ultraviolet spectra were determined in 95% ethanol on a Beckman model DU spectrophotometer.

Rubijervine.—The sample of rubijervine[9,47] used for the transformations reported in this work was purified by recrystallization from 95% ethyl alcohol. It consisted of colorless rods, m.p. 242–244°, $[\alpha]^{27.5}D$ +8° (*c* 0.54, chf.) $[\alpha]^{27.5}D$ +20° (*c* 1.04, MeOH), $[\alpha]^{27.5}D$ +11 (*c* 1.00, dioxane).[48]

Anal. Calcd. for $C_{27}H_{43}O_2N$: C, 78.40; H, 10.48. Found: C, 78.08; H, 10.23.

Solanidine Benzoate.—A sample of solanidine benzoate,[49] prepared by benzoylation of solanidine in pyridine, had m.p. 213–214°, $[\alpha]^{27}D$ −6° (*c* 1.40, chf.).

Anal. Calcd. for $C_{34}H_{47}O_2N$: C, 81.39; H, 9.44. Found: C, 81.44; H, 9.27.

Rubijervine 3-Benzoate.—The monobenzoate of rubijervine was prepared as reported by Sato and Jacobs[11] and was isolated directly from the reaction mixture by crystallization from benzene without recourse to chromatography. Colorless prisms were obtained, m.p. 256–259°, $[\alpha]^{28}D$ +22° (*c* 1.60, chf.).

Anal. Calcd. for $C_{34}H_{47}O_3N$: C, 78.87; H, 9.15. Found: C, 78.94; H, 8.97.

Rubijervone-12 Benzoate.—Oxidation of rubijervine monobenzoate according to the directions of Sato and Jacobs[11] gave rubijervone-12 benzoate, m.p. 227–231°, with a prior change in crystalline form at *ca.* 210°. A double melting point is reported, 214–216°, 233–234°. This compound showed in the infrared (Nujol) a single peak in the carbonyl region at 1708 cm.$^{-1}$.

(43) G. W. Kenner and N. R. Williams, *J. Chem. Soc.*, 522 (1955).

(44) We wish to thank Professor L. F. Fieser for a generous sample of 3-phenanthrol.

(45) This type of substitution is characterized by an additional absorption band at 786–792. The phenol from rubijervine shows no absorption in this region.

(46) *Cf.* the spectrum of 1,-methylcyclopentenophenanthrene which has a strong band at 754 cm.$^{-1}$ (KBr).

(47) The authors wish to thank Dr. A. Stoll of Sandoz for placing at their disposal a generous sample of rubijervine.

(48) *Cf.* Fig. 1. The values obtained for $[\alpha]D$ (dioxane) in Prof. Djerassi's rotatory dispersion studies were −4° (*c* 0.05) and −7° (*c* 0.095). The accuracy at the sodium D-line is rather poor, due to the dilute solutions used.

Rubijervone-12.—Hydrolysis of rubijervone-12 benzoate gave material melting at 229.5–232°. In our hands the sample prepared by Sato and Jacobs[11] melted at 226–228° (reported[11] m.p. 236–238° (uncor.)). A mixture of these two samples showed intermediate melting. The infrared spectrum (Nujol) of this compound shows hydroxyl absorption at 3185 cm.$^{-1}$ and carbonyl absorption at 1706 cm.$^{-1}$.

12-Epirubijervine. A. From Rubijervone-12.—A solution of 352 mg. of rubijervone-12 in 20 ml. of refluxing *n*-propyl alcohol was saturated slowly with small pieces of sodium over a period of several hours. After cooling to room temperature, the mixture was treated with several drops of ethyl alcohol and evaporated to dryness *in vacuo*. The residue was taken up in benzene and water. The aqueous layer was extracted with benzene, and the combined benzene extracts were washed with a small amount of water, which gave rise to an emulsion. Filtration of the mixture gave a crystalline solid, m.p. 226–228°. The benzene layer was evaporated to dryness *in vacuo* giving further crystalline material melting at 224–228°, showing partial melting at 208°. The former gave on recrystallization from benzene 123 mg. of large rods converted above 160° to tiny needles, m.p. 230–231°. The latter gave 155 mg. of material showing the same prior change in crystalline form and a final melting point of 224–228°.

An analytical sample was prepared by two recrystallizations from acetone, m.p. 231–233°, $[\alpha]^{27}D$ −18° (*c* 1.07, chf.). The infrared absorption spectrum is included in Fig. 2.

Anal. Calcd. for $C_{27}H_{43}O_2N$: C, 78.40; H, 10.48. Found: C, 78.46; H, 10.56.

B. From Rubijervone-12 Benzoate.—A solution of 90 mg. of rubijervone-12 benzoate in 5 ml. of refluxing *n*-propyl alcohol was saturated with sodium and worked up as above (without emulsion formation) to give 87 mg. of crude product, m.p. 226–229°, with the same preliminary change in crystalline form as noted above. Recrystallization from acetone gave needles, m.p. 232–234°. A mixture of this sample with an authentic sample of rubijervine (m.p. 240–242°) melted at 222–229°.

Solanidane-3β,12β-diol.—A solution of 55 mg. of 12-epirubijervine in methanol containing a small amount of acetic acid was treated with hydrogen in the presence of 28 mg. of platinum oxide. In 1 hr. one mole of hydrogen was consumed. The catalyst was then removed by filtration, and the filtrate was evaporated to dryness *in vacuo*. The residue was recrystallized from ether to give 46 mg. of needles, m.p. 218–220°. An analytical sample prepared by several recrystallizations from acetone–ligroin melted at 220–221°, $[\alpha]^{26}D$ +27 (*c* 1.45, chf.).

Anal. Calcd. for $C_{27}H_{45}O_2N$: C, 78.02; H, 10.91. Found: C, 78.13; H, 11.17.

Solanidane-3,12-dione.—To a solution of 12 mg. of solanidane-3β,12β-diol in 2 ml. of glacial acetic acid was added 5 mg. of chromic oxide in 1 ml. of 90% acetic acid. After standing at room temperature for 1 hr., the solution was poured into 25 ml. of water and extracted with chloroform. The chloroform extracts were washed successively with sodium bicarbonate and water, dried and evaporated to dryness *in vacuo* to give 5 mg. of plates, m.p. 237–239°, undepressed on admixture with an authentic sample.[11]

Sodium Borohydride Reduction of Rubijervone-12 Benzoate. 12-Epirubijervine 3-Benzoate.—To a solution of 54 mg. of rubijervone-12 benzoate in 50 cc. of ether–methanol (60/40) was added 167 mg. of sodium borohydride. After standing at room temperature for 3 hr., the solution was evaporated to dryness *in vacuo*. The residue was taken up in chloroform and water, and the aqueous layer was extracted with chloroform. Concentration of the chloroform extracts gave 54 mg. of crude material, m.p. 215–230° (softens *ca.* 205°).

A partial fractional crystallization of this material furnished two fractions, one of m.p. 252–254° and the other with m.p. 220–222°. From the former was isolated by chromatography over alumina and recrystallization from benzene 4 mg. of crystals, m.p. 255–259°, undepressed on admixture with an authentic sample of rubijervine benzoate.

The 220–222° fraction on chromatography over alumina and subsequent recrystallization from ligroin furnished 16.5 mg. of tiny, fine needles of 12-epirubijervine 3-benzoate, m.p. 230.5–231.5°, $[\alpha]^{26}D$ −4° (*c* 0.83, chf.).

Anal. Calcd. for $C_{34}H_{45}O_3N$: C, 79.18; H, 8.80. Found: C, 79.10; H, 9.07.

Hydrolysis of 12-Epirubijervine 3-Benzoate.—A solution of 5 mg. of 12-epirubijervine 3-benzoate in 3 ml. of 1% methanolic potassium hydroxide was refluxed on the steam-bath for 0.5 hr. The solution was then evaporated to dryness *in vacuo* and taken up in chloroform and water. The chloroform layer was washed with water, dried and evaporated to dryness *in vacuo*. The residue was crystallized from acetone to give 3 mg. of long rods, m.p. 234–236°. A mixture with 12-epirubijervine (m.p. 231–233°) melted at 232–235°.

1′-Methyl-1,2-cyclopentenophenanthrene. A. From Rubijervine.—The original sample of the hydrocarbon obtained by Jacobs and Craig[9] from the selenium dehydrogenation of rubijervine was subjected to repeated chromatography over alumina and recrystallization from petroleum ether at 5°. This procedure gave material melting at 78–80° with an ultraviolet absorption spectrum almost identical with Diels' hydrocarbon[35] and with cyclopentenophenanthrene.[36] Its infrared spectrum showed aromatic C–H bands at 868, 830, 819, 758 sh. and 754 cm.$^{-1}$ (Fig. 3).

Anal. Calcd. for $C_{15}H_{16}$: C, 93.06; H, 6.94. Found: C, 92.88; H, 6.80.

The melting point of this material was strongly depressed on admixture with samples of 3-methyl-1,2-cyclopentenophenanthrene[37,38] and 5-methyl-1,2-cyclopentenophenanthrene.[38,39] It was not depressed on admixture with 1′-methyl-1,2-cyclopentenophenanthrene as prepared below. The infrared (Fig. 3) and ultraviolet spectra of the hydrocarbon from rubijervine were identical with those of 1′-methyl-1,2-cyclopentenophenanthrene.

A picrate of this hydrocarbon prepared in methanol melted at 130.5–131.5° (reported 131–132°).[9] A mixture melting point with a sample of the picrate from synthetic 1′-methyl-1,2-cyclopentenophenanthrene (described below) was not depressed.

A TNB of the hydrocarbon from rubijervine prepared in methanol melted at 143–143.5° (reported[9] 144–145°). A mixture melting point with authentic 1′-methyl-1,2-cyclopentenophenanthrene TNB was not depressed.

B. Synthetic.—The synthesis of **2-(1-naphthyl)-ethanol** was accomplished by lithium aluminum hydride reduction of 1-naphthylacetic acid. Reduction of 25 g. of acid for 1 hr. in boiling ether with 5.1 g. of lithium aluminum hydride gave 17.5 g. of 2-(1-naphthyl)-ethanol, m.p. 59–61° (reported 62°).[50] This alcohol was converted to **2-(1-naphthyl)-ethyl bromide**, b.p. 130–135° at *ca.* 0.3 mm., reported[51] b.p. 145–148° at 0.3 mm., in 88% yield by the method of Haworth and Mavin.[51] **Ethyl 5-methylcyclopentanone-2-carboxylate** was synthesized according to the directions of Cornubert and Borrel[52] giving material boiling at 114–119° at *ca.* 14 mm., reported[53] b.p. 105° at 12 mm. The condensation of β-(1-naphthyl)-ethyl bromide with ethyl 5-methylcyclopentanone-2-carboxylate was carried out by the directions of Kon[54] to give the β-keto ester, b.p. 195–208° at *ca.* 1 mm. (reported[54] b.p. 227° at 4 mm.) in 56% yield. This material (8.3 g.) was cyclized and aromatized by the method of Ruzicka, Ehmann, Goldberg and Hösli.[29] The product was isolated from the reaction mixture by chromatography over alumina. Elution with light petroleum gave a first fraction of 2.5 g. of a colorless oil with a blue fluorescence, which partially crystallized on standing. Further elution with the same solvent gave 2.0 g. of faintly yellow oil with a blue fluorescence, which crystallized completely on standing, m.p. 72–76°. Recrystallization of this latter material from ethanol gave 1.5 g. of material of m.p. 78–80°. Further recrystallization raised the melting point to 79–81° (reported[29] m.p. 76–77°).

A picrate of this hydrocarbon was prepared in methanol, m.p. 131–132°. *Anal.* Calcd. for $C_{18}H_{16}C_6H_3N_3O_7$: C, 62.47; H, 4.15. Found: C, 62.78; H, 4.04.

The TNB derivative prepared in methanol melted at 143–144° (reported 143–144°). *Anal.* Calcd. for $C_{18}H_{16}$-$C_6H_3N_3O_6$: C, 64.71; H, 4.30. Found: C, 64.86; H, 4.23.

The Phenol $C_{18}H_{16}O$ from Dehydrogenation of Rubijervine.—A sample of the material obtained by Jacobs and Craig[9] was used without further purification for the experiments reported in this paper. In our hands it melted at 130–132° (reported[9] m.p. 136–138°). Its infrared spectrum (KBr) was characterized by bands at 3240 cm.$^{-1}$ (OH stretching) and 859, 853, 844, 827, 817, 755sh. and 748 cm.$^{-1}$ (aromatic C–H).

Reduction of the Phenol $C_{18}H_{16}O$ with Zinc Dust.—A mixture of 55 mg. of the phenol and 2.1 g. of zinc dust was heated in a sealed tube at 350–360° for 2 hr. After cooling to room temperature, the tube was opened and the contents were extracted repeatedly with benzene. On evaporation to dryness *in vacuo*, the benzene solution gave 39 mg. of a dark brown gum. This material was chromatographed over alumina giving 8 mg. of brown oil on elution with benzene and an additional 30 mg. of brown oil on elution with ether and methanol. The former resisted attempts at further purification and the latter furnished, on rechromatography and recrystallization (Norit) from ether, colorless needles, m.p. 133–134°, undepressed on admixture with starting material.

A mixture of 51 mg. of the phenol and 1.0 g. of zinc dust was heated at 400 ± 10° for 6 hr. to give 18 mg. of crude product which on chromatography over alumina gave on elution with benzene 11.5 mg. of an amorphous colorless glass. This material was crystallized from ethanol to give irregular crystals subliming above 220°, with a melting point *ca.* 242–248°, much dependent on the rate of heating. The melting point of a mixture of this material and a sample of chrysene (m.p. 256–258°) was 252–256°. The ultraviolet absorption spectrum was identical with that reported for chrysene[55] within experimental error.

Reduction of 3-Phenanthrol to Phenanthrene *via* Its Diethyl Phosphate Ester.[43]—Solutions containing 0.28 mmole of diethyl phosphite[56] and of triethylamine in carbon tetrachloride were prepared. A 52-mg. (0.26 mmole) sample of 3-phenanthrol[44] was dissolved in a 1-ml. aliquot of the diethyl phosphite solution, and this solution was cooled in an ice-bath. A 1-ml. aliquot of the triethylamine solution was then added, and the solution was allowed to stand at room temperature overnight. An additional 10 ml. of carbon tetrachloride was added, and the solution was washed with dilute hydrochloric acid and cold dilute sodium hydroxide (four times) and finally water. The organic layer was evaporated to dryness *in vacuo* giving 67 mg. of light brown oil. This material was taken up in a minimum of ether and cooled in a Dry Ice–Cellosolve-bath. A large excess of liquid ammonia was then run in until only one liquid phase was present and a solid had separated. The solution was then removed from the bath, and when it had reached the boiling temperature of the liquid ammonia several drops of ether were added to bring the solid into solution. Small pieces of sodium were added until a permanent blue color developed. Several drops of alcohol were added, and the solution was allowed to evaporate overnight. The residue was taken up in ether, washed with sodium bicarbonate, sodium hydroxide and finally water and then dried and evaporated to dryness *in vacuo* to give 27 mg. of nearly colorless oil. This was chromatographed over alumina to give 14.5 mg. of white crystals, m.p. 83–91°. Recrystallization from ethanol gave colorless scales 95–98°, undepressed when mixed with authentic phenanthrene. The infrared absorption spectrum of this material in KBr was identical with that of an authentic sample.

Reduction of the Phenol $C_{18}H_{16}O$ *via* Its Diethyl Phosphate Ester.—A sample of 45 mg. of the phenol from the dehydrogenation of rubijervine was converted to its diethyl phosphate ester (54 mg.) by the above procedure. Reduction was accomplished as above, 11 mg. (2 moles) of sodium being added without a permanent blue color developing. The reaction mixture was worked up as before giving 28 mg. of crude petroleum ether-soluble product. This material on chromatography over alumina furnished 15 mg. of white crystals, m.p. 75.5–78.5°. Rechromatography and recrystallization from ethanol gave crystals of m.p. 79–81°, undepressed on admixture with authentic 1′-methyl-1,2-cyclopentenophenanthrene. The infrared (Fig. 3) and ultraviolet absorption spectra of this material are identical with those of 1′-methyl-1,2-cyclopentenophenanthrene.

Preparation and Properties of the Isomeric Forms of Cystine and S-Benzylpenicillamine

BY ROBIN MARSHALL, MILTON WINITZ, SANFORD M. BIRNBAUM AND JESSE P. GREENSTEIN

RECEIVED MARCH 28, 1957

Racemization of bis-(acetyl)-L-cystine in glacial acetic solution was achieved readily through the action of acetic anhydride at room temperature, and the epimeric mixture of optically inactive bis-(acetyl)-cystine so derived isolated in high yield. The asymmetric hydrolytic action of the L-directed renal acylase I upon this latter derivative, at *p*H 7.5 and 37°, resulted in a mixture of free L-cystine, monoacetyl-*meso*-cystine (acetyl moiety at D-position), and bis-(acetyl)-D-cystine. The marked insolubility of the former compound permitted its direct isolation from the enzymic digest by filtration, while the two latter compounds were acid hydrolyzed to *meso*-cystine and D-cystine, respectively, after their separation and isolation from the filtrate on a Dowex-50 column in the acid phase. Specific rotation values were −211 and +208° (1% in *N* HCl) for the L- and D-enantiomorphs, respectively, whereas the *meso*-cystine was completely devoid of detectable optical activity. In addition, a resolution of S-benzyl-DL-penicillamine was effected *via* the hydrolytic action of hog kidney amidase on the amide derivative at *p*H 8.0. Subsequent separation of the liberated S-benzyl-L-penicillamine from the unhydrolyzed S-benzyl-D-penicillamine amide on an Amberlite XE-64 column, followed by acid hydrolysis of the latter compound, ultimately yielded the pure enantiomorphs with specific rotation values of +91.3 and −90.6° (1% in *N* HCl) for the L- and D-forms, respectively. Infrared spectra for each of the stereoisomeric forms of cystine, in addition to data on the susceptibility of these compounds or certain of their selected derivatives to the enzymic action of L- and D-amino acid oxidase and hog renal acylase I, are presented.

Cystine is a symmetrical diaminodicarboxylic acid which, although hitherto found in nature only as the L-form, may in fact exist as two racemic modifications, one an internally compensated *meso*-form, and the other a mixture of externally compensated isomerides. Since L-cystine may be relatively inexpensively isolated from acid hydrolysates of certain natural materials, *e.g.*, hair or wool, such source has provided the major supply of commercially available cystine. However, the drastic hydrolytic conditions employed in its manufacture might also lead to rather extensive racemization, and commercial samples of "L-cystine" whose specific rotation values differ by as much as thirty or forty degrees from the generally accepted value of −212° (in *N* HCl) have not been uncommon. With the view in mind that certain biochemical studies demand not only L-cystine, but also the D-

and *meso*-forms, in a high degree of stereochemical purity, the preparation of these isomers *via* the general enzymic resolution procedures developed in this Laboratory[1] is here presented. In addition, an enzymic resolution procedure for preparing the optical antipodes of S-benzylpenicillamine is also described.

Results and Discussion

Racemization and Resolution of Cystine.—The preparation of inactive cystine by Mörner,[2] in 1899, subsequently led to a series of investigations[3–5] concerned with the question of its stereochemical identity. Such question was resolved when du Vigneaud, in collaboration with Hollander[4] and Loring,[5] demonstrated that the racemization of L-cystine, upon boiling for five days in hydrochloric acid, led to an epimeric mixture of DL- and *meso*-cystine. Separation of the *meso*- from the DL-form could be effected through a series of fractional crystallizations of the hydrochloride salts. Treatment of the bis-(acetyl) derivative of the epimeric mixture with brucine resulted in a separation of the alkaloid salt of bis-(acetyl)-D-cystine, which, after some twelve crystallizations, yielded D-cystine with $[\alpha]_D^{20}$ +212° (in HCl).[4] Preparation of D-cystine with $[\alpha]_D^{26}$ +208° could be achieved, in addition, from the insoluble salt which arose from the treatment of bis-(formyl)-DL-cystine with strychnine.[6] Alternative preparations of D-cystine with $[\alpha]_D^{20}$ +224°[7] and +221.2°[8,9] (in HCl) resulted from the debenzylation of S-benzyl-D-cysteine with the sodium–liquid ammonia procedure, followed by oxidation of the D-cysteine so liberated.[10]

The direct resolution of DL-cystine was handicapped by virtue of the prolonged refluxing (5 days) of L-cystine with concentrated HCl required for its conversion to the epimeric starting material, as well as by the tedious fractional crystallizations necessitated for the separation of the DL- and the *meso*-forms.[5] A search for methods whereby these difficulties could be obviated was therefore undertaken. The former difficulty was resolved with the observation that the action of a glacial acetic acid–acetic anhydride mixture[11] on bis-(acetyl)-L-cystine, at room temperature, readily proceeded with the formation of an epimeric mixture of bis-(acetyl)-DL- and *meso*-cystine, which could be isolated in high yield (84% of theory).[12] With an eye toward the previous success achieved in the separation of the D-, L- and *meso*-forms of α,ϵ-diaminopimelic acid *via* the asymmetric enzymic hydrolysis of a mixture of their amide derivatives,[13] it appeared particularly tempting to subject the epimeric mixture of acetylcystine to an analogous scheme. Such scheme, if successful, would lead to an easily separable mixture of L-cystine, bis-(acetyl)-D-cystine and monoacetyl-*meso*-cystine (acetyl moiety at the D-position). Although a previous report from this Laboratory[9] had indicated that the N-acylated cystines were highly resistant to the hydrolytic action of hog renal acylase I, under the conditions given, re-investigation of the hydrolytic reaction with varying concentrations of enzyme revealed that it could be induced to proceed at a rate which was of sufficiently large magnitude to make the resolution of inactive bis-(acetyl)-cystine practicable.

Racemization of bis-(acetyl)-L-cystine was effected upon treatment of a glacial acetic acid solution thereof with an excess of acetic anhydride at room temperature. The course of the racemization was followed polarimetrically. As is revealed in Fig. 1, a plot of observed rotation *vs.* time

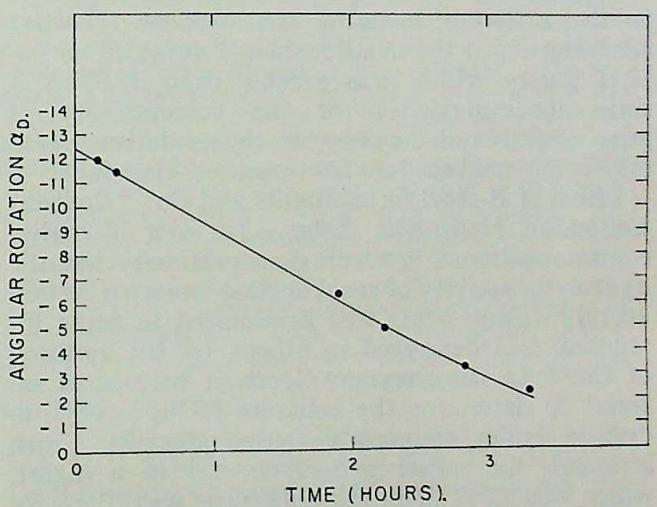

Fig. 1.—Change in optical rotation, with time, of a solution of 20 g. of bis-(acetyl)-L-cystine in 150 ml. of glacial acetic acid upon the addition of 12 moles of acetic anhydride at room temperature (about 27°). A 2 dm. tube was employed.

revealed a linear relationship over approximately the first three hours, during which time the observed rotation fell to about 25% of its initial value. In order to ensure complete optical inactivation, the reaction mixture was permitted to stand for some 16 hours prior to the isolation of the epimeric substance. No detectable desulfuration of the cystine residue was apparent during the entire course of the reaction under the conditions employed herein.

The bis-(acetyl) derivative of inactive cystine was subjected to the asymmetric hydrolytic action of the L-directed renal acylase I. Description of the preparation of this enzyme from hog kidney homogenates has appeared elsewhere.[14] Digestion of a 0.1 *M* solution of the epimeric substrate with the lyophilized enzyme, at *p*H 7.5, was effected at 37°. An initial rate of hydrolysis, as measured by the Van Slyke manometric ninhydrin-CO_2 procedure, was 10 micromoles per hr. per mg. of protein nitrogen. Upon completion of the reaction, the liberated L-cystine, by virtue of its extreme insolubility, could be isolated directly from the enzymic digest by simple filtration. The mixture of bis-(acetyl)-D-cystine and monoacetyl-*meso*-cystine, which remained in the filtrate, could ultimately be separated upon passage through a Dowex-50 column in the acid phase. Acid hydrolysis of each of the latter two compounds subsequently yielded pure D- and *meso*-cystine, respectively, which could be crystallized from water through the hydrochloride salts.[15] Optical rotation values for the enantiomorphic D- and L-forms were equal and opposite within the limits of experimental error, while the *meso*-form was devoid of any detectable optical activity, an indication of its freedom from optical contamination. The D-cystine, when subjected to the action of L-amino acid oxidase (*Crotalus adamanteus*) in the usual fashion,[16] revealed an optical purity which was greater than 99.9%. A time–rate comparison of the susceptibility of *meso*-cystine and L-cystine to the oxidative action of L-amino acid oxidase has appeared elsewhere.[17,18]

Effect of N-Acyl Substituents and Co^{++} Concentration on Hydrolytic Rates.—In view of earlier communications[19,20] which demonstrated that the hydrolytic activity of renal acylase I toward certain acetyl-L-amino acids was accelerated in some instances, and depressed in others, by the addition of Co^{++} to the enzymic digest, it became of interest to determine the behavior of bis-(acetyl)-L-cystine under comparable circumstances. Thus, although the initial hydrolytic rate of a digest, which was 0.017 *M* in this substrate, was 10 micromoles per hr. per mg. of protein nitrogen, such rate was progressively increased to a value of 19.6 at a Co^{++} concentration of 10^{-3} *M*. An even greater increase in activation was shown with bis-(chloroacetyl)-L-cystine, with the rate of hydrolysis in the presence of a 10^{-3} *M* concentration of Co^{++} increasing some 186% over the digest devoid of added cobalt. Such results indicated that the degree of activation of acylase I by Co^{++}, in addition to being dependent upon the nature of the amino acid residue, as hitherto observed,[20] was also highly dependent upon the nature of the N-acyl substituent. Substantiation of this latter view was obtained with digests containing acetyl-L-alanine and D-chloropropionyl-L-alanine[21] as substrates, with a 10^{-3} *M* Co^{++} concentration leading to a 60% activation in the former instance and a 147% activation in the latter. The results secured with various levels of Co^{++} are revealed in Table I.

TABLE I

EFFECT OF Co^{++} ON THE SUSCEPTIBILITY OF N-ACYLAMINO ACIDS TO THE HYDROLYTIC ACTION OF RENAL ACYLASE I

Substrate	Rate[a] without added Co^{++}	Increase in rate on addn. of Co^{++} at concn., % 1×10^{-4} *M*	1×10^{-3} *M*	1×10^{-2} *M*	4×10^{-2} *M*
Bis-(acetyl)-L-cystine	10.2	+ 14	+ 96	+81	−75
Bis-(chloroacetyl)-L-cystine	36.6	+109	+186	+87	−59
D-Chloropropionyl-L-alanine	32.3	+ 63	+147	+80	−61
Acetyl-L-alanine	5800	+ 12	+ 60	+25	− 9

[a] Rates expressed as micromoles of substrate hydrolyzed per hr. per mg. of protein N in the reaction mixture at *p*H 7.0 and 37°; substrate at 0.017 *M* concentration; hydrolysis figures taken within 30% of complete cleavage so as to approximate a zero order reaction.

It should perhaps be noted, in addition, that preliminary studies on the hydrolytic susceptibility of various acylated cystines to acylase I indicated that while the monocarbobenzoxy derivative of L-cystine[22,23] was completely resistant to enzymic cleavage, the bis-(chloroacetyl) and bis-(glycyl) derivatives were hydrolyzed at rates of 37 and 60 micromoles per hr. per mg. of protein nitrogen, respectively. This finding was of interest in the light of previous data[19] that, with the exception of the tryptophan and tyrosine derivatives, the acylase I induced hydrolysis of a given chloroacetyl-L-amino acid generally proceeded at a greater rate than that of the corresponding glycyl-L-amino acid. The anomalous behavior of the part of the tyrosine and tryptophan derivatives was attributed to the presence of one or more as yet unidentified highly specific acylases in hog kidney. On the basis of the data here obtained, the association of the hydrolytic activity toward the acylated cystines with an unidentified acylase is likewise suggested.[24]

(15) E. Fischer and K. Raske, *Ber.*, **41** 893 (1908).

(16) A. Meister, L. Levintow, R. B. Kingsley and J. P. Greenstein, *J. Biol. Chem.*, **192**, 535 (1951).

(17) N. Izumiya and J. P. Greenstein, *Arch. Biochem. Biophys.*, **52**, 203 (1954).

(18) The initial rates of oxidation for L- and *meso*-cystine by L-amino acid oxidase (*Crotalus adamanteus*) here observed were 59 and 28 micromoles of oxygen consumed per hr. per mg. of protein nitrogen, respectively. The former value is in full accord with that previously observed,[17] while the latter, although still considerably less than that of L-cystine, is somewhat larger than the value recorded earlier.[17]

(19) K. R. Rao, S. M. Birnbaum, R. B Kingsley and J. P. Greenstein, *J. Biol. Chem.*, **198**, 507 (1952).

(20) R. Marshall, S. M. Birnbaum and J. P. Greenstein, THIS JOURNAL, **78**, 4636 (1956).

(21) S.-C. J. Fu, S. M. Birnbaum and J. P. Greenstein, *ibid.*, **76**, 6054 (1954).

(22) Carbobenzoxy-*cyclo*-L-cystinyl was also resistant to enzymic cleavage. The only carbobenzoxy-amino acid which has thus far proved susceptible to hydrolysis by acylase I was the L-glutamic acid derivative (L. Levintow, J. P. Greenstein and R. B. Kingsley, *Arch. Biochem. Biophys.*, **31**, 77 (1951)).

(23) Preparation of this derivative was effected by the treatment of a several-fold excess of L-cystine with carbobenzoxy chloride under Schotten–Baumann conditions. Removal of the excess L-cystine was achieved by adjustment of the *p*H to 6, followed by filtration. Subsequent adjustment of the *p*H of the filtrate to 3.2 led to the precipitation of the desired monocarbobenzoxy derivative which, upon being copiously washed with ethanol, was freed from any contaminating dicarbobenzoxy derivative. The compound should prove of value for the synthesis of unsymmetrical cystine peptides.

(24) The peptidase action of an 87% glycerol extract of hog intestinal mucosa has been earlier employed to cleave L-cystinylglycine and L-cystinylbisglycine, the cystine thus liberated isolated in pure, crystalline form (J. P. Greenstein, *J. Biol. Chem.*, **124**, 255 (1938)).

Resolution of S-Benzylpenicillamine.—The synthetic work related to penicillin during the early 1940's stimulated considerable interest in the general preparation and chemistry of the penicillamines. Resolution of DL-penicillamine was generally effected *via* the action of alkaloids on N-formyl-DL-penicillamine,[25] N-formylisopropylidene-DL-penicillamine[25] and various derivatives of S-benzylpenicillamine.[25,26] Application of the general enzymic procedures developed in this Laboratory to the resolution of DL-penicillamine assumed especial interest in view of the previous behavior exhibited toward hydrolytic enzymes by derivatives of the structurally related *t*-leucine. Thus, although the complete resistance of chloroacetyl-DL-*t*-leucine to the hydrolytic action of renal acylase I could be conceivably attributed to the high degree of steric hindrance arising from complete substitution about the β-carbon atom of the substrate, no such absolute resistance was encountered upon subjecting *t*-leucine amide to the hydrolytic action of hog kidney amidase.[27] That the same general pattern was followed for the N-acetyl derivatives of S-benzyl- and S-methylpenicillamine was indicated by the inability of renal acylase I to effect their cleavage. However, the ability of the L-directed hog kidney amidase[28] to induce an asymmetric cleavage of S-benzyl-DL-penicillamine amide, albeit slow, nonetheless made an enzymic resolution feasible here.

The S-benzyl-DL-penicillamine amide employed in the present investigation was prepared by the conversion of carbobenzoxy-S-benzyl-DL-penicillamine to the corresponding amide derivative, *via* the mixed carbonic–carboxylic anhydride procedure,[29] followed by decarbobenzoxylation of this latter compound with hydrogen bromide in glacial acetic acid.[30] Asymmetric cleavage of the amide with a hog kidney amidase preparation[28] proceeded at a rate of 5 micromoles per hr. per mg. protein nitrogen at *p*H 8.0, 38°, and a substrate concentration of 0.01 to 0.02 *M*. Isolation of the liberated S-benzyl-L-penicillamine and S-benzyl-D-penicillamine amide was achieved through the utilization of an Amberlite XE-64 resin in the acid phase.[31] It is especially noteworthy that the steric hindrance imposed by the groups about the β-carbon atom presumably made the D-amide extremely resistant to acid hydrolysis, for less than 10% cleavage occurred upon refluxing the compound with ten volumes of 2 *N* HCl for 2 hr.[32] Conversion of the D-amide to S-benzyl-D-penicillamine was achieved upon its treatment with 5 *N* HCl, under reflux, for some 6 hr. An $[\alpha]^{24}D$ −90.6° (1% in *N* HCl) was revealed for the D-amino acid so procured, a value which was equal and opposite, within the limits of experimental error, to the $[\alpha]^{24}D$ +91.3° (1% in *N* HCl) secured for the L-antipode. Unfortunately, the complete resistance of these enantiomers to D-amino acid oxidase and L-amino acid oxidase (*Crotalus adamanteus*), respectively, did not permit measurements of their optical purity.[16]

Infrared Spectra.—The absorption spectra of L-cystine and of such peptides as cyclo-L-cystinyl and of L-cystinyl-L-cystine have been described.[33] L-Cystine and D-cystine were mixed in equal amounts and the mixture recrystallized as described above. The solid state spectrum in the infrared region of the resulting DL-cystine was found to be identical with that of L-cystine which in turn is identical with that of D-cystine The spectra of *meso*-cystine was found to be almost indistinguishable from that of L-, D- or DL-cystine.

Experimental

I. Resolution and Derivatives of Cystine. Monocarbobenzoxy-L-cystine.—One hundred grams (0.42 mole) of L-cystine was dissolved in 1 l. of cold 1.65 *N* NaOH. The solution was placed in an ice-bath and 25 ml. of carbobenzoxy chloride added thereto over a period of 1 hr. with vigorous stirring. After an additional 20 min., the reaction mixture was carefully adjusted to *p*H 6 with 6 *N* HCl and the stirring and cooling continued for 20 min. longer. The precipitate of excess L-cystine was filtered over suction and washed with 100 ml. of water. The combined filtrate and washings were adjusted to exactly *p*H 3.2 with 6 *N* HCl and, after cooling at 4° for several hours, was filtered and washed copiously with alcohol, then ether. A yield of 37.5 g. of pure monocarbobenzoxy-L-cystine was so secured. Recrystallization could be effected by suspending the material in 1 l. of water, bringing the *p*H to 6.5 by the addition of 2 *N* NaOH with stirring to effect solution filtering off any undissolved material, and then adjusting the *p*H downward to 3.2 by the addition of 6 *N* HCl. After cooling, the precipitate was filtered, and washed successively with a little cold water, ethanol and ether; $[\alpha]^{23}D$ −126° (1% in 5 *N* HCl) and −120° (1% in 1 *N* NaOH).

Anal. Calcd. for $C_{14}H_{18}O_6N_2S_2$: C, 44.9; H, 4.8; N, 7.5; S, 17.1. Found: C, 44.6; H, 4.9; N, 7.4; S, 16.7.

Carbobenzoxycyclo-L-cystinyl.—This compound was prepared by the carbobenzoxylation of cyclo-L-cystinyl[34] according to the usual Schotten–Baumann procedure. The precipitate secured after acidification of the reaction mixture was recrystallized from ethyl acetate–petroleum ether; dec. p. 170–172° with preshrinking at 141°, $[\alpha]^{24}D$ −52.5° (1% in methanol).

Anal. Calcd. for $C_{14}H_{16}O_5N_2S_2$: C, 47.2; H, 4.5; N, 7.9; S, 18.0. Found: C, 47.6; H, 4.8; N, 7.6; S, 17.6.

Bis-(glycyl)-L-cystine.—Preparation of this compound has been reported by several investigators.[35–38] The material here employed was prepared by amination of the precursor bis-(chloroacetyl)-L-cystine[39] according to a modification of the procedure of Abderhalden and Wybert[35]; $[\alpha]^{23}D$ −118° (1% in water) for the monohydrate, and −114° (1% in *N* HCl).

Bis-(acetyl)-L-cystine.—To a solution of 24.0 g. of L-cystine in 100 ml. of ice-cold 2 *N* NaOH were added alter-

nately, and in small portions, 500 ml. of 2 *N* NaOH and 50 ml. of acetic anhydride, with vigorous cooling and shaking. The reaction mixture was shaken for an additional 30 min. and then acidified to congo red with 6 *N* HCl. The mixture was exhaustively extracted with ethyl acetate and the combined ethyl acetate fractions dried over anhydrous sodium sulfate and concentrated to dryness. The residual oil was taken up in hot acetone and a white solid precipitated upon the addition of petroleum ether. This was filtered off, again dissolved in hot acetone, filtered and the solution permitted to stand for 2 hr. at 10°. Microscopic examination revealed white, prism-shaped crystals which were highly hygroscopic upon exposure to air. The bis-(acetyl)-L-cystine was therefore separated from the acetone supernatant by centrifugation and subsequent decantation, and immediately placed in a vacuum desiccator where the residual solvent was removed. After drying over phosphorus pentoxide at 80° for some 12 hr., the compound appeared no longer hygroscopic; yield 19 g., m.p. 121–122°, $[\alpha]^{23}D$ −118° (1% in water). This compound was previously prepared[4] as a non-crystalline solid for which no physical constants were given, and as a white solid with m.p. 120° (J. P. Greenstein and F. M. Leuthardt, *Archiv. Biochem.*, 18, 377 (1948)).

Anal. Calcd. for $C_{10}H_{16}O_6N_2S_2$: C, 37.0; H, 4.9; N, 8.6; S, 19.8. Found: C, 37.1; H, 5.1; N, 8.6; S, 19.5.

Racemization of Bis-(acetyl)-L-cystine.—To a solution of 20 g. of bis-(acetyl)-L-cystine in 150 ml. of glacial acetic acid, at room temperature (*ca.* 27°), was added 30 ml. of acetic anhydride. A very small quantity of crystalline material appeared within a few minutes but did not change noticeably in amount during the next 16 hours. An aliquot of the solution was removed and its change in optical rotation followed polarimetrically. A plot of the optical rotation value *versus* time is given in Fig. 1. After some 16 hr., the optically inactive solution was filtered and the filtrate evaporated to dryness under a jet of air. A white, sticky residue remained which began to crystallize upon rubbing under ether and which appeared to be completely crystalline after standing for two days in the cold. Since the material was highly hygroscopic, it was separated from the ethereal layer by centrifugation and decantation, and then immediately placed in a vacuum desiccator where the residual ether was drawn off. After drying over potassium hydroxide *in vacuo*, the yield of the epimeric mixture of bis-(acetyl)-cystine was 16.8 g. (84%), dec. point 78°, $[\alpha]^{23}D$ 0° (in water). The compound exhibited a slight hygroscopicity and was analyzed after drying *in vacuo* at 60°.

Anal. Calcd. for $C_{10}H_{16}O_6N_2S_2$: C, 37.0; H, 4.9; N, 8.6. Found: C, 37.2; H, 5.2; N, 8.2.

One gram of the epimeric mixture was hydrolyzed by refluxing with 100 ml. of 2 *N* HCl for 2 hr. The solution was concentrated to dryness *in vacuo* at 37°, and the evaporation repeated several times subsequent to the addition of water. The residue was taken up in water, the solution filtered, and the *p*H adjusted to 5.5 with aqueous ammonia. After standing for several hours in the cold, the optically inactive cystine was recovered by filtration over suction; yield 0.43 g. (58%), $[\alpha]^{23}D$ 0° (1% in 1 *N* HCl).

Anal. Calcd. for $C_6H_{12}O_4N_2S_2$: C, 30.0; H, 5.0; N, 11.7; S, 26.7. Found: C, 29.9; H, 5.0; N, 11.6; S, 26.5.

Enzymic Resolution.—A solution of 9.72 g. (0.03 mole) of optically inactive bis-(acetyl)-cystine in 150 ml. of water was prepared, the *p*H adjusted to 7.5 with 2 *N* NaOH, and the volume brought to 300 ml. with distilled water. After the addition of 1 g. of hog renal acylase I powder,[14] the digest was incubated at 37° for some 16 hr., at which point the degree of hydrolysis, as measured by the van Slyke manometric-CO_2 procedure,[40] had proceeded to only 18.5% of theory. The *p*H of the digest was adjusted to 7.5 and an additional 8 g. of "crude" acylase I[41] was added. After some 24 hr., a 50% hydrolysis of the total substrate was indicated. This value remained unchanged upon the further addition of 1 g. of crude acylase I and subsequent incubation for an additional 16 hr. The hydrolysate was then adjusted to *p*H 5.5 with glacial acetic acid and concentrated to 100 ml. *in vacuo* at 35–40° in the presence of capryl alcohol to eliminate foaming. The concentrate was warmed over the steam-bath for some 10 min. (to denature the protein), allowed to stand in the cold overnight, and the precipitate of L-cystine plus coagulated protein filtered and washed with 100 ml. of cold water. The combined filtrate and washings, which contained both the bis-(acetyl)-D-cystine and monoacetyl-*meso*-cystine, was concentrated to about 50 ml. *in vacuo* at 40°, and the concentrate then run onto a Dowex 50-X[4] column (30 × 2.5 cm.) in the acid phase which had been previously washed with water. Fractions were collected in 30–35-ml. cuts, with water as the eluent, and the presence of bis-(acetyl)-D-cystine was indicated in tubes 2 to 16 by the drop in *p*H of the eluate. The column was further eluted with 1 l. of water, which was discarded, and then with 1 *N* HCl, which was collected in 30–35-ml. cuts and examined for the presence of monoacetyl-*meso*-cystine with ninhydrin as the indicator. All "positive" fractions were combined.

L-Cystine.—The combined precipitate of L-cystine and denatured protein, secured above, was extracted twice with 250-ml. portions of warm (70°) 1 *N* HCl, the extracts treated with Norite, filtered and the filtrate adjusted to *p*H 5.5 with aqueous ammonia. After standing for 6 hr. in the cold, the L-cystine was filtered, washed with water and recrystallized from water *via* the hydrochloride derivative according to the procedure of Fischer and Raske.[15] An over-all yield of 0.8 g. of L-cystine was obtained, $[\alpha]^{23}D$ −211° (1% in *N* HCl).

Anal. Calcd. for $C_6H_{12}O_4N_2S_2$: C, 30.0; H, 5.0; N, 11.7; S, 26.7. Found: C, 29.9; H, 5.3; N, 11.7; S, 26.5.

D-Cystine.—The combined eluates of tubes 2 to 16, secured above, were concentrated to dryness *in vacuo* and the residual oil was dissolved in 100 ml. of 2 *N* HCl. After refluxing for 2 hr., the hydrolysate was decolorized with Norite and the *p*H brought to 5.5 with aqueous ammonia. The precipitated D-cystine was recrystallized in the same manner employed for the L-antipode; yield 0.95 g., $[\alpha]^{23}D$ +208° (1% in *N* HCl).

Anal. Found: C, 30.1; H, 5.1; N, 11.6; S, 26.5.

Mesocystine.—The combined 1 *N* HCl eluates, secured above, were concentrated to dryness and the residual monoacetyl-*meso*-cystine taken up in 100 ml. of 2 *N* HCl and refluxed for 2 hr. Recovery of the *meso*-cystine from the acid hydrolysate, as well as its recrystallization, was effected as given for the D-stereoisomer; yield 0.8 g., $[\alpha]^{23}D$ 0° (1% in *N* HCl).

Anal. Found: C, 29.8; H, 5.0; N, 11.7; S, 26.5.

II. Resolution, Derivatives and Analogs of S-Benzyl-penicillamine. N-Acetyl-S-benzyl-DL-penicillamine.—To a solution of 19.1 g. (0.1 mole) of acetyl-DL-penicillamine[25] in 500 ml. of liquid ammonia was added small pieces of sodium metal, with stirring, until a slight excess was present (as indicated by a permanent light blue color). S-Benzylation[42] was effected by the dropwise addition of benzyl chloride until the blue color just disappeared, and then the further dropwise addition of an additional 12.7 ml. (0.11 mole) of benzyl chloride. The mixture was stirred for 3 hr. after the addition was complete, the liquid ammonia then allowed to evaporate spontaneously, and the resulting residue extracted into water. Following filtration of a slight amount of insoluble residue, the *p*H of the solution was adjusted to 1.7 with 6 *N* HCl and the mixture extracted exhaustively with ethyl acetate. The ethyl acetate extracts were pooled, dried over anhydrous sodium sulfate, filtered and the filtrate concentrated to dryness. After recrystallization of the crystalline residue from 50% ethanol, a yield of 21.9 g. (78%) of N-acetyl-S-benzyl-DL-penicillamine was secured, m.p. 174°.

Anal. Calcd. for $C_{14}H_{19}O_3NS$: C, 59.8; H, 6.8; N, 5.0; S, 11.4. Found: C, 60.0; H, 6.9; N, 5.0; S, 11.4.

N-Acetyl-S-methyl-DL-penicillamine.—This compound was prepared in the same general manner as employed for the S-benzyl analog through the use of methyl iodide *in lieu* of benzyl chloride.[43] A 76% yield of the desired product

(40) Although the precipitation of free L-cystine accompanied the hydrolysis, a representative aliquot could be removed successfully from the well-shaken reaction mixture and the degree of hydrolysis measured with a high degree of precision.

(41) This acylase I preparation has not been carried as far as the acetone fractionation step, but rather is a lyophilized powder of a dialysate prepared just subsequent to the ammonium sulfate precipitation stage (*cf.* ref. 14).

was secured after recrystallization from water; m.p. 196–197°.

Anal. Calcd. for $C_8H_{15}O_3NS$: C, 46.8; H, 7.3; N, 6.8; S, 15.6. Found: C, 46.7; H, 7.2; N, 6.7; S, 15.6.

N-Carbobenzoxy-S-methyl-DL-penicillamine.—N-Acetyl-S-methyl-DL-penicillamine was hydrolyzed to S-methyl-DL-penicillamine upon refluxing with 2 *N* HCl (10 ml. per g. of acetyl derivative) for 2 hr. After evaporation of the hydrolysate to dryness *in vacuo*, the residue was extracted into water, the *p*H adjusted to *p*H 5.5 with aqueous ammonia, and the resulting crystals of S-methyl-DL-penicillamine filtered, washed with water, and finally recrystallized from water. This compound has been previously prepared[43] *via* methylation of penicillamine with methyl iodide in the sodium–liquid ammonia system.

Anal. Calcd. for $C_6H_{13}O_2NS$: C, 44.2; H, 8.0; N, 8.6; S, 19.6. Found: C, 44.1; H, 8.0; N, 8.2; S, 19.4.

Preparation of the carbobenzoxy derivative was effected in a manner comparable to that given below for the S-benzyl analog. A 67% yield was obtained after recrystallization from benzene–petroleum ether; m.p. 89°.

Anal. Calcd. for $C_{14}H_{19}O_4NS$: C, 56.6; H, 6.5; N, 4.7; S, 10.8. Found: C, 57.0; H, 6.5; N, 4.6; S, 10.3.

N-Carbobenzoxy-S-benzyl-DL-penicillamine.—A solution of 105.5 g. of S-benzyl-DL-penicillamine in 450 ml. of 1 *N* NaOH was cooled to about 5° and a total of 95.4 ml. of carbobenzoxy chloride and 650 ml. of 1 *N* NaOH added alternately thereto, in small portions, with vigorous shaking and cooling. Separation of an oil was noted at this stage. The reaction mixture was shaken for an additional 2 hr. in the cold and then acidified to *p*H 1.7 with 6 *N* HCl. An oil was precipitated which was taken up in half-saturated sodium bicarbonate solution, filtered, and reprecipitated with 6 *N* HCl. Although an oil was initially formed, crystallization soon commenced. The crystals were dissolved in ethyl acetate and the solution dried with anhydrous sodium sulfate, filtered and concentrated to dryness in a stream of dry air. An oil was secured which readily crystallized upon rubbing with water; yield 99 g., m.p. 81°.

Anal. Calcd. for $C_{20}H_{23}O_4NS$: C, 64.3; H, 6.2; N, 3.8; S, 8.6. Found: C, 64.0; H, 6.2; N, 3.7; S, 8.4.

N-Carbobenzoxy-S-benzyl-DL-penicillamine Amide.—A solution of 98.5 g. of carbobenzoxy-S-benzyl-DL-penicillamine and 37.1 ml. of triethylamine in 1.5 l. of dry dioxane was cooled to 10°, and 35.2 ml. of isobutyl chloroformate added thereto. The reaction mixture was maintained at 10° for 1 hr., with occasional shaking, and 34.4 ml. of concentrated aqueous ammonia then added. As no carbon dioxide was evolved at this temperature, the mixture was warmed to 80° over a steam-bath and was maintained at this temperature for 10–15 minutes, during which time vigorous gas evolution was observed. An additional 34.4 ml. of concentrated ammonia was then added, the mixture allowed to stand at room temperature overnight, the precipitate of triethylamine hydrochloride removed by filtration, and the filtrate concentrated to dryness *in vacuo*. The residue was dissolved in chloroform and the chloroform layer washed successively with half-saturated sodium bicarbonate, water, 1 *N* HCl and water. The chloroform layer was evaporated to dryness *in vacuo*, benzene added, and the evaporation repeated. Crystallization of the residue was effected from ether–petroleum ether. Since the precipitate was slightly colored, it was taken up in ethyl acetate, the solution decolorized with Norite, dried over anhydrous sodium sulfate, and evaporated to dryness. The white crystals were recrystallized from absolute ethanol; yield 63.5 g. (65%), m.p. 123–124°.

Anal. Calcd. for $C_{20}H_{25}O_3N_2S$: C, 64.3; H, 6.7; N, 7.5; S, 8.6. Found: C, 64.2; H, 6.6; N, 7.4; S, 8.4.

S-Benzyl-DL-pencillamine Amide Hydrobromide.—Decarbobenzoxylation of carbobenzoxy-S-benzyl-DL-penicillamine amide was effected according to the general procedure of Ben-Ishai and Berger.[30] A stream of dry hydrogen bromide was passed through a solution of 60 g. of the carbobenzoxy-amide in 1 l. of glacial acetic acid to saturation, the temperature being maintained below 35°. After 0.5 hr. at room temperature, the mixture was concentrated to 500 ml. and 3 l. of dry ether added thereto. After standing overnight in the cold, the mixture was filtered and the precipitate washed with ether, dried *in vacuo* over potassium hydroxide and recrystallized from 95% ethanol; yield 44 g. (86%), m.p. 227–228°.

Anal. Calcd. for $C_{12}H_{25}ON_2SBr$: C, 45.1; H, 6.0; N, 8.8; S, 10.0; Br, 25.0. Found: C, 45.0; H, 6.0; N, 8.6; S, 9.7; Br, 25.0.

Enzymic Resolution.—The *p*H of a solution of 4 g. of S-benzyl-DL-penicillamine amide hydrobromide and 50 mg. of $MnCl_2 \cdot 4H_2O$, in water, was adjusted to 8.0 with 2 *N* LiOH; 30 ml. of a hog kidney amidase[44] solution containing 5 mg. of nitrogen per ml. was added thereto, and the final volume diluted to 250 ml. The mixture was subsequently digested at 38° for 18 hr., at which point the manometric ninhydrin-CO_2 procedure revealed 50% hydrolysis of the total substrate. No change in the degree of hydrolysis was revealed upon digestion for an additional 24 hr. after the addition of 7 ml. more of amidase solution. The digest was adjusted to *p*H 5.2 with glacial acetic acid, deproteinized by filtration in the presence of Norite, the precipitate washed with water and the filtrate and washings combined. Since the precipitate contained some adsorbed substrate, this was extracted twice with hot methanol, filtered, the filtrate evaporated to dryness *in vacuo* at 35° and the resulting residue taken up in the pooled aqueous filtrate. This latter was concentrated to about 250 ml. *in vacuo* and the concentrate run onto an Amberlite XE-64 column (28 × 2.5 cm.) in the acid phase. With water as the eluent, fractions were collected every 8 ml. and examined for ninhydrin-positive material. The presence of S-benzyl-L-penicillamine in tubes 10 to 170 was so indicated. After emergence of the L-amino acid, the column was washed with 2 l. of distilled water and the S-benzyl-D-penicillamine amide then eluted with 0.3 *N* HCl (fractions tested for ninhydrin positive material, as previously).

S-Benzyl-L-penicillamine.—The combined eluate of tubes 10 to 170 was concentrated to dryness *in vacuo* at 40°. The residue was dissolved in 1 *N* HCl and the *p*H brought to 5.5 with aqueous ammonia. A crystalline precipitate of S-benzyl-L-penicillamine was so obtained in 96% yield. Recrystallization was effected from water; $[\alpha]^{24}D$ +87.5° (1% in NaOH) and $[\alpha]^{24}D$ +91.3° (1% in *N* HCl).

Anal. Calcd. for $C_{12}H_{17}O_2NS$: C, 60.3; H, 7.1; N, 5.9; S, 13.4. Found: C, 60.2; H, 7.3; N, 5.8; S, 13.1.

S-Benzyl-D-penicillamine Amide Hydrochloride.—The 0.3 *N* HCl eluate from the column, which contained the D-amide, was brought to *p*H 4.5 with silver carbonate and filtered. Adsorbed material on the silver chloride precipitate was eluted off with hot methanol, the methanol extracts filtered, concentrated to dryness and the residue taken up in the aqueous filtrate. Hydrogen sulfide was passed through the latter to remove silver ions, the suspension filtered, and the filtrate concentrated to dryness *in vacuo*. The residue was dissolved in approximately 100 ml. of methanol, the solution filtered, the filtrate concentrated to dryness, and the residue crystallized from 80% ethanol to yield S-benzyl-D-penicillamine amide hydrochloride. This material contained approximately one molecule of water of crystallization which could be removed upon drying *in vacuo* at 80°; yield 1.4 g. (81%) of anhydrous product, m.p. 182–183°, $[\alpha]^{24}D$ −73.0 (1% in ethanol).

Anal. Calcd. for $C_{12}H_{19}ON_2SCl$: C, 52.4; H, 6.9; N, 10.2; S, 11.7; Cl, 12.9. Found: C, 52.4; H, 7.0; N, 10.0; S, 12.0; Cl, 13.0.

S-Benzyl-D-penicillamine.—A solution of 0.7 g. of S-benzyl-D-penicillamine amide hydrochloride in 20 ml. of 5 *N* HCl was refluxed for 6 hr. and the hydrolysate then concentrated to dryness *in vacuo* at 38°. After the addition of a little water, the evaporation was repeated. The residue was dissolved in a few ml. of water and the *p*H adjusted to 5.5 with 2 *N* LiOH. The D-isomer, which crystallized out on standing, was filtered, washed with water and dried; yield 0.58 g. Recrystallization was effected from water; $[\alpha]^{24}D$ −90.6 (1% in 1 *N* HCl).

(44) The amidase preparation employed was prepared as described previously,[28] but without prior adsorption on calcium phosphate gel. Its rate of hydrolysis toward L-leucine amide, under the same conditions as utilized for the S-benzylpenicillamine amide, was 2880 μmoles

Synthesis of Ethyl β,β-Diethoxyalanyl-L-cysteinate Hydrochloride[1]

BY HOMER ADKINS[2] AND BURRIS D. TIFFANY[3]

RECEIVED MARCH 19, 1957

Ethyl β,β-diethoxyalanyl-L-cysteinate hydrochloride (XIX) has been synthesized through the coupling of N-carbobenzoxy-β,β-diethoxyalanine azide (XI) with S-benzyl-L-cysteine, followed by selective removal of the protecting N-carbobenzoxy and S-benzyl groups by mild reduction. The azide XI was prepared by the carbobenzoxylation of ethyl β,β-diethoxyalanate (IV) followed by conversion of the ester IX to the hydrazide X and then to the azide. The primary coupling product, N-carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteine (XIV) and (XV), was separated into its component D,L- and L,L-diastereoisomers by fractional crystallization of its methyl esters and sodium salts. D,L-N-Carbobenzoxy-β,β-diethoxyalanylglycine (XII) resulted from a preliminary investigation of the synthetic route using glycine. An attempt to couple the unprotected β,β-diethoxyalanine azide (VI) with glycine yielded 3-diethoxymethyl-2,5-piperazinedione (VIII).

In connection with a study of the structure of benzylpenicillin,[4] it was of interest to synthesize the stereoisomeric ester hydrochlorides (I) of β,β-diethoxyalanylpenicillamine, a dipeptide incorporating certain structural features known to be present in benzylpenicillin itself.

$$(CH_3CH_2O)_2CHCHCONHCHCO_2CH_2CH_3 \qquad \begin{matrix} \text{I, R} = CH_3 \\ \text{II, R} = H \end{matrix}$$
$$\qquad\qquad\quad H_2N{\cdot}HCl \qquad\quad CR_2SH$$

This paper describes the synthesis of one of the stereoisomers of the lower homolog, ethyl β,β-diethoxyalanyl-L-cysteinate hydrochloride (II), derived from L-cysteine, as a model for the synthesis of the dipeptide ester hydrochlorides I, which require the less available penicillamine.

The first approach studied was the azide coupling of β,β-diethoxyalanine (III) with ethyl glycinate. The latter amino acid was employed in developing the method to avoid difficulties due to the sensitive sulfhydryl group and the complications of diastereoisomeric dipeptides.

Ethyl β,β-diethoxyalanate (IV), prepared from ethyl glycinate,[5] was converted to the hydrazide V in good yield, using anhydrous hydrazine. The hydrazide was surprisingly stable, considering the functional groups present, and could be distilled at reduced pressure without change.

We were encouraged by the unusual stability of the hydrazide to attempt direct conversion to the azide VI and coupling with glycine without protecting the amino group. When this unconventional series of reactions was tried, the product, obtained in 10% yield, was not the dipeptide ester VII, however, but a white water-soluble solid which gave correct carbon and hydrogen values for 3-diethoxymethyl-2,5-piperazinedione (VIII) *i.e.*, the compound to be expected upon cyclization of the coupled product VII. The failure, therefore, appeared not to be in the coupling, although of low yield, but rather in preventing the subsequent cyclization. Herein is implied the existence of a moderately stable aliphatic primary amino acid azide, which seems to be unprecedented.[6]

For a successful coupling procedure we turned to Bergmann's method for protection of the amino group. Carbobenzoxylation of ethyl β,β-diethoxyalanate (IV) was accomplished in 81% yield, and the resulting ethyl N-carbobenzoxy-β,β-diethoxyalanate (IX) was converted readily to the hydrazide X with 85% hydrazine hydrate in ethanol. Before treatment with nitrous acid this acetal-containing hydrazide was tested for stability in aqueous acid. It could be dissolved in three equivalents of cold 1 *N* hydrochloric acid and largely recovered unchanged upon neutralization of the acid. The azide XI was prepared from the hydrazide using nitrous acid and coupled with glycine in potassium carbonate solution, giving N-carbobenzoxy-β,β-diethoxyalanylglycine (XII) as a white crystalline solid in good yield. The crystalline methyl ester XIII was prepared readily from the acid upon treatment with diazomethane.

Having demonstrated that the acetal system would survive in the coupling reaction, attention was next turned to the dipeptide containing the L-cysteine residue. The sensitive sulfhydryl group was protected with a benzyl group as described by Wood and du Vigneaud.[7] When the coupling procedure was carried out with S-benzyl-L-cysteine, the product, obtained in 80% yield, was a solid with a broad melting range and presumably was a mixture of the D,L- and L,L-diastereoisomers of the dipeptide XIV and XV.

For separation of the diastereoisomers the mixture of acids was converted to the methyl esters

XVI and XVII with diazomethane, and recrystallized from a mixture of benzene and petroleum ether in which the dextrorotatory ester was the less soluble. Material of good quality was obtained in 25% over-all yield from the hydrazide (based on the total amount of all isomers expected). Hydrolysis of the ester to the free acid apparently was accompanied by some decomposition or partial racemization, since material of sharp melting point could not be obtained. Attempts to separate the isomers by fractional recrystallization of the acids instead of the esters was not promising.

The levorotatory form of the dipeptide XIV was obtained by hydrolysis of the residual methyl esters from which the dextrorotatory ester had been crystallized, extraction of the *sodium salts* into chloroform and fractional recrystallization of these salts from absolute ethanol. The alkali salts of these isomeric acids showed a remarkable solubility in chloroform, being much more soluble in this solvent than in water. Furthermore, the sodium salt of the levorotatory form, which was isolated in a fairly pure state, had a surprisingly low melting point, 169–173°. The levorotatory free acid XIV was prepared from a dilute aqueous solution of the salt by treatment with dilute acid and was recrystallized from chloroform. Reaction with diazomethane converted it to the crystalline methyl ester (XVI).

Both protecting groups in the dipeptides, the N-carbobenzoxy and the S-benzyl groups, were removed simultaneously upon reduction with sodium in liquid ammonia. The process was successful however, only when applied to the methyl ester and not with the free acid as suggested by the literature.[9] Hopkins mercuric sulfate reagent, which usually is successful for separation of cysteine-containing peptides, failed to precipitate the product in either case here. The product from reduction of the dextro methyl ester was a crystalline solid but apparently a mixture. By means of an ester interchange in ethanolic hydrogen chloride, however, it was converted to a homogeneous product consisting of the ethyl ester hydrochloride, ethyl β,β-diethoxyalanyl-L-cysteinate hydrochloride (XIX), a sensitive white crystalline solid. A test with sodium nitroprusside reagent verified the presence of the sulfhydryl group and a Zeisel determination indicated the presence of three ethoxyl groups. The free amino group was evidenced by the formation of a hydrochloride.

Acknowledgment.—We wish to express our appreciation to Dr. A. L. Wilds for advice concerning the preparation of the manuscript.

Experimental[10]

β,β-Diethoxyalanine Hydrazide (V).—Ethyl β,β-diethoxyalanate (IV) required in this preparation was prepared from sodium ethyl α-N-formylamino-β-hydroxyacrylate in 30% yield by a procedure described in a report from Charles

(8) In these compounds (+) and (−) are used to designate an observed rotation with no implication regarding actual configurations. Small capital D and L are employed as usual to designate known configurations.

Pfizer and Co., Inc.[5]; however, the results were not readily reproducible. The sodium enolate was prepared from ethyl N-formylglycinate in 97% yield (crude) as described in a report from the Northern Regional Research Laboratories.[5]

In a stoppered 25-ml. erlenmeyer flask, a mixture of 10.25 g. (0.050 mole) of ethyl β,β-diethoxyalanate and 2.4 g. (0.075 mole) of anhydrous hydrazine[11] was kept under nitrogen at room temperature with occasional shaking for one day, whereupon it crystallized to a dense mass when seeded. Upon treatment with Norit and recrystallization twice from ether, this produced 7.55 g. (79%) of white needles, m.p. 63–65°. The product could be distilled at 111–112° (0.2 mm.), giving a solid which, upon further recrystallization from ether, melted at 64.5–65.5° and showed no m.p. depression with the solid before distillation.

Anal. Calcd. for $C_7H_{17}N_3O_3$: C, 43.97; H, 8.96; neut. equiv., 191. Found: C, 44.09; H, 9.16; neut. equiv., 190, 193.

3-Diethoxymethyl-2,5-piperazinedione (VIII).—A solution of 0.38 g. (0.0020 mole) of β,β-diethoxyalanine hydrazide in 5 ml. of water was treated, while swirling in an ice–salt-bath, with 10 drops (0.004 mole) of concentrated hydrochloric acid followed immediately by 0.14 g. (0.0020 mole) of sodium nitrite in 3 ml. of water. The solution was treated with 0.42 g. (0.0030 mole) of potassium carbonate, the azide quickly extracted well into ethyl acetate (Mallinckrodt analytical reagent), dried over anhydrous sodium sulfate and added to a dried ethereal extract of ethyl glycinate, previously prepared from 0.28 g. (0.0020 mole) of ethyl glycinate hydrochloride and 0.28 g. (0.0020 mole) of potassium carbonate. After one day at room temperature the resulting solution was concentrated under reduced pressure to give several milligrams of white crystalline solid in a small amount of pale yellow oil. Stirring with 50 ml. of ether removed the oil, leaving 0.045 g. (10%) of water-soluble solid, m.p. 176–177.5° without recrystallization.

Anal. Calcd. for $C_9H_{16}N_2O_4$: C, 50.00; H, 7.40. Found: C, 49.76; H, 7.29.

Ethyl N-Carbobenzoxy-β,β-diethoxyalanate (IX).—The preparation of this compound by procedures differing from the one given below has been described previously.[12] In a 250-ml. three-necked flask equipped with a mechanical stirrer and two dropping funnels was placed 23.3 g. (0.100 mole) of ethyl β,β-diethoxyalanate, rinsing in with 23 ml. of water. This was stirred and cooled in an ice–salt-bath while 20.0 g. (0.115 mole) of carbobenzoxy chloride[13] and 60 ml. of 2 *N* sodium hydroxide were added simultaneously during 25 minutes causing an orange oil to separate. After an additional 15 minutes of cooling and stirring, the mixture was extracted with three 100-ml. portions of ether and these washed with water, dried over sodium sulfate, filtered and concentrated under reduced pressure. Distillation of the resulting 29.4 g. of brown oil produced 27.4 g. (81%) of a pale yellow viscous oil, b.p. 164–168° (0.2 mm.), $n^{25}D$ 1.4903.

N-Carbobenzoxy-β,β-diethoxyalanine Hydrazide (X).—In a 125-ml. erlenmeyer flask 27.35 g. (0.080 mole) of ethyl N-carbobenzoxy-β,β-diethoxyalanate, 12 ml. of 85% hydrazine hydrate and 25 ml. of absolute ethanol were shaken until homogeneous and kept at room temperature for 20 hr. The crystals which formed were collected, rinsed with 20 ml. of 50–50 ethanol–ether and dried, giving 16.5 g. of solid, m.p. 139.5–140.5°. The filtrate yielded an additional 6.0 g., m.p. 139.5–140.5°, and 0.6 g., m.p. 134–136°, for a total of 23.1 g. (89%). A sample was recrystallized from ethanol–ether for analysis, m.p. 139.5–140.5°.

Anal. Calcd. for $C_{15}H_{23}N_3O_5$: C, 55.33; H, 7.13. Found: C, 55.47; H, 7.03.

Stability of N-Carbobenzoxy-β,β-diethoxyalanine Hydrazide (X) toward 1 *N* Hydrochloric Acid.—In 3 ml. of 1 *N* hydrochloric acid[14] at 0–5° was dissolved 0.34 g. (0.0010 mole) of N-carbobenzoxy-β,β-diethoxyalanine hydrazide, m.p. 139.5–140.5°. After 5 minutes at this temperature the solution was made alkaline by slow addition of a solution of 0.28 g. (0.0020 mole) of potassium carbonate in 3 ml. of water. The white flocculent precipitate which separated was collected on a filter, dried and recrystallized from absolute ethanol. A total of 0.25 g. of solid, m.p. 139.5° and mixed m.p. with starting material, 138–139°, was obtained.

N-Carbobenzoxy-β,β-diethoxyalanylglycine (XII).—A mixture of 1.00 g. (0.0030 mole) of N-carbobenzoxy-β,β-diethoxyalanine hydrazide and 9 ml. (0.0090 mole) of 1 *N* hydrochloric acid was stirred mechanically at 0–5° for 3 minutes until the hydrazide was dissolved and then 10 ml. of dioxane added. Immediately a solution of 0.25 g. (0.0036 mole) of sodium nitrite in 3 ml. of water was added with stirring over a period of one minute, followed quickly by the addition of a solution of 0.45 g. (0.0060 mole) of glycine and 1.38 g. (0.010 mole) of potassium carbonate in 5 ml. of water. Stirring was continued 1 hr., the latter half without cooling. The resulting clear solution was concentrated under reduced pressure at less than 45°. The gelatinous residue was added to 15 ml. of water and the resulting suspension filtered and dried, giving 0.05 g. of solid, m.p. 142–148°. Extraction of the clear filtrate with ether yielded 0.015 g. of additional solid, m.p. 149–150°. Upon acidification of the aqueous layer, extraction of the oil which separated with ether and concentration of the extracts, there was obtained 1.09 g. of tiny white needles, m.p. 111–115°. This was dissolved in 3 ml. of ethanol, diluted with 20 ml. of hot water and seeded. Upon cooling, the solution became milky and tiny needles replaced this milkiness only on long standing at room temperature. The needles, when collected, weighed 0.96 g. (83%), m.p. 119–120°. Further recrystallization raised the m.p. to 119.5–121°.

Anal. Calcd. for $C_{17}H_{24}N_2O_7$: C, 55.43; H, 6.57; neut. equiv., 368. Found: C, 55.59; H, 6.44; neut. equiv., 378.

Methyl N-Carbobenzoxy-β,β-diethoxyalanylglycinate (XIII).—A suspension of 0.37 g. (0.0010 mole) of N-carbobenzoxy-β,β-diethoxyalanylglycine, m.p. 120–122°, in 50 ml. of ether was treated in portions with excess ethereal diazomethane[15] causing gas evolution as the suspended solid dissolved. After 20 minutes at room temperature the solution was concentrated to 2 ml., and the rosettes which then slowly formed were collected and dried, giving 0.35 g. (92%) of white crystals, m.p. 94–96°. A sample was recrystallized from ether–petroleum ether (40–60°), m.p. 94.5–96°.

Anal. Calcd. for $C_{17}H_{24}N_2O_7$: C, 56.54; H, 6.85. Found: C, 56.83; H, 7.09.

N-Carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteine (XIV and XV).—A mixture of 26.1 g. (0.080 mole) of N-carbobenzoxy-β,β-diethoxyalanine hydrazide, 240 ml. (0.240 mole) of 1 *N* hydrochloric acid and 240 ml. of dioxane was stirred mechanically at 0°, whereupon the hydrazide dissolved rapidly. After 10 minutes a solution of 6.6 g. (0.096 mole) of sodium nitrite in 72 ml. of water was added with continued stirring at 0° during one minute causing a cloudiness. Immediately, a previously prepared solution of 21.1 g. (0.100 mole) of S-benzyl-L-cysteine[7] and 41.5 g. (0.300 mole) of potassium carbonate in 120 ml. of water was added over about 4 minutes at 0–5°. The resulting oily suspension was stirred with cooling for 30 minutes and without cooling for another 60 minutes, whereupon it became an essentially clear yellow solution which was then concentrated under reduced pressure to a thick white paste of tiny needles. These were suspended in 700 ml. of water and stirred with 150 ml. of chloroform into which they were quickly extracted.[16] Without separating the layers, the mixture was acidified to congo red with about 160 ml. of 3 *N* hydrochloric acid and the extraction of the resulting free organic acid completed with two additional 120-ml. portions of chloroform. The combined extract was washed with two 100-ml. portions of water, dried over sodium sulfate, filtered and concentrated under reduced pressure on the steam-bath. The clear red residue (40 g.) crystallized from a mixture of 75 ml. of benzene and 110 ml. of petroleum ether (60–68°) only as a gelatinous precipitate which was

used directly in the preparation of the methyl ester described below.

In a similar experiment starting with 11.3 g. (0.035 mole) of the hydrazide there was isolated 14.1 g. (80%) of a solid, m.p. 95–109°, which was presumably a mixture of diastereoisomers.

Anal. Calcd. for $C_{25}H_{32}N_2O_7S$: neut. equiv., 504. Found: neut. equiv., 513.

In another experiment starting with 32.5 g. (0.100 mole) of the hydrazide, only 15.9 g. (31%) of crystalline solid was obtained, but this was apparently largely the (+)-isomer since it was subsequently converted to the (+)-methyl ester, m.p. 131–132°, $[\alpha]^{27}D$ 17.8° (*c* 2.8, chloroform) in 82% yield.

(+)-Methyl N-Carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteinate[8] (XVII).—A solution of the crude N-carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteine from the preceding preparation in 150 ml. of benzene was treated slowly with excess diazomethane in ether while stirring at 5°, causing the separation of a crystalline precipitate. This was collected after 20 hr. at room temperature, washed with a mixture of benzene and petroleum ether (40–60°) and dried. The 24 g. of crystals, m.p. 116–120° with softening at 110°, was recrystallized from a mixture of benzene and petroleum ether (90–100°) to afford 10.1 g. (25% calculated from the hydrazide and based on the total amount of all isomers possible) of white crystals, m.p. 130–131.5°. Two similar runs gave yields of 26%, m.p. 131–132°, and 27%, m.p. 130–131°. Further recrystallization raised the m.p. to 131.0–131.5°, $[\alpha]^{27}D$ +17.8°, +17.9° (*c* 2.8, 1.8, chloroform).

Anal. Calcd. for $C_{26}H_{34}N_2O_7S$: C, 60.23; H, 6.61. Found: C, 60.25; H, 6.44.

The filtrates from above were concentrated to yield 11.7 g. of crystals, m.p. 109–112°, $[\alpha]^{27}D$ −9.7°, and 1.8 g. of amorphous solid which were used without further purification in the preparation of (−)-sodium N-carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteinate described below.

(−)-Sodium N-Carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteinate.—The 11.7 g. of solid, m.p. 109–112°, and 1.8 g. of amorphous methyl N-carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteinate from the preceding preparation were dissolved in 40 ml. of dioxane with slight warming, cooled to room temperature and treated with 8 ml. of 5 *N* sodium hydroxide. After 50 minutes with occasional shaking at room temperature, the two-phase system was diluted with 400 ml. of water, causing first a clear solution and then an oily suspension. This was extracted well with chloroform (in which sodium N-carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteinate is quite soluble) and the combined extract washed with two 20-ml. portions of water, dried over sodium sulfate, filtered and concentrated to a viscous yellow sirup. The latter crystallized from 40 ml. of absolute ethanol at room temperature upon seeding and then diluting with 30 ml. of petroleum ether (60–68°) when rosettes began to grow. After two days the crystals were collected, rinsed with a mixture of ethanol and petroleum ether (40–60°) and dried, affording 2.0 g., m.p. 169–173°, $[\alpha]^{25}D$ −18.6° (*c* 1.7, chloroform). From the concentrated filtrate was obtained 1.7 g. of fluffy needles, m.p. 167–171°, and from the original aqueous layer an additional 1.5 g., m.p. 165–170°.

(−)-N-Carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteine (XIV).—Several samples of (−)-sodium N-carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteinate representing material melting in the range of 165–175° were combined (2.7 g., 0.0051 mole) and dissolved in 75 ml. of water by warming. The gelatinous precipitate which resisted solution was removed by filtration and the clear solution acidified by dropwise addition of 6 *N* hydrochloric acid producing an oily suspension which coagulated and solidified overnight. The solid was collected, pressed on the filter, dissolved in chloroform, dried over sodium sulfate and concentrated to an almost colorless sirup which changed to a suspension of fine white crystals when ether was added. Upon isolating a small portion (155 mg.) of these crystals, triturating them with ether, collecting and drying, they melted at 126.0–126.5°, $[\alpha]^{29}D$ −13.5° (*c* 1.6, chloroform).

Anal. Calcd. for $C_{25}H_{32}N_2O_7S$: C, 59.53; H, 6.38. Found: C, 59.46; H, 6.51.

(−)-Methyl N-Carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteinate (XVI).—The bulk of the ether suspension of (−)-N-carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteine from the preceding preparation (0.0048 mole) was treated in portions with excess ethereal diazomethane while cooling and swirling, resulting in gas evolution but no visible change in the suspended material. After standing overnight the suspension was concentrated, petroleum ether (40–60°) added, the suspension concentrated again to 40 ml. and the fine white precipitate collected and dried. The 2.1 g. (84%) of solid melted at 114.5–116° with softening at 112°, $[\alpha]^{27}D$ −16.9° (*c* 2.1, chloroform). An additional 0.10 g. (88% total), m.p. 111–114°, was obtained from the filtrate. A sample which was recrystallized by dissolving in ether and adding petroleum ether (40–60°) melted at 116.0–116.5°.

Anal. Calcd. for $C_{26}H_{34}N_2O_7S$: C, 60.23; H, 6.61. Found: C, 60.49; H, 6.65.

(+)-N-Carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteine (XV).—In a 25-ml. erlenmeyer flask 0.52 g. (0.0010 mole) of (+)-methyl N-carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteinate, m.p. 131–132°, $[\alpha]^{27}D$ 17.8° (*c* 2.8, chloroform), was dissolved with stirring and slight warming in 3 ml. of dioxane. Then 1.5 ml. (0.0015 mole) of 1 *N* sodium hydroxide was added dropwise with stirring over a period of 5 minutes and stirring continued 45 minutes longer, the solution becoming essentially clear after 15 minutes. Gradual dilution with 20 ml. of water produced a cloudiness which was removed by treating with Norit and filtering. The clear solution was acidified to congo red by dropwise addition of 1 *N* hydrochloric acid with rapid stirring and the white gelatinous precipitate which separated was stirred 45 minutes, filtered, washed with water and sucked dry on the filter affording 0.45 g. (89%), m.p. 118–122°. Another run in which the precipitated acid was extracted into chloroform, dried, concentrated and recrystallized from a mixture of benzene and petroleum ether (60–68°) yielded 0.29 g. (57%), m.p. 129–133°, which could not be improved by further recrystallization.

(+)-Ethyl β,β-Diethoxyalanyl-L-cysteinate Hydrochloride (XIX).—In a 250-ml. three-necked flask equipped with a mechanical stirrer, drying tube containing soda-lime and nitrogen inlet was placed 40 ml. of liquid ammonia and 1.04 g. (0.0020 mole) of (+)-methyl N-carbobenzoxy-β,β-diethoxyalanyl-S-benzyl-L-cysteinate, m.p. 130–131.5°, and a pinch of iron rust added. While the suspension was stirred, 0.18 g. (0.008 mole) of sodium was added in 0.02-g. pieces during two minutes, the characteristic blue color disappearing almost immediately after each addition until the reduction was complete, whereupon the color persisted. (During this process the original white suspension first dissolved completely and then a new white suspension formed.) Almost immediately, 0.70 g. (0.005 mole) of ammonium sulfate was added, whereupon the color gradually disappeared. The ammonia was evaporated under a stream of nitrogen during 1 hr., the white residue treated with 2 ml. of water and the gray solution neutralized to Alkacid test paper with 42 drops of 6 *N* sulfuric acid which produced a short-lived gas evolution and a strong odor of hydrogen sulfide at each addition. While the neutral solution was stirred, it was treated slowly with 25 ml. of absolute ethanol, causing the separation of a white granular precipitate which was removed by filtration and discarded. The clear colorless filtrate was concentrated under reduced pressure below 40° to a yellow sirup (which always crystallized spontaneously in later runs). It was dissolved in 30 ml. of absolute ethanol, this saturated with anhydrous hydrogen chloride while cooling and after 2 hr. at room temperature concentrated under reduced pressure. Fresh solvent was added and this also removed, leaving an orange moist cake of crystals which was triturated with 1.5 ml. of methyl ethyl ketone. The solid was collected on a filter stick, rinsed with 1 ml. of methyl ethyl ketone, then with ether and dried under diminished pressure at 70°. The almost white crystalline product weighed 249 mg., m.p. 168–170° (micro block), $[\alpha]^{29}D$ +25.5° (*c* 0.64, chloroform).

Anal. Calcd. for $C_{12}H_{25}N_2O_5SCl$: C, 41.80; H, 7.28; alkoxyl (calcd. as 3 ethoxyl), 39.25. Found: C, 42.17; H, 7.01; alkoxyl (ethoxyl), 39.58.

A sample of the product dissolved in 10% sodium hydroxide and treated with aqueous sodium nitroprusside

solution gave a deep red color indicating the presence of a sulfhydryl group.

Hopkins reagent was of no value in isolating this product. When added to an acidified aqueous solution of the residue after the liquid ammonia was removed, it sometimes caused a yellow color but gave no precipitate. The final crystalline hydrochloride also failed to give a precipitate with this reagent.

Studies on the Occurrence and Structure of Acetylandromedol (Andromedotoxin)

BY W. H. TALLENT, MARY L. RIETHOF AND E. C. HORNING

RECEIVED FEBRUARY 15, 1957

A procedure for the detection of acetylandromedol in plant extracts was developed through use of paper electrophoresis with borate buffer solutions. Positive results were found for some but not all species of *Kalmia, Leucothoe, Lyonia, Pernettya, Pieris* and *Rhododendron*. A particularly good source was found in *K. angustifolia* var. *caroliniana*. New evidence indicated that the empirical formula for andromedol is $C_{20}H_{34}O_6$, and that acetylandromedol, grayanotoxin I and rhodotoxin are identical and have the formula $C_{22}H_{36}O_7$.

The reported toxicity to stock of *Andromeda, Kalmia, Leucothoe* and *Lyonia* species indicates that a number of plants of the *Ericaceae* in addition to those of the genus *Rhododendron* contain physiologically active compounds. Acetylandromedol,[1] isolated[2] from leaves of *Rhododendron maximum*, was found to be a potent hypotensive agent,[3] and in order to determine if commonly occurring species of these genera contained acetylandromedol or related substances a survey was made of a number of plants of the *Ericaceae* with reported or potential physiological activity. These included *Andromeda japonica* from which Eykman[4] isolated in 1882 a crude toxic substance to which the name asebotoxin was given, and *Rhododendron luteum*, reported by Xenophon to be the source of a poisonous honey given to Grecian soldiers in an early campaign in Asia Minor. It was necessary to develop a method for the identification of acetylandromedol in plant samples, and this work is described in Part I together with the results of a limited survey made for ten genera in the *Ericaceae*.

Part II describes further chemical studies on acetylandromedol.

I. Plant Studies

Acetylandromedol is known to contain a 1,2-glycol structure.[2] This suggested the possibility of utilizing paper electrophoresis with a borate electrolyte for the separation and identification of plant components in the acetylandromedol fraction. The rate of migration of a borate diol complex during paper electrophoresis depends on the borate–diol equilibrium and upon the absorption characteristics of the complex with regard to cellulose. In dilute borate solutions a 2:1 diol–borate complex may be formed in addition to a 1:1 complex, and this effect usually can be recognized by studying the effect of borate concentration changes. The 2:1 diol–borate complex is the stronger acid of the two.[5]

It was found that acetylandromedol migrated toward the anode on paper electrophoresis with sodium tetraborate solutions. The vanillin–perchloric acid spray of Godin[6] was an excellent visualizing reagent. With 0.05 *M* sodium tetraborate concentration, a single migrating species was observed (curve B, Fig. 1), and with 0.01 *M* electrolyte concentration two ionic species were observed (1a and 1b in curve D, Fig. 1). The principal species under the latter conditions was assumed to be the expected 1:1 borate–diol complex. The secondary species with higher mobility occurring in very dilute borate solution was assumed to be the 2:1 complex. An alternate but less likely explanation for the two ionic species is that they represent borate complexes with two different pairs of hydroxyl groups of acetylandromedol.[5a,5e]

When this procedure was used with crude acetylandromedol fractions from *Rhododendron maximum* leaves, the characteristic behavior of acetylandromedol with different borate concentrations was exhibited (curves A and C in Fig. 1), and compounds responsible for two additional colored areas (marked 2 and 3 in curves A and C) were indicated by the spray reagent. The recognition of these and other compounds in successive runs was aided materially by the strong and distinctive colors produced by the Godin reagent.

This procedure was applied to a number of plant specimens from the U. S., Cuba and Costa Rica. Figure 2 shows examples of the results obtained after electrophoresis. Data taken from such electrophoretograms are summarized in Table I. The presence of acetylandromedol was checked, where it occurred, in two concentrations of sodium tetraborate electrolyte (0.01 and 0.05 *M*) in order to confirm the characteristic equilibrium behavior.

(1) This is proposed in Part II as a change in name from andromedotoxin.

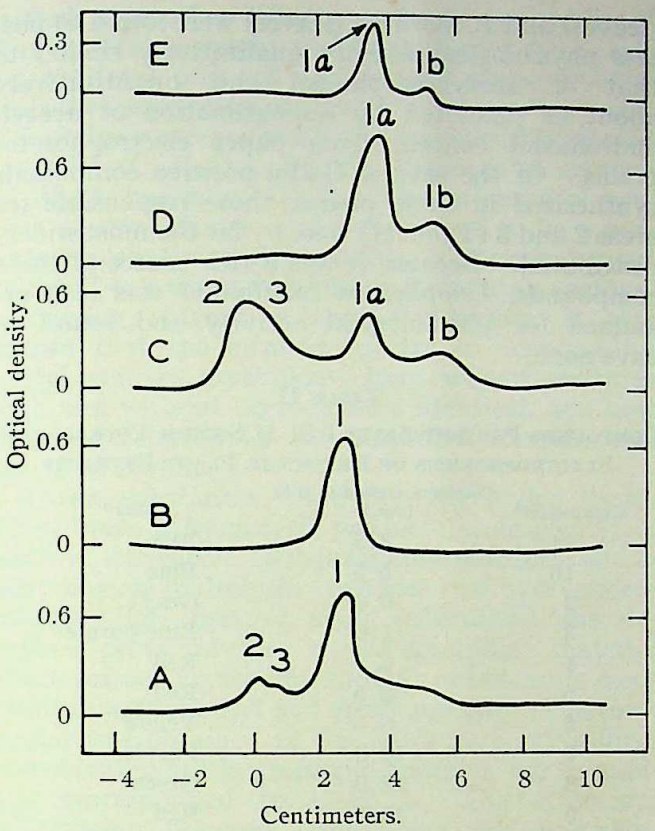

Fig. 1.—Densitometer tracings of paper electrophoretograms obtained with 0.05 *M* sodium tetraborate solution for crude *Rhododendron maximum* extract (curve A) and acetylandromedol (curve B) and of paper electrophoretograms obtained with 0.01 *M* sodium tetraborate solution for crude *Rhododendron maximum* extract (curve C) and acetylandromedol (curve D). Grayanotoxin I from *Leucothoe grayana*[11] was used for curve E with 0.01 *M* sodium tetraborate solution. The times were 4 hours for A and B, and 6 hours for C, D and E. A vanillin–perchloric acid spray was used as a visualizing reagent. Colors are noted in Table II.

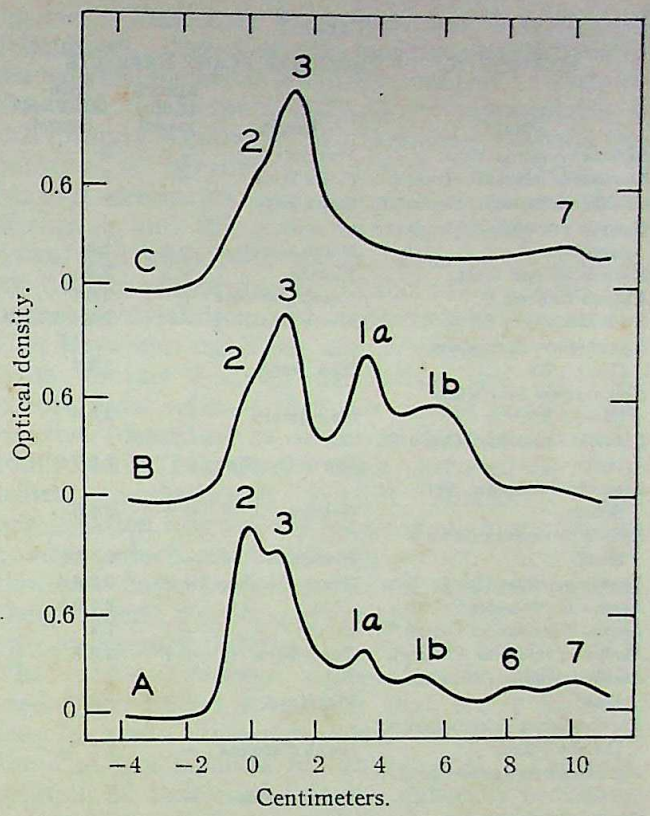

Fig. 2.—Densitometric tracings of paper electrophoretograms obtained with 0.01 *M* sodium tetraborate solution (6 hours) for extracts of *R. japonicum* (curve A), *K. angustifolia* (curve B) and *Leucothoe axillaris* (curve C). A vanillin–perchloric acid spray was used as a visualizing reagent.[6] Colors are in Table II. Bioassays for hypotensive activity were negative for the sample used for C, while a low order of activity was found for A. The plant used for B contained the highest amount of acetylandromedol of all of those investigated.

It was not possible to secure quantitative data relating to acetylandromedol, but by working with selected quantities of the extracts and by estimating the intensity of color it was found that some degree of differentiation could be made between plants containing much acetylandromedol and those containing little. This is indicated by the ratings of + to +++ in Table I. The highest concentration observed for acetylandromedol was in *K. angustifolia* var. *caroliniana*, and in separate isolation experiments (on a large scale) it was found that the yield of acetylandromedol from fresh leaves of this plant was about 0.06–0.09%.[7]

Rhododendron species showed a considerable variation in their acetylandromedol content; *R. calendulaceum*, *R. canadense* and *R. canescens* gave completely negative results. *R. luteum*, believed to be the source of the poisonous *Rhododendron* honey mentioned by Xenophon and Dioscorides, contained acetylandromedol. It was not possible to examine the flowers of this species, but flowers of *R. catawbiense* contained more acetylandromedol than the leaves. Two common species of the genus *Kalmia* were examined. *K. latifolia* ("mountain laurel"), although reported to be toxic to stock, contained far less acetylandromedol than *K. angustifolia* ("sheep-kill"). *Lyonia* and *Leucothoe* species are also regarded generally as being poisonous to stock, and *Leucothoe editorum* was found to contain acetylandromedol in a quantity comparable to *R. maximum* and *R. luteum*. *Lyonia* species contained little (*L. mariana*) or no acetylandromedol.

There has been uncertainty about the identity or non-identity of the substances described by Eykman[4] (asebotoxin, from *A. japonica*), de Zaayer[8] (andromedotoxin, m.p. 228–229°, from *Andromeda* species), Hardikar[9] (andromedotoxin, m.p. 258°, from an unidentified *Rhododendron* species), Makino[10] (rhodotoxin, m.p. 245°, from *R. hymenanthes*), Takemoto[11] (grayanotoxin I, m.p. 259–260°, from *L. grayana*) and acetylandromedol from *R. maximum*[2] and *K. angustifolia*. Through the courtesy of Dr. Takemoto, samples were exchanged and compared. The infrared spectra of all samples were identical[11] (rhodotoxin from *R. metternichii*, grayanotoxin I, and acetylandromedol). The borate electrophoresis behavior

(7) Yields from *R. maximum* collected in North Carolina averaged about 0.008%. This was estimated as a ++ concentration.

[a] Leaves or leaves and stems were used unless otherwise specified. [b] See Table II for additional data. [c] Flowers. [d] Bark. [e] *Andromeda japonica*.

for grayanotoxin I was identical with that observed for acetylandromedol (curve E, Fig. 1). The paper electrophoresis patterns for extracts of *A. japonica* also showed areas 1 and 1a and 1b, and it therefore seems likely that all of these descriptions relate to the same compound.

In carrying out this work, it was evident that certain reservations were required. Experiments with different species showed that a number of compounds giving positive color reactions were always present in the crude fractions (Tables I and II). One or more of these compounds, or possibly other substances which did not give a Godin color, might well exhibit physiological activity similar to that of acetylandromedol. In order to examine this possibility, several fractions from plants reported to be toxic and found to contain several Godin-positive compounds but little or no acetylandromedol were compared with fractions from *K. angustifolia* with regard to their physiological activity. These fractions included extracts of *L. axillaris* (leaves), *L. myrtilloides* (leaves) and *K. latifolia* (flowers), and in these cases it was found that the physiological activity was negligible. Extracts from *R. japonicum* (leaves), *R. latifolia* (leaves) and *L. mariana* (leaves) were found to possess physiological activity qualitatively similar to that of acetylandromedol and quantitatively about as predicted by approximation of acetylandromedol content from paper electrophoretograms. Of the several Godin-positive compounds synthesized in these plants, those responsible for areas 2 and 3 (Table II) were by far the most widely distributed. Because it was a rich source of these compounds, *Leiophyllum buxifolium* was also examined for physiological activity and found to have none.

TABLE II

COMPOUNDS PRESENT AFTER 0.01 *M* SODIUM TETRABORATE ELECTROPHORESIS OF ERICACEAE PLANT EXTRACTS

Compound[a]	Distance moved in 6 hr. (cm.)[b]	Color[c]

[a] Diol complexes 1a and 1b are derived from acetylandromedol (see Fig. 1). [b] Conditions: 7.5 volts per cm., 1–2 ma., 6 hours, corrected for electroendosmosis. [c] After spraying with vanillin–perchloric acid reagent.[6]

These results do not exclude the possibility that a second compound with the same characteristics as acetylandromedol may exist, but the chemical and bioassay data obtained up to the present time point to the identification of a common substance as the principal physiologically active agent of the Ericaceae.[12] The compounds responsible for colored areas described here as 2 and 3 are widely distributed through the family, but their presence or absence has no apparent relationship to the acetylandromedol content of the plant.

II. Chemical Studies

The presence of physiologically active materials in *Rhododendron*, *Kalmia*, *Pieris* (*Andromeda*) and *Leucothoe* species has been confirmed in every laboratory that has studied the problem, but there has been no general agreement on the physical properties and empirical formulas of the agent or agents responsible for the activity. (The two most recent formulas are $C_{19}H_{30}O_6$ and $C_{22}H_{36}O_7$.) The work in the previous section points to the occurrence of a common substance throughout these plants, and it is proposed that this be named acetylandromedol.[13]

Acetylandromedol (from *R. maximum*) was sub-

(12) Investigations of grayanotoxins I, II and III (see Part II) point to three substances with physiological activity. The Japanese workers used a fresh-water fish for their work; the activity described in this paper relates only to hypotensive action studied in anesthetized dogs. There is a possibility that andromedol (grayanotoxin III) accompanied acetylandromedol in crude fractions, but we have not observed this compound in our isolation work up to the present time.

(13) It is desirable to use a name which reflects the functional groups of the molecule and which permits a systematic naming of derivatives. The parent polyhydroxy compound has been named andromedol, following the plant first used by Eykman[4] and de Zaayer and Plugge.[5]

mitted to another laboratory for X-ray studies.[14] The molecular weight was found to be 410.2, calculated from unit cell and density measurements, with the assumption of four molecules per unit cell. This value corresponded to the previously suggested formula[2] ($C_{19}H_{30}O_6$) and the elements of acetone ($C_{22}H_{36}O_7$ has m.w. 412.5). The presence of acetone of crystallization was considered to be a possible explanation for this result; the crystals used in the X-ray work were obtained from an acetone-containing solvent mixture. However, it was known that the infrared spectra of acetylandromedol samples crystallized from solvent mixtures with and without acetone were identical, and new evidence relating to the empirical formula was therefore sought.

Three substances were brought under study. These were a hydrolysis product (andromedol), a benzoyl derivative (tribenzoylandromedol), and a dehydration–hydrolysis product (anhydroandromedol). The first of these substances was described previously[2] as a non-crystalline material which formed crystalline adducts of indefinite composition with methyl and ethyl acetate. The compound was obtained in this work as a crystalline, non-solvated but hygroscopic material, whose analysis corresponded to $C_{20}H_{34}O_6$. The structural relationship between andromedol and acetylandromedol is the same as that between grayanotoxin III and grayanotoxin I[15] (to which the formula $C_{22}H_{36}O_7$ was assigned), and andromedol and grayanotoxin III should therefore be identical. A more direct comparison is not possible since grayanotoxin III has been described only as a solvated material with one-half molecule of water or ethyl acetate.[15] We have not observed this compound as a component of *Rhododendron* or *Kalmia* species, but it may be present in low concentration in these plants.

Miyajima and Takei[15] also described anhydrograyanotoxin III as a compound obtainable from both grayanotoxin III and grayanotoxin I. In our work, acetylandromedol was subjected to acid treatment in aqueous solution, and from the mixture of products there was isolated by countercurrent distribution a crystalline substance of formula $C_{20}H_{32}O_5$. The melting point (and empirical formula) is in agreement with that given by Miyajima and Takei[15] for anhydrograyanotoxin III. Additional points of comparison are lacking. It is likely that these compounds are identical, but melting points in this series are not a reliable index of identity.

The calculated and found C, H analytical values for acetylandromedol, rhodotoxin and grayanotoxin I reported in this and other papers[2,9–11,15] do not distinguish between the formulas $C_{19}H_{30}O_6$ and $C_{22}H_{36}O_7$ (different acetyl analyses have been reported; these may have been due to analytical difficulties). However, the reported derivatives of the isolated materials should be subject to correlation with the formula $C_{20}H_{34}O_6$ for andromedol, if this formula is correct. We therefore reviewed the question of benzoyl and acetyl derivatives. A benzoyl derivative was prepared from acetylandromedol, and this compound was found by analytical and ultraviolet spectra data to correspond to tribenzoylandromedol (Table III). The tribenzoylacetylandromedol (tribenzoylgrayanotoxin I) of Miyajima and Takei and of Yamashita[15] represents another benzoyl derivative, and the analytical data indicate that our earlier benzoyl derivative (described as dibenzoylandromedotoxin[2]), confirmed by Takemoto[11] was a methanol solvate of tribenzoylandromedol. Further studies of the benzoylation reaction are required to determine the point at which ester exchange occurs. Acetyl derivatives have been reported in several papers; these include diacetylandromedol (Table III) and two apparently different tetraacetyl derivatives.[15] The carbon–hydrogen values for diacetylandromedol correspond so closely that either formula may be used; the acetyl values, however, point to the $C_{20}H_{34}O_6$ formula for andromedol. The acetylation of andromedol to the naturally occurring acetylandromedol has not been accomplished, and a triacetylandromedol is not known.

A remaining problem concerns the structure of isopropylideneanhydroandromedotoxin,[2] which should now correspond, on the basis of its infrared spectrum, to an isopropylideneanhydroacetylandromedol with one double bond. The reaction leading to this compound is under investigation.

Table III contains newly determined analytical data for acetylandromedol and a number of derived compounds. These data, with the comparisons made as a consequence of Takemoto's recent reisolation of grayanotoxin I and rhodotoxin mentioned in Part I and the molecular weight determination for acetylandromedol,[14] indicate that the correct formula for andromedol is $C_{20}H_{34}O_6$ and that the acetyl derivatives, grayanotoxin I, rhodotoxin and acetylandromedol, are identical.

Recent work on grayanotoxin II has resulted in a structural proposal (I).[16] It seems reasonable to accept a close structural relationship between acetylandromedol and a second polycyclic polyhydroxy compound isolated from *L. grayana*, but our observations do not particularly support structure I as a basic system subject to elaboration for acetylandromedol. Anhydroandromedol and andromedol were examined for evidence of unsaturation by ultraviolet absorption studies to 195 mμ. Both

[a] Carbon, hydrogen and acetyl determinations by Mr. J. F. Alicino, Metuchen, N. J. [b] Direct oxygen determinations by Dr. W. Zimmermann, Melbourne, Australia.

substances showed no ultraviolet absorption. Anhydroandromedol was unaffected by bromine and by hydrogenation conditions, and this may be taken to indicate an ether bridge possibly similar to that found for some steroids. If the empirical formula $C_{20}H_{34}O_6$ for andromedol is correct, a tetracyclic system must be allocated to the parent compound. One of the hydroxyl groups of the 1,2-diol structure evidently is involved in ether formation in anhydroandromedol, since the anhydro-compound does not form a borate–diol complex.

Terminal methyl determinations were made for andromedol, acetylandromedol and anhydroandromedol. These indicate that two or three methyl groups may be tentatively assigned to andromedol. We suspect that andromedol may be a hexahydroxy compound; positive evidence bearing on this point is an active hydrogen determination on anhydroandromedol (four active hydrogens were indicated). In the absence of additional supporting evidence this should not be taken as a definitive structural assignment. There is no strong evidence for the nature of the ring system of andromedol, but the cell measurements for crystalline acetylandromedol suggest that a steroid-like skeleton is possible. The most attractive part of this hypothesis lies in the possibility that suitably substituted steroids may have a direct effect on blood pressure control centers.

Oxidation and dehydrogenation experiments present additional possibilities for further study, and this approach is under investigation.

Acknowledgments.—We are indebted to the Section of Plant Introduction, Agricultural Research Service, U. S. Department of Agriculture, for the collection and identification of plant materials, and to Dr. N. C. Moran for the pharmacological data. Mr. D. L. Rogerson carried out the plant extraction work; Miss Catherine Monaghan and Miss Patricia Wagner performed the spectroscopic work, and the analytical data were supplied by Mr. J. F. Alicino, Dr. W. Zimmermann and the Clark Microanalytical Laboratories.

Experimental[17]

Plant Extractions.—A 500-g. sample of undried plant material was ground in a Wiley mill and suspended in 5 l. of water. The *p*H was adjusted to 7.0–7.5 with barium hydroxide, and the suspension was heated to 90–100° for 1 hour with efficient stirring. It was filtered (Supercel pad) and the filter cake was washed well with hot water. The combined filtrates were concentrated (reduced pressure) to 500 ml.; the *p*H was adjusted to 7.0–7.5 and 4.5 l. of ethanol was added. A precipitate was removed by filtration and washed with alcohol. The filtrate and washes were combined and concentrated to 300 ml. (reduced pressure). The solution was adjusted to *p*H 6.5 and filtered. The filter cake was washed with water, and the solution was concentrated to 300 ml. and continuously extracted with chloroform for 24 hours. The solvent was removed from the organic extract *in vacuo*, and the residue was examined for the presence of acetylandromedol and related compounds by paper electrophoresis.

After the observation was made that *K. angustifolia* was a particularly rich source of acetylandromedol, several large-scale isolation experiments were carried out according to the published procedure.[2] One run, on a 100 lb. scale, gave 28.6 g. of acetylandromedol. The yields were in the range 0.06–0.09% (about ten times that observed for *R. maximum*).

Paper Electrophoresis.—Strips of Whatman #1 paper 42 cm. long and 26.5 cm. wide were used. For solid samples, solutions containing 10 mg. per ml. in ethanol or chloroform were employed. Approximately 0.02 ml. of the solution was applied to the paper. For crude plant extracts, 0.06 ml. of solutions containing 25 mg. per ml. in chloroform or ethanol was used. The mixtures or compounds were spotted at 4 cm. intervals along a center line parallel to the short edge of the paper. The strip was supported at the center line by a glass rod, and the ends dipped about 1 cm. into electrode compartments containing sodium tetraborate solution. The entire system was enclosed in a Lucite box. The strip was allowed to wet by a capillary action, and the separation was carried out at 300 v. (a gradient of 7.5 v. per cm.). This resulted in a current of 1–2 ma. when 0.01 *M* sodium tetraborate was used and 5–6 ma. when the buffer concentration was 0.05 *M*. The time for electrophoresis was 6 hours for a 0.01 *M* buffer and 4 hours for a 0.05 *M* buffer. Acetylandromedol and related compounds were detected by spraying the air-dried strip with a solution prepared just before use by mixing equal volumes of solutions of 3% perchloric acid in ethyl alcohol and 1% vanillin in ethyl alcohol.[6] Electroendosmosis was determined by spotting urea (0.02 ml. of a water solution containing 10 mg./ml.) on the strip and determining its position after electrophoresis by cutting the appropriate part of the strip and spraying it with a 0.5% solution of *p*-dimethylaminobenzaldehyde in 1.0 *N* hydrochloric acid. A yellow spot resulted, the center of which represented "0 cm. moved" for all curves and data reported in this paper.

Optical density measurements were made with a Photo-

(17) All melting points were taken on a Kofler stage. Optical rotations were determined with a Rudolph photoelectric-matching polarimeter. Ultraviolet spectra were taken with Cary Recording Spectrophotometers (Models 11 and 14). Infrared spectra were taken with a Perkin–Elmer Model 21 instrument. Infrared spectra of all new compounds described here have been deposited as Document No. 5130 with the ADI Auxiliary Publications Project, Photoduplication Service, Library of Congress, Washington 25, D. C. A copy may be secured by citing the Document number and by remitting $1.25 for photoprints, or $1.25 for 35 mm. microfilm, by check or money order payable in advance to Chief, Photoduplication Service, Library of Congress. Other spectra are available through a previous paper.[2]

volt Electronic Densitometer, Model 525. A tungsten light source (no filter) was used, and the sensitivity dial was at 2.

Comparison of Samples.—A sample of grayanotoxin I[18] (identical with rhodotoxin), was compared with acetylandromedol samples from *R. maximum* and *K. angustifolia*. The infrared spectra of all of these materials were identical. The behavior on electrophoresis, including the borate concentration effect, was identical for all samples. Curve E, Fig. 1, shows the characteristic result found with 0.01 *M* buffer solution for the grayanotoxin I sample.

Physiological Activity.—The hypotensive action of crude plant extracts and related materials was determined as described elsewhere.[3]

Acetylandromedol.—The molecular weight of acetylandromedol was determined by measurements of the crystal density and unit cell dimensions.[14] Assuming four molecules per unit cell, the value was 410.2 (calcd. for $C_{22}H_{36}O_7$, 412.5; for $C_{19}H_{30}O_6$, 354.4).

A C-methyl determination showed the presence of at least three such groups (one must be allocated to the acetyl group).

Anal. Calcd. for $C_{22}H_{36}O_7$: C-CH_3, 10.93 (for three). Found: C-CH_3, 9.16, 9.19.

Additional analytical data are in Table III. The sample used for these analyses was prepared for clinical studies; the isolation followed our earlier work.[2]

Diacetylandromedol.—Newly determined analytical data are in Table III. The sample was from a previous preparation.[2]

Tribenzoylandromedol.—Benzoyl chloride (15 ml.) was added to a previously chilled (0°) solution of 500 mg. of acetylandromedol in 60 ml. of pyridine. After 12 hours at 0°, the mixture was added to stirred iced 10% sodium carbonate solution. The suspension was stirred for 1 hour, and the product was extracted with chloroform. The chloroform solution was washed (sodium bicarbonate solution and water), and the solvent was removed under reduced pressure. After trituration of the residue with benzene–hexane, 433 mg. remained; this was crystallized from benzene–methanol to give 295 mg. of colorless crystalline solid, m.p. 213–216°. Recrystallization from chloroform–benzene gave a sample melting at 217–219°, and this was not changed by further recrystallization from methanol–chloroform, chloroform–benzene, methanol–benzene, and ethyl acetate–benzene.

Optical rotation values were found to be $[\alpha]^{24}_{589}$ + 85.5, $[\alpha]^{24}_{436}$ +200.0 (*c* 0.93, chloroform).

Analytical data are in Table III.

The ultraviolet spectrum of this substance in ethanol was qualitatively similar to that of ethyl benzoate. The maxima for the two spectra were at 230 and 228 mμ, respectively. The ϵ_{max} values were 3.71×10^4 and 1.22×10^4. The ϵ_{max} value for the andromedol derivative is therefore in close agreement with that expected for three benzoyl groups (calcd. value 3.66×10^4), and since the acetyl analysis showed no acetyl groups, the structure assigned to this compound is that of tribenzoylandromedol.

The infrared spectrum was similar to that of our previous benzoyl derivative (reported m.p. 226.5–227.5°) except for differences in bands at 9.70 and 9.80 μ. Three carbonyl bands were found at 5.80, 5.85 and 5.90 μ, and a sharp hydroxyl band at 2.80 μ. Since the earlier sample was used for analytical purposes, it was not possible to obtain mixed m.p. or additional analytical data on the original sample. It should be pointed out that the material described previously as "dibenzoylandromedotoxin" was prepared by benzoylation in pyridine at steam-bath temperature, and it was recrystallized for analysis from methanol–benzene. The analytical data and the great similarity in infrared spectra with that from the compound prepared at 0° suggest that the earlier product was a methanol solvate of tribenzoylandromedol (*Anal.* Calcd. for $C_{42}H_{50}O_{10}$: C, 70.57; H, 7.05. Found[2]: C, 70.27; H, 6.78). The occurrence of solvates in this series is not uncommon. The analytical sample for the new benzoyl derivative was recrystallized from chloroform–benzene immediately before analysis and solvation is not indicated. It is not possible to define the relationship of this tribenzoyl derivative to the "tribenzoylgrayanotoxin I" (tribenzoylacetylandromedol) of Yamashita,[15] except that the analytical data point to solvation as a possible explanation. The experimental conditions described here were chosen to allow the use of a large excess of benzoyl chloride, but to avoid ester exchange or dehydration effects which might result from heating the reaction mixture. Since ester exchange occurred in this case at 0°, it is likely that it also occurred in cases where reaction mixtures were heated.

Andromedol.—A solution of 3.0 g. of acetylandromedol in water (135 ml.) and ethanol (30 ml.) containing 15 g. of sodium hydroxide was heated under reflux for 7 hours. The alkali was removed with Amberlite IRC-50 (H+) resin, and the product was extracted with chloroform (continuous extraction). The chloroform solution was reduced to a small volume, and a crystalline material separated slowly. This product, m.p. 224–227° dec., was hygroscopic and could not be recrystallized in satisfactory form.

The infrared spectrum showed no carbonyl band. A strong, broad band at 2.90 μ indicated a hydroxyl group or groups.

Optical rotations were found to be $[\alpha]^{26}_{589}$ −16.7, $[\alpha]^{26}_{436}$ −29.6 (*c* 0.96, ethanol).

Analytical data are in Table III. A C-methyl determination showed at least two such groups.

Anal. Calcd. for $C_{20}H_{34}O_6$: C-CH_3, 8.12 (for two). Found: C-CH_3, 8.10, 8.18.

This compound was water-soluble, and its ultraviolet absorption properties were measured in water solution to 195 mμ. No absorption of any kind was found; this suggests that unsaturation was not present.

When examined by paper electrophoresis with a borate electrolyte, andromedol was found to migrate very much like acetylandromedol. The behavior was similar with different borate concentrations, indicating that the stereochemical relationships of the hydroxyl groups involved in the borate complexes were essentially the same for the two compounds. The Godin color was blue, and sufficiently similar to that from acetylandromedol to make differentiation difficult.

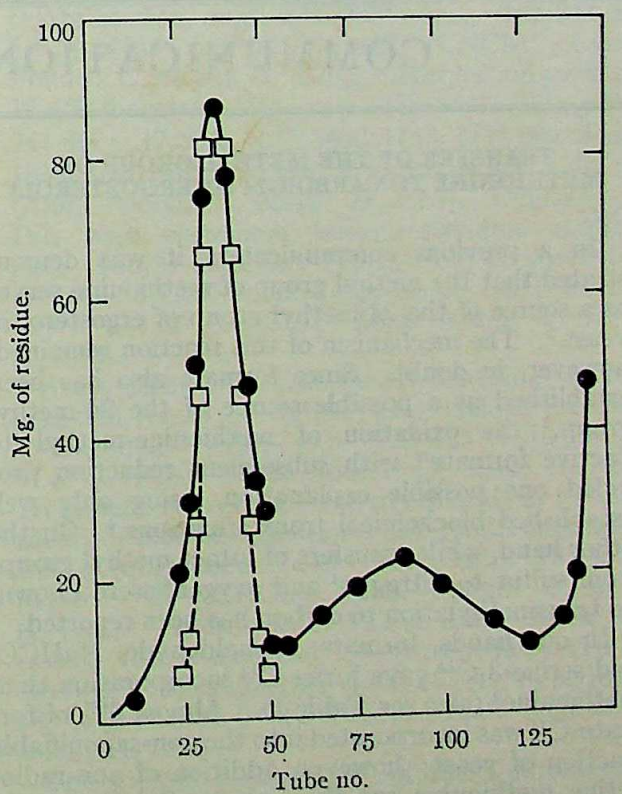

Fig. 3.—Countercurrent distribution of reaction products from treatment of acetylandromedol with acid. The solvent system used was prepared by mixing equal volumes of cyclohexane, ethyl acetate, ethanol and water. The operation was carried out with a 50 tube, 100 ml. per phase apparatus. Tubes 50 to 149 in the figure represent withdrawal fractions of top phase. The closed circles represent experimental points, and the calculated values for the theoretical curve are shown as open squares.

(18) We are indebted to Dr. Takemoto for this sample.

The physiological activity is under study. Preliminary work indicates that the compound has some degree of hypotensive action, and comparison studies are in progress with andromedol, acetylandromedol and the crystalline adduct of andromedol and ethyl acetate.

Andromedol has not been observed in isolation studies with *R. maximum* and *K. angustifolia* var. *caroliniana*, but it might have been present in low concentration in these plants. It has been reported to be present, along with grayanotoxin I (acetylandromedol) in extracts from *L. grayana*.[15]

Anhydroandromedol.—A solution of acetylandromedol (12.5 g.) in 2.5 l. of water containing 7.5 ml. of concd. sulfuric acid was heated under reflux for 4 hr. The dark mixture was neutralized with sodium hydroxide and filtered to remove polymerized material. The filtrate was extracted with chloroform; the chloroform was removed under reduced pressure to yield 3.8 g. of dark, amorphous material. The usual chromatographic methods (alumina, silica) failed to yield a pure substance. Preliminary small-scale studies indicated that purification by countercurrent distribution might be successful. With a solvent system containing equal parts of water, ethanol, ethyl acetate and cyclohexane (this mixture gives two phases of about equal volume) a separation of components was effected. The separation was carried out with 3.6 g., in a 50-tube apparatus with 100 ml. per phase capacity, and with an arrangement for collecting withdrawal fractions of top phase.

The shape of the major band with a peak concentration in tube 37 was compared with a theoretical curve; Fig. 3 shows the experimental and theoretical values. The close correspondence provides evidence for the purity and homogeneity of this product. The contents of tubes 30 to 45 were combined to yield 1.1 g. of crystalline material, m.p. 223–226° after recrystallization from benzene–ethyl acetate.

The infrared spectrum (Nujol) of this compound showed a broad hydroxy band (2.80 μ) but no evidence of a carbonyl group or unsaturation. The ultraviolet absorption was examined to 195 mμ in water solution, but no evidence of unsaturation was found. The compound did not decolorize bromine in chloroform solution, and an ethanol solution did not absorb hydrogen in the presence of a 10% Pd–C catalyst (the compound was recovered unchanged).

The optical rotation was found to be $[\alpha]^{25}_{589}$ −9.3, $[\alpha]^{25}_{436}$ −15.2 (*c* 0.76, ethanol).

When subjected to electrophoresis on paper with a borate solution, the substance gave a purple Godin color and had a mobility of zero. It displayed no physiological activity.

In addition to the analytical data in Table III, the compound was examined for C–CH_3 and active hydrogen.

Anal. Calcd. for $C_{20}H_{32}O_5$: C–CH_3, 8.53 (for two), 12.80 (for three); active H, 0.86 (for three), 1.14 (for four). Found: C–CH_3, 9.84; active H, 1.04.

The broad band with maximum at tube 90 (Fig. 3) was not characteristic of a pure substance; when material from this tube was examined through paper electrophoresis with a borate solution, two compounds were indicated. Both gave purple Godin colors; one was uncharged and the other moved slightly toward the anode. The mixture showed ultraviolet absorption in ethanol solution (λ_{max} 248 mμ) and therefore consisted in part of an unsaturated compound. Tubes 60 to 110 were combined and attempts to separate the components were not successful.

Tubes 125 to 149 contained dark material which was not investigated.

COMMUNICATIONS TO THE EDITOR

TRANSFER OF THE METHYL GROUP OF METHIONINE TO CARBON-24 OF ERGOSTEROL[1]

Sir:

In a previous communication it was demonstrated that the methyl group of methionine serves as a source of the 24-methyl group of ergosterol in yeast.[2] The mechanism of this reaction remained, however, in doubt. Since formate also has been established as a possible source of the 24-methyl group,[3] the oxidation of methionine-methyl to "active formate" with subsequent reduction provided one possible explanation, using only well established biochemical transformations.[4] On the other hand, while transfers of intact methyl groups from sulfur to nitrogen[4] and oxygen[5] were known, no transmethylation to carbon has been reported.

In our hands, formate, formaldehyde, $NaHCO_3$ and serine-3-C^{14} gave lower C^{14} incorporation than methionine[2] (also see Table I). Almost 6% of formate-C^{14} was incorporated into the non-saponifiable fraction of yeast; however, addition of non-radioactive methionine cut the formate-C^{14} incorporation to 0.3%. Under similar conditions, 24.8% of methionine-methyl-C^{14} was incorporated and addition of non-radioactive formate did not affect this incorporation significantly. Addition of homocysteine, which reacts with formate to give methionine,[6] doubled the yields from formate-C^{14}. Folic acid, which is essential in *de novo* methyl synthesis, further increased the yield. On the other hand, aminopterin, a folic acid antagonist, decreased the formate-C^{14} incorporation to 2.3%. While formate itself had only a slight effect on the incorporation of methionine-methyl-C^{14}, formate and homocysteine cut this incorporation sharply. Aminopterin, which prevents the condensation of formate and homocysteine, counteracted the formate homocysteine effect. In the absence of exogeneous formic acid, aminopterin increased the yields from methionine-methyl-C^{14}, probably by preventing partial oxidation of the S-methyl groups.

Serine-3-C^{14} was 50% as efficient as methionine but twice as efficient as formate as the source of C-28 of ergosterol. Non-radioactive serine raised the yield of C-28 from methionine, possibly by acting as an acceptor of the homocysteine moiety, left after the methyl transfer from methionine to ergosterol. The cystathionine thus formed has been shown to be biologically inactive.[6,7]

When doubly labeled methionine, made by mixing methionine-methyl-C^{14} with methionine-

[a] Each flask contained 4 ml. of homogenate made from 1 g. of dry yeast, 2×10^{-4} *M* ATP and 0.5 μc. of C^{14} (1 mc./mmole). [b] Additions per flask (where indicated): homocysteine, 5 mg.; folic acid, 1 mg.; aminopterin, 2 mg.; methionine, 15 mg.; HCOONa, 5 mg.; serine, 15 mg.

TABLE II

TRITIUM:CARBON^{14} RATIOS IN METHIONINE AND ERGOSTEROL

Each experiment consisted of 5 flasks, each containing 4 ml. of yeast extract, 5 mg. of serine, 2 mg. of aminopterin, 1 mg. of ATP, and 0.175 mg. of doubly labeled methionine. Incubation time was 48 hr.; radioactivities were determined on a Packard Tri-Carb Scintillation Counter. The values given are the averages of four samples.

Expt.	T:C^{14} Ratio Methionine	Ergosterol
1	1.12 ± 0.06	0.97 ± 0.06
2	1.12 ± 0.06	1.02 ± 0.02

methyl-T, was incubated with yeast homogenates and the resulting ergosterol rigorously purified, the T:C^{14} ratios of the substrate and product showed that all three hydrogen atoms of the methyl group of methionine are transferred to ergosterol. Were the methyl group oxidized to the level of formaldehyde, one third of the tritium would be lost, and the T:C^{14} ratio in ergosterol (Table II) would have been 67%. Since the ratio is 86–91%, at least some methyl groups of methionine must have been transferred intact to the carbon 24 of the sterol.

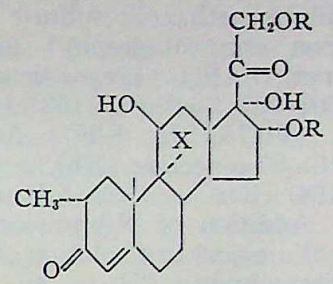
16-HYDROXYLATED STEROIDS. V.[1] THE SYNTHESIS OF THE 16α-HYDROXY DERIVATIVES OF 2α-METHYL-STEROIDS

Sir:

In view of our previous Communication[1] concerning the ability of the 16α-hydroxyl group to abolish the sodium retaining property of a steroid without destroying its glucocorticoid activity, we have investigated the effect of 16α-hydroxylation on the activities of 2α-methyl steroids.[2]

Hydrolysis of 21-acetoxy-3,20-bis-ethylenedioxy-5-pregnene-11β,16α,17α-triol (I)[3] in dilute acetic acid afforded 21-acetoxy-20-ethylenedioxy-11β,16α,-17α-triol-4-pregnen-3-one (II), m.p. 262–263°, $[\alpha]^{25}D$ + 85° ($CHCl_3$); (*Anal.* Found: C, 64.77; H, 8.03). Treatment of compound II with ethyl oxalate and sodium methoxide in *t*-butyl alcohol formed the sodium enolate of 20-ethylenedioxy-2-ethoxyoxalyl- 11β,16α,17α,21 -tetrahydroxy-4-pregnen-3-one (III) as a pale yellow amorphous solid. Methylation of III with methyl iodide and potassium carbonate in acetone followed by removal of the ethoxyoxalyl group by sodium methoxide in methanol gave a glass. After removal of the 20-ketal group with dilute ethanolic sulfuric acid, partition chromatography[4] yielded 11β,16α,17α,21-tetrahydroxy- 2α -methyl- 4 -pregnene- 3,20 -dione (IVa) apparently with one molecule of acetone of crystallization, m.p. 201–203°, $\lambda_{max.}$ 240–241 mμ (ϵ 16,600),[5] $[\alpha]^{25}D$ + 145° ($CHCl_3$); (*Anal.* Found: C, 65.59; H, 8.39). Acetylation gave the 16α,21-diacetate IVb, m.p. 253–254°, $\lambda_{max.}$ 240–241 mμ (ϵ 17,500), $\upsilon_{max.}^{KBr}$ 3450, 1743, 1726 (shoulder), 1654, 1620 and 1238 cm.$^{-1}$, $[\alpha]^{25}D$ + 92° ($CHCl_3$); (*Anal.* Found: C, 65.43; H, 7.75). Oxidation of IVb with chromium trioxide–pyridine reagent[6] gave 16α,21-diacetoxy-17α-hydroxy-2α-methyl-4-pregnene-3,11,20-trione (V), m.p. 240.5–241.5°, $[\alpha]^{25}D$ + 129° ($CHCl_3$); (*Anal.* Found: C, 65.49; H, 7.30).

IVa, X = H, R = H
IVb, X = H, R = Ac
XIIIa, X = F, R = H
XIIIb, X = F, R = Ac



Acetylation of 3,20-bis-ethylenedioxy-5-pregnene-11β,16α,17α,21-tetrol (VIa)[7] yielded the 16α,-21-diacetate (VIb), m.p. 129–135°,[8] $[\alpha]^{25}D$ − 61.5° ($CHCl_3$); (*Anal.* Found: C, 62.49; H, 7.81). Treatment with phosphorus oxychloride in pyridine afforded 3,20-bis-ethylene-dioxy-16α,21-diacetoxy-5,9(11)-pregnadien-17α-ol (VII), m.p. 221–224°, $[\alpha]^{25}D$ − 48° ($CHCl_3$); (*Anal.* Found: C, 65.52; H, 7.67). Hydrolysis of VII in dilute acetic acid gave 16α,21-diacetoxy-20-ethylenedioxy-17α-hydroxy-4,9(11)-pregnadien-3-one (VIII), m.p. 184.5–186°, $[\alpha]^{25}D$ ± 0° ($CHCl_3$); (*Anal.* Found: C, 66.63; H, 7.65).

The sodium enolate (IX) of the 2-ethoxyoxalyl

Digitized by Arya Samaj Foundation Chennai and eGangotri

derivative of VIII (free steroid) was obtained as an amorphous solid in the manner described above. Treatment with methyl iodide and potassium carbonate in acetone followed by reaction with sodium methoxide in methanol and finally hydrolysis in dilute methanolic sulfuric acid yielded after partition chromatography[4] 16α,17α,21-trihydroxy-2α-methyl-4,9(11)-pregnadiene-3-20-dione, (Xa), m.p. 203–207, $[\alpha]^{25}D$ + 103° ($CHCl_3$); (*Anal.* Found: C, 70.75; H, 8.29). Acetylation afforded the 16α,21-diacetate (Xb), m.p. 221.5–224°, $[\alpha]^{25}D$ + 104° ($CHCl_3$); (*Anal.* Found: C, 68.10; H, 7.53).

Addition of N-bromoacetamide and 10% perchloric acid to a solution of Xb in dioxane gave the bromohydrin XI as an amorphous solid, m.p. 131–134° which could not be purified. Treatment of XI with potassium acetate in acetone furnished the 9β,11β-epoxide XII, m.p. 222–223°, $[\alpha]^{25}D$ − 34° ($CHCl_3$); (*Anal.* Found: C, 65.57; H, 7.49). Hydrofluoric acid converted XII to 16α,21-diacetoxy- 9α -fluoro -11β,17α- dihydroxy- 2α -methyl-4-pregnene-3,20-dione (XIIIb), m.p. 140–200°[8], λ_{max} 237–238 mμ (ϵ 16,300), ν_{max}^{KBr} 3420, 1740, 1732, 1725, 1660, 1627 (shoulder) and 1235 cm^{-1}; (*Anal.* F, 3.87. Found: F, 4.29). The corresponding 16α,21-diol XIIIa formed from XIIIb by potassium hydroxide hydrolysis melted at 231–234° d., λ_{max} 237–238 mμ (ϵ 15,100), ν_{max}^{KBr} 3450, 1720, 1660, and 1635 $cm.^{-1}$, $[\alpha]^{25}D$ + 115° (pyridine); (*Anal.* Found: C, 64.30; H, 7.66; F, 4.57).

Bio-assays.[9]—Preliminary assay (rat liver glycogen procedure) of 11β,16α,17α,21-tetrahydroxy-2α-methyl-4-pregnene-3,20-dione (IVa) indicated definite activity (less than that of hydrocortisone); the 16α,21-diacetate IVb and the 16α,21-diacetoxy-11-one V were inactive. In the same assay, 9α-fluoro - 11β,16α,17α,21 - tetrahydroxy - 2α - methyl-4-pregnene-3,20-dione (XIIIa), and its diacetate XIIIb were found to be at least two times as active as hydrocortisone.

In the rate electrolyte (sodium retention) assay, IVa, IVb and V were inactive. The 9α-fluoro-compounds XIIIa and XIIIb exhibited minor activity (much less than that of desoxycorticosterone).

(9) The assays were done by L. Bortle, E. Heyder, J. Perrine, E. Ross, and I. Ringler (Experimental Therapeutics Research Section of these Laboratories).

STEROIDS. LXXXIX.[1] 19-NORDIHYDROTESTOSTERONE DERIVATIVES. A POTENT CLASS OF ANTI-ESTROGENIC COMPOUNDS.

Sir:

Following Birch's[2] synthesis of 19-nortestosterone (Ia) in 1949 a number of 19-nor analogs of the steroid hormones and metabolites have been prepared[3a–h] and many of these substances exhibited unusual biological activity.

We now wish to describe the synthesis of a new series of biologically active 19-nor compounds, namely, the 4,5-dihydroallo derivatives of nortestosterone and 17α-alkyl substituted nortestosterones as well as the corresponding 3β,17β-diols.

While catalytic hydrogenation of Ia, Ib and Ic led to mixtures of the rings A/B *cis* and *trans* compounds, it was found that reduction of the unsaturated ketones in ether–dioxane solution with lithium in liquid ammonia[4] followed by ammonium chloride decomposition, furnished in excellent yield the dihydroallo derivatives: 19-norandrostan-17β-ol-3-one (IIa) (m.p. 130–132°, $[\alpha]D$ + 60°.[5] Found for $C_{18}H_{28}O_2$: C, 78.34; H, 9.94); 17α-methyl-19-norandrostan-17β-ol-3-one (IIb) (m.p. 145–146°, $[\alpha]D$ +35°. Found for $C_{19}H_{30}O_2$: C, 78.49; H, 10.40); and 17α-ethyl-19-norandrostan-17β-ol-3-one (IIc) (m.p. 212–213°, $[\alpha]D$ +33°. Found for $C_{20}H_{32}O_2$: C, 78.47; H, 10.49). Reduction of the 17-vinyl (Id) and the 17-ethynyl (Ie) compounds by this technique resulted in saturation of the 4,5-double bonds only, furnishing, respectively, 17α-vinyl-19-norandrostan-17β-ol-3-one (IId) (m.p. 192–193°, $[\alpha]D$ +47°. Found for $C_{20}H_{30}O_2$: C, 79.18; H, 10.05) and 17α-ethynyl-19-norandrostan-17β-ol-3-one (IIe) (m.p. 222–223°, $[\alpha]D$ +6°. Found for $C_{20}H_{28}O_2$: C, 80.30; H, 9.52). That the unsaturated side-chains had withstood the reduction conditions was demonstrated conclusively by the conversion of IIe to IId by partial hydrogenation (palladium on calcium carbonate–pyridine) and the derivation of IIc from either IId or IIe by reduction over palladium–carbon in methanol solution. The A/B allo configuration for compounds II which could be predicted on thermodynamic grounds,[6] is firmly established by the rotatory dispersion curves[7] of these dihydro compounds, the curves being virtually identical with that of androstan-17β-ol-3-one.

Treatment of IIa through IIe with sodium borohydride in aqueous dioxane gave the corresponding 19-norandrostan-3β,17β-diols: IIIa (m.p. 168–170°, $[\alpha]D$ +37°. Found for $C_{18}H_{30}O_2 \cdot 2C_3H_6O$: C, 72.88; H, 10.94); IIIb (m.p. 174–176°, $[\alpha]D$ ±0°. Found for $C_{19}H_{32}O_2.2C_3H_6O$: C, 73.76; H, 11.12); IIIc (m.p. 181–183°, $[\alpha]D$ +2°. Found for $C_{20}H_{34}O_2$: C, 78.20; H, 11.03[8]); IIId (m.p. 167–169°, $[\alpha]D$ +9°. Found for $C_{20}H_{32}O_2$: C,

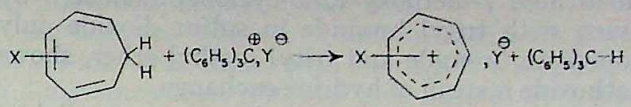
SYNTHESIS OF TROPENIUM (CYCLOHEPTATRIENYLIUM) SALTS BY HYDRIDE EXCHANGE[1]

Sir:

The previously reported[2] novel method of synthesis of tropenium[3] perchlorate by hydride abstraction from cycloheptatriene by trityl perchlorate in acetonitrile has been found to be versatile and adaptable to the preparation of a number of tropenium salts containing various anions and/or nuclear substituents, some previously unknown or unavailable by other methods.



Hydride exchange reactions between cycloheptatrienes and trityl salts occur rapidly and quantitatively only in solvents which effect dissociation of these salts. In consonance with conductivity studies, trityl halides function satisfactorily as hydride abstractors in liquid sulfur dioxide but trityl perchlorate or fluoborate gives equally good results in acetonitrile or sulfur dioxide. Most tropenium salts may be prepared by the following general procedure (all reactants and conditions anhydrous): equivalent quantities of trityl salt and the cycloheptatriene[4] in acetonitrile (minimum amount) at room temperature or sulfur dioxide (30–50 ml./g. triene) at −20° or lower are allowed to react for a few minutes, all solvent then evaporated (acetonitrile *in vacuo;* sulfur dioxide by warming, finally *in vacuo*), triphenylmethane removed by trituration and extraction with ether from the tropenium salt product; pure perchlorate and fluoborate salts obtained by recrystallization from acetonitrile–ethyl acetate, halide salts by sublimation at 80–100° (1 mm.); yields of crude salts almost quantitative, of pure salts 60–90%. Tropenium salts prepared (λ_{max} and ϵ_{max} in concd. sulfuric acid): (i) X = H, Y = ClO_4,[2] white, m.p. >300°, 217 mμ (41,000) and 273.5 mμ (4350)(ii, iii, iv, v show same spectrum), 44.03% C, 3.71% H; (ii) X = H, Y = BF_4,[5c] white, m.p. dec. slowly above 210°, 47.17% C, 3.59% H; (iii) X = H, Y = Cl,[5] white, 66.61% C, 5.56% H; (iv) X = H, Y = Br,[2,5] yellow, m.p. 203°; (v) X = H, Y = I,[5] red, m.p. 127°, readily transformed into tropenium triiodide, deep red-black, m.p. 127°, 292 mμ (39,800) and 361 mμ (22,100) in acetonitrile, 18.06% C, 1.51% H; (vi) X = Cl, Y = ClO_4, white, m.p. 164°, 237 mμ (29,800) and 310 mμ (8220), 37.37%, C 2.77% H, converted to tropone by water or ethanol[5b] (analogous preparation of bromide or iodide salts gives mixed halotropenium halides due to halogen interchange); (vii) X = Br, Y = ClO_4, white, m.p. 149.5°, 247 mμ (22,750) and 323 mμ (8900), 31.27% C, 1.89% H, converted to tropone by water or ethanol[5b]; (viii) X = MeO, Y = ClO_4, white, m.p. 107°, 234 mμ (32,100) and 315 mμ (10,050), 43.38% C, 4.34% H (similarly prepared bromide or iodide salts yield tropone and methyl bromide or iodide on warming); (ix) X = Me, Y = ClO_4,[5c] white, m.p. 109°, 226 mμ (37,100) and 288 mμ (3500), 46.89% C, 4.73% H (yellow bromide salt preparable in sulfur dioxide at −70° but decomposes on warming). Perchlorate and fluoborate salts, due to greater stability and non-hygroscopicity, are easier to handle than chloride (very hy-

groscopic), bromide (hygroscopic) or iodide (non-hygroscopic but unstable) salts. The allylically substituted 7-methoxy-1,3,5-cycloheptatriene,[5a] by giving with trityl bromide in sulfur dioxide only tropenium bromide and trityl methyl ether, shows methoxide instead of hydride exchange.

With more complete spectral data now available, it is evident that both predicted bands (4.33 ev, weak; 6.37 ev, intense)[6] for tropenium ion agree reasonably well with observed values (4.54 ev, 4350; 5.73 ev, 41,000). Results to date indicate that substituent effects on both $^1E_{1u}$ and $^1E_{3u}$ bands of substituted tropenium ions are in accord with those on $^1E_{1u}$[7] and $^1B_{1u}$, but not $^1B_{2u}$, bands of monosubstituted benzenes and are interpretable in terms of highly polar excited states for the ions.

Additional hydride exchange studies on tropenium and other systems for preparative and theoretical purposes are in progress.

AN INTERMEDIATE IN THE DEACETYLATION OF MONO-ACETYL-δ-CHYMOTRYPSIN HAVING THE PROPERTIES OF ACETYL-IMIDAZOLYL[1]

Sir:

In a previous communication,[2] evidence was presented which indicated that upon acetylation of δ-chymotrypsin by *p*-nitrophenylacetate, there was no detectable change in the spectral characteristics of the enzyme in the region of 245 mμ. This region was studied carefully since a postulated intermediate in the reaction, acetyl-imidazolyl-,[3,4] possesses a characteristic absorption maximum at this wave length.[4] Recently, a mechanism of reaction of δ-chymotrypsin with NPA has been proposed[5] which accounts for this observation and several others: (1) The stability of monoacetyl-δ-chymotrypsin at low *p*H[6] (2) a difference of 0.7–0.8 *pK* unit for acetylation and deacetylation of the enzyme[6] (3) the reversible sensitivity of the acetylation and deacetylation reactions to denaturation by urea,[2] (4) the reversible loss of reactivity of the acetyl with hydroxylamine in urea.[2] This scheme is presented in Fig. 1 with certain modifications, the evidence for which will be presented below.

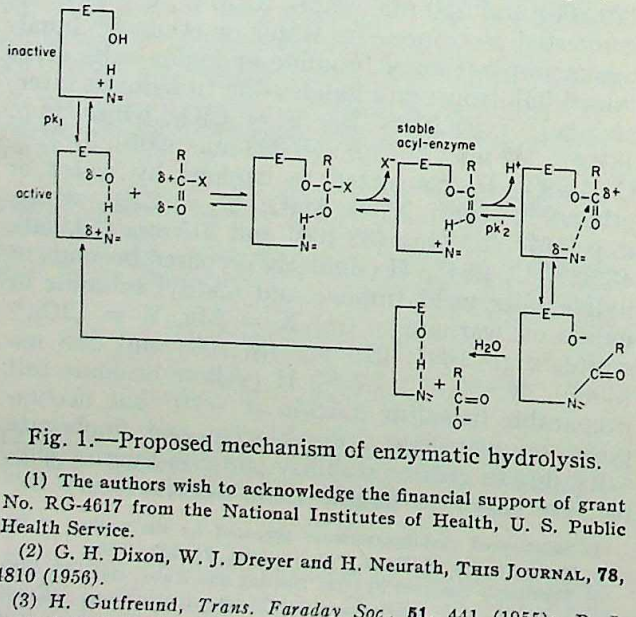

Fig. 1.—Proposed mechanism of enzymatic hydrolysis.

A solution of monoacetyl-δ-chymotropysin (1.95 mgm./ml.) at *p*H 3.5 was allowed to deacetylate at *p*H 9.0 in a Beckman DK-1 spectrophotometer which was set at 245 mμ. The resulting record of ΔE_{245} with time is seen in Fig. 2, curve 1; a control of non-acetylated δ-chymotrypsin is seen in curve 2. Curve 2 was also followed when a portion of the acetyl-δ-chymotrypsin was allowed to deacetylate at *p*H 7.2 for 15 minutes at room temperature and then adjusted to *p*H 3.5 with acid before the reaction.

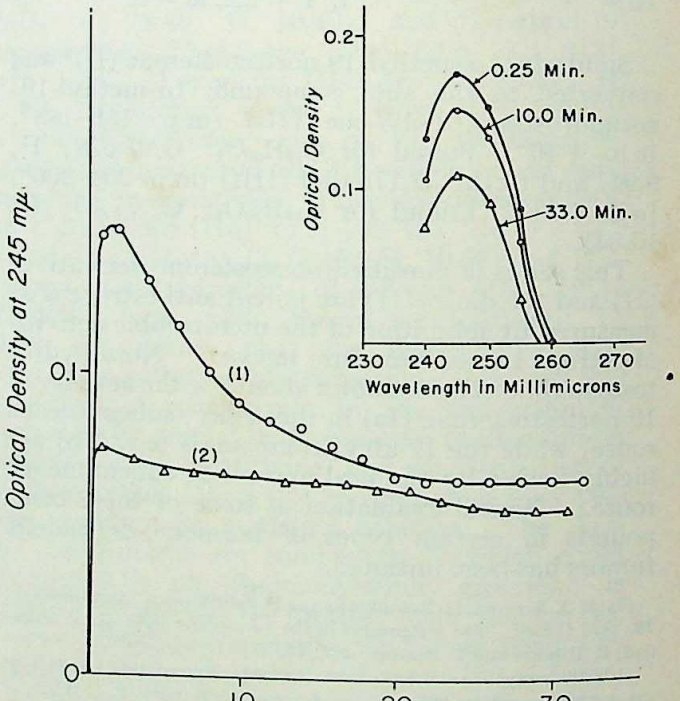

Fig. 2.—Both sample and reference cuvettes in a Beckman DK-1 spectrophotometer contained 3.0 ml. of the same solution of acetyl-δ-chymotrypsin[7] at *p*H 3.5; the temperature was 10.0 ± 0.2°. The *p*H of the sample was raised to 8.9 ± 0.1 by adding a small aliquot of a triethylammonium-ammonium acetate buffer on a plunger type rapid mixer.

It is clear that only in the case of acetyl-δ-chymotrypsin is there the rapid formation of a species absorbing at 245 mμ which decreases slowly in concentration with time. The control curve indicates that part of the initial increase at 245 mμ is due to a non-specific, *p*H dependent, spectral change in the enzyme.

When deacetylation was allowed to occur at the same *p*H but at 5.0 ± 0.2° and the spectrum was scanned from 270–230 mμ both before and, at a series of times, after the addition of base, the resulting difference spectra (inset to Fig. 2) show the rapid appearance of a peak with its maximum at 245 mμ which slowly declines with time, corresponding closely to that described for acetyl-imidazole.[4] According to the published extinction coefficient of this compound[4] ($\epsilon = 3 \times 10^3$), the observed maximum increase and subsequent decrease at 245 mμ is equivalent to 0.41–0.42 mole acetylimidazole per mole of reactive acetyl in the enzyme. Similar results were obtained in glycine buffer, but in phosphate the magnitude of the change at 245 mμ was reduced.

It is postulated, therefore, that as indicated in Fig. 1, the deacetylation of mono-acetyl-δ-chymotrypsin occurs by a rapid intramolecular transfer of acetyl- from serine hydroxyl to imidazolyl- followed by a slower hydrolysis of acetyl-imidazolyl-. The first order rate constant for the disappearance of the E_{245} compound corresponds closely with that observed for the rate of deacetylation of δ-chymotrypsin as measured by the reappearance of enzyme activity,[6] which in turn corresponds to the rate of base catalyzed hydrolysis of acetyl-imidazole in a model system.[8]

SYNTHESIS OF POTENTIAL ANTICANCER AGENTS. X. 2-FLUOROADENOSINE[1]

Sir:

Recently the biological activity of three fluoro derivatives of naturally occurring pyrimidines has been reported.[2]

Of these three fluoropyrimidines, 5-fluorouracil and 5-fluoroörotic acid have shown appreciable tumor-inhibitory activity against a variety of rat and mouse tumors[2a] and 5-fluorouracil was selected for clinical trials.[2b] The biological activity of the fluoropyrimidines increased our interest in the preparation of fluoropurines and their ribosides, especially fluoro derivatives of naturally occurring purines. Although Bendich, Giner-Sorolla and Fox were unable to prepare 6-fluoropurine from adenine by the Schiemann reaction,[3] Weisbach successfully prepared 2-fluoropyrimidine from 2-aminopyrimidine by this method.[4] The success of the latter reaction led us to attempt the preparation of 2-fluoroadenosine from 2,6-diaminopurine riboside by diazotization in fluoboric acid.

An aqueous solution of sodium nitrite (360 mg. in 2.4 ml.) was added with stirring to a solution of 2,6-diaminopurine riboside[5] (846 mg.) in 48% fluoboric acid (9.6 ml.) at −10°. The solution was stirred at −10° to 0° for 15 minutes, cooled to −20° and neutralized with 50% sodium hydroxide solution. The water was removed *in vacuo* and the residue chromatographed on a Celite column using water-saturated butanol. The crude 2-fluoroadenosine obtained (149 mg.) was recrystallized from absolute ethanol and dried *in vacuo* over P_2O_5 at 70° for several hours: yield, 75 mg. (8.7%), dec. at 200°; $(\alpha)^{26}D$ −60.3 ± 11.1 (0.127% in ethanol); $\lambda_{max}^{pH\ 1}$ 260.5 mμ (a_M 13,700); $\lambda_{max}^{pH\ 7}$ 260.5 mμ (a_M 14,300); $\lambda_{max}^{pH\ 13}$ 260.5 (a_M 14,800). *Anal.* Calcd. for $C_{10}H_{12}FN_5O_4 \cdot {}^1/_4C_2H_5OH$: C, 42.45; H, 4.60; N, 23.60. Found: C, 42.34; H, 4.93; N, 23.40. A qualitative test for fluorine was positive. The ratio of the R_f values of 2-fluoroadenosine and adenine in butanol–water on a descending paper chromatogram (Watman No. 1) was 0.9.

2-Fluoropurine was prepared in the same manner from 2-aminopurine[6] (850 mg.): yield, 254 mg. (41%) dec. at 216°; $\lambda_{max}^{pH\ 1}$ 264 mμ (a_M 8,300) $\lambda_{max}^{pH\ 7}$ 266.5 mμ (a_M 8,400), $\lambda_{max}^{pH\ 13}$ 272 mμ (a_M 8,800). *Anal.* Calcd. for $C_5H_3FN_4$: C, 43.48; H, 2.20; N, 40.60. Found: C, 43.52; H, 2.01; N, 40.37. A qualitative test for fluorine was positive.

In preliminary tests 2-fluoroadenosine inhibits the growth of Human Epidermoid Carcinoma (HE 2) at 10^{-8} g./ml. Five times this concentration is required to inhibit monkey kidney cells. Azaserine and 6-diazo-5-oxo-L-norleucine inhibit the growth of these tissues at 10^{-7} g./ml.

The preparation of other 2-fluoropurines is now under way in this laboratory.

THE SYNTHESIS OF 5-FLUOROPYRIMIDINES

Sir:

We wish to report the synthesis of a new class of compounds, some of which were designed to function as nucleic acid antagonists, by substituting fluorine for hydrogen in naturally occurring pyrimidines.

The 5-fluoropyrimidines (III) were obtained from pseudourea and pseudothiourea salts (I) and α-fluoro-β-keto ester enolates (II) by adaptation of the Wheeler synthesis.[1]

Crystalline IIa was prepared by the addition at 0° of 2.4 moles of methyl formate and 1.2 moles of ethyl fluoroacetate (IV) to 1.2 moles of potassium ethoxide in 800 ml. of toluene and letting the mix-

ture stand at 25° for 16 hours.[2] After IIa was refluxed for 2 hours with 0.6 moles of Ia and 0.6 moles of sodium methoxide in 1440 ml. of ethanol, evaporation, extraction with water and acidification gave IIIa (24% yield from IV), m.p. 192–193° dec. (recrystallized from ethyl acetate) (Calcd. for $C_6H_7FN_2OS$: C, 41.38; H, 4.05; F, 10.91. Found: C, 41.45; H, 4.25; F, 11.48.) Hydrochloric acid hydrolysis[1] of IIIa afforded 72% of 5-fluorouracil (IIIb), m.p. 282–283° dec., $\lambda_{max}^{0.1N\ HCl}$ 265–266 mμ (ε 7070)[3] (Calcd. for $C_4H_3FN_2O_2$: C, 36.93; H, 2.32; F, 14.61. Found: C, 37.07; H, 2.30; F, 14.69). Similarly Ib and IIa gave IIIc, m.p. 206–207° dec. (Calcd. for $C_5H_5FN_2O_2$: C, 41.67; H, 3.50; OCH_3, 21.63; F, 13.18. Found: C, 42.01; H, 3.87; OCH_3, 21.70; F, 13.51). This was hydrolyzed to yield IIIb. Hydrogenation of IIIb (1 mole hydrogen) with palladium charcoal in 2 moles of sodium hydroxide yielded 80% of uracil, whereas rhodium catalyst[4] in acetic acid produced a mixture from which 6.5% of 5-fluorodihydrouracil, m.p. 237–238° dec. (Calcd. for $C_4H_5FN_2O_2$: C, 36.37; H, 3.82; F, 14.38. Found: C, 36.32; H, 3.43; F, 14.59) was isolated by cellulose powder chromatography.[5] Condensation of Ic and IIa gave IIId, m.p. 241–243° dec. (Calcd. for $C_5H_5FN_2OS$: C, 37.49; H, 3.15; N, 17.49. Found: C, 37.98; H, 3.44; N, 17.52) which on demethylation[6] afforded 49% of IIIe, m.p. 227–229° dec. (Calcd. for $C_4H_3FN_2OS$: C, 32.87; H, 2.07; F, 13.00; Found: C, 33.45; H, 2.36; F, 12.78). Chlorination[7] of IIIa produced oily IIIf, which by autoclaving (12 hours, 100°) with liquid ammonia gave IIIg, m.p. 94°, in 88% over-all yield (Calcd. for $C_6H_8FSN_3$: C, 41.60; H, 4.66; N, 24.26. Found: C, 41.43; H, 4.73; N, 23.96). Hydrobromic acid hydrolysis of IIIg afforded 52% of 5-fluorocytosine (IIIh), m.p. 295–297° dec., $\lambda_{max}^{0.1N\ HCl}$ 285 mμ (ε 8900) (Calcd. for $C_4H_4FN_3O$: C, 37.21; H, 3.12; F, 14.72. Found: C, 36.92; H, 3.07; F, 14.47).

Diethyl oxalate (2 moles), potassium ethoxide and IV gave IIc[8] (Calcd. for $C_8H_{10}FKO_5$: C, 39.34; H, 4.12; K, 16.01; F, 7.78. Found: C, 39.03; H, 4.34; K, 16.48; F, 7.59). Condensation (as described for IIa) of Ia and IIc yielded, after processing IIIi (23% from IV), m.p. 168–169° dec. (Calcd. for $C_9H_{11}FN_2O_3S$: C, 43.89; H, 4.50. Found: C, 43.96; H, 4.61). Hydrochloric acid hydrolysis of IIIi yielded 88% of 5-fluoroörotic acid monohydrate (IIIj) m.p. 255° dec., $\lambda_{max}^{0.1N\ HCl}$ 284–285 mμ (ε 7100)[3] (Calcd. for $C_5H_3FN_2O_4,H_2O$: C, 31.26; H, 3.13; F, 9.89. Found: C, 31.36; H, 2.95; F, 10.11), which on refluxing in Dowtherm yielded 86% of IIIb.[9] Condensation of Ic and IId[10] (2 moles sodium methoxide) gave IIIk m.p. 221–222° dec. which was impure, due to partial loss of side chain fluorine (Calcd. for $C_6H_6F_2N_2OS$: C, 37.49; H, 3.15; F, 19.77. Found C, 37.68; H, 2.79; F, 13.01). This upon refluxing with hydrochloric acid yielded III (40% over-all yield from IId) m.p. 240–241° dec. (Calcd. for $C_5H_4ClFN_2O_2$: C, 33.63; H, 2.26; Cl, 19.86; F, 10.64. Found: 34.03; H, 2.11; Cl, 19.47; F, 10.64).

5-Fluorouracil and 5-fluoroörotic acid have profound activity[11] against bacteria *in vitro* and against several transplanted tumors in animals. The former is under clinical investigation in neoplastic diseases.

We are indebted to Mrs. Ellen Chiamulera for technical assistance and to Dr. Al Steyermark for the microanalyses.

(2) The compound is impure and unstable; it should be used without undue delay in the next step. In a similar run with sodium ethoxide the obtained IIb was converted by treatment with ethanolic hydrochloric acid at 25° into ethyl fluoromalonaldehydate diethyl acetal (9.3% from IV), b.p. 115–118° (24 mm.), $n^{25}D$ 1.4041. (Calcd. for $C_9H_{17}FO_4$: C, 51.91; H, 8.23; F, 9.12; OC_2H_5, 64.92. Found: C, 52.19; H, 8.38; F, 9.02; OC_2H_5, 64.55.)

SOME SELECTIVE REACTIONS OF THE SILICON-HYDROGEN GROUP WITH ORGANOMETALLIC COMPOUNDS

Sir:

We are reporting a series of reactions which readily make available the synthesis of a wide variety of organosilicon compounds, particularly those of an unsymmetrical nature. The introduction of the various R groups can be effected stepwise by the proper choice of solvent and organometallic compound. The synthesis is particularly appropriate for the preparation of low-melting organosilicon compounds of the type R_4Si where all of the R groups can be different.

Previous reports have shown that organolith-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

ium compounds react with the silicon–hydrogen group in diethyl ether to give tetrasubstituted products. Triethylsilane[1a,b] has been found to react with methyl-, *n*-propyl-, *n*-butyl- and phenyllithium to give the respective tetrasubstituted organosilicon compounds. Triphenylsilane[2] also has been found to react similarly.

Nebergall[3] has shown that phenylsilane reacts with an excess of phenyllithium and ethyllithium in diethyl ether to give tetraphenylsilane and triethylphenylsilane, respectively. That the solvent plays an important role in the reaction was demonstrated when excess ethyllithium was treated with phenylsilane in petroleum ether. The product from this reaction was diethylphenylsilane. Nebergall reported that no reaction occurred between phenylsilane and a large excess of phenylmagnesium bromide in diethyl ether.

Triphenylsilane[2] has been found to be unreactive toward phenylmagnesium bromide in ether, refluxing xylene, and a mixture of ether and dioxane. West and Rochow[4] have reported that di-*n*-butylsilane does not react with ethylmagnesium bromide in a mixture of ether and toluene at 100°.

One of the steps in the cleavage[5] of symmetrical diphenyldisiloxane with Grignard reagents in diethyl ether has been shown to lead to alkylation of the silicon–hydrogen group.

We have found that triphenylsilane, diphenylsilane, and phenylsilane will react with Grignard reagents in tetrahydrofuran (THF). Triphenylsilane reacted with phenylmagnesium bromide, after 24 hours of refluxing in THF, to give a 14% yield of tetraphenylsilane which was identified by infrared spectrum and by mixed melting point with an authentic sample. Triphenylsilane also gave allyltriphenylsilane in a 53% yield when treated for 24 hours with allylmagnesium chloride[6] in refluxing THF.

Diphenylsilane when allowed to react with excess phenylmagnesium bromide for a period of two days in refluxing THF gave a 79% yield of triphenylsilane. Diphenylsilane also reacted with excess *n*-butylmagnesium bromide under similar conditions to give a 72% yield of *n*-butyldiphenylsilane, b.p. 110–112° (1 mm.), $n^{20}D$ 1.5541, d^{20}_4 0.9604. *Anal.* Calcd. for $C_{16}H_{21}Si$: Si, 11.68; MR, 80.17. Found: Si, 11.53, 11.52; MR, 80.24. Refluxing a solution of diphenylsilane with an excess of phenylmagnesium bromide in diethyl ether gave a 31% yield of triphenylsilane.

Phenylsilane after reaction with one equivalent of phenylmagnesium bromide in THF at room temperature for 6.5 hours gave a 66% yield of diphenylsilane; while the same reaction, when carried out in diethyl ether at room temperature for 24 hours, gave a 52% yield of diphenylsilane. Likewise, phenylsilane reacted with one equivalent of *n*-dodecylmagnesium bromide in THF to give a 78% yield of *n*-dodecylphenylsilane, b.p. 130–131° (0.6 mm.), $n^{20}D$ 1.4480, d^{20}_4 0.8629. *Anal.* Calcd. for $C_{18}H_{32}Si$: Si, 10.16; *MR*, 92.29. Found: Si, 10.13, 9.99; *MR*, 92.41.

n-Dodecylphenylsilane, prepared as previously stated, reacted with one equivalent of benzylmagnesium chloride, after refluxing for 18 hours in THF, to give a 63% yield of benzyl-*n*-dodecylphenylsilane, b.p. 180–183° (0.12 mm.), $n^{20}D$ 1.5233, d^{20}_4 0.9209. *Anal.* Calcd. for $C_{25}H_{38}Si$: Si, 7.66; MR, 121.05. Found: Si, 7.59, 7.62; MR, 121.68.

Related reactions, with a variety of RM compounds, are in progress with other combinations having one or more hydrogens attached to various metals and metalloids. Some dialkylsilanes appear to behave differently than the diarylsilanes.

Acknowledgments.—This research was supported in part by the United States Air Force under Contract AF 33(616)-3510 monitored by Materials Laboratory, Directorate of Laboratories, Wright Air Development Center, Wright-Patterson AFB, Ohio. The authors wish to express their appreciation to Mr. E. Miller Layton of the Institute of Atomic Research, Ames, Iowa, for infrared spectra.

A NEW FAMILY OF ANTIBIOTICS: THE DEMETHYLTETRACYCLINES

Sir:

Among the most useful of the broad-spectrum antibiotics is a small group of substances derived from perhydronaphthacene and called the tetracyclines. Tetracycline, 7-chlorotetracycline, and 5-hydroxytetracycline[1] are used in therapy.

	R	R'
Tetracycline	H	H
7-Chlorotetracycline	Cl	H
5-Hydroxytetracycline	H	OH

We now wish to describe four members of a new family of compounds closely related to the previously known tetracyclines. On the basis of physical and chemical properties presented here and on the basis of degradation studies presented in the accompanying papers, it has been established that these four new compounds are 6-demethyltetracycline (I), 7-chloro-6-demethyltetracycline (II), 6-demethyl-4-*epi*-tetracycline (III), and 7-chloro-6-demethyl-4-*epi*-tetracycline (IV). 6-Demethyltetracycline hydrochloride hemihydrate: $[\alpha]^{25}D$ −259° (0.5% in 0.1 *N* H_2SO_4); m.p., dec. 203–209°; *Anal.* Calcd. for $C_{21}H_{24}N_2ClO_{8.5}$: C, 53.00; H, 5.08; N, 5.89; Cl, 7.45; O, 28.58; H_2O, 1.89. Found: C, 52.52; H, 5.34; N, 6.05;

TABLE II

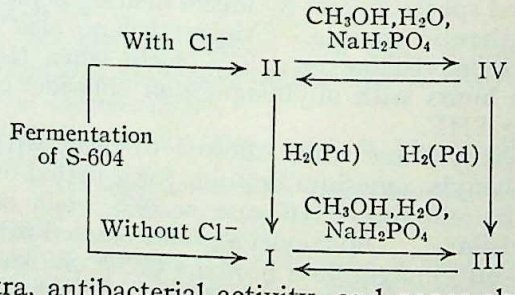
COMPARISONS OF STABILITIES TOWARD ACID AND BASE AND OF *in Vitro* ANTIBACTERIAL ACTIVITIES

	Half destruction time (min.) in: 1.0 *N* H_2SO_4 at 100°	0.1 *N* NaOH at 100°	% of *in vitro* antibact-activ. of 7-chlorotetracycline against *S. aureus* (turbidimetric meas.)
7-Chloro-6-demethyltetracycline (II)	445	40	75
7-Chlorotetracycline	2.1	<0.3	100
7-Chloro-6-demethyl-4-*epi*-tetracycline (IV)	322	35.6	7
7-Chloro-4-*epi*-tetracycline	5.8	<0.6	4.2
6-Demethyltetracycline (I)	24.8	31.5	24
Tetracycline	1.0	6.8	25
6-Demethyl-4-*epi*-tetracycline (III)	25.8	46	3
4-*epi*-Tetracycline	0.9	7.2	1.6
5-Hydroxytetracycline	4.5	2.2	24
5-Hydroxy-4-*epi*-tetracycline	2.6	3.3	1.1

Additional constants obtained on II hydrochloride were: Calcd.: N-methyl, for one dimethylamino group, 6.0; O-methyl, 0; O, 25.54. Found: N-methyl, 7.4; O-methyl, 0; O, 26.2 (Unterzaucher).

Compounds I and II are produced by a mutant of *Streptomyces aureofaciens* Duggar, coded as Mutant S-604 and derived ultimately from the original 7-chlorotetracycline-producing *S. aureofaciens* A-377 soil isolate of Duggar. Compounds III and IV are derived from I and II, respectively, by a process analogous to that used in the conversion of the previously known tetracyclines to their epimers.[2] Differentiation of these new compounds from each other and from the previously known tetracyclines can be accomplished by paper chromatography (Table I). The ultraviolet absorption spectra of these new compounds are essentially unchanged from those of their previously known 6-methyl analogs. A striking feature of all four new compounds is their great resistance to degradation by acid or by alkali. Comparisons are given in Table II. Relative *in vitro* antibacterial activities against *Staphylococcus aureus* are presented in Table II.[3]

The inter-relationships of these 6-demethyltetracyclines are established by the following observations. Catalytic hydrogenation (palladium on charcoal, 1.1 atm. of hydrogen) of II yields I and of IV yields III. Chloride-containing fermentations produce predominantly II; chloride-free fermentations produce I.[4] I and III are reversibly interconvertible under epimerizing conditions and II and IV behave analogously. Assignment of configuration at C.4, relative to the tetracyclines, was made on the basis of ultraviolet and infrared



spectra, antibacterial activity, and paper chromatographic behavior.

The great resistance of these new compounds to degradation by acid or by alkali was interpreted as meaning that the common difference between the new compounds and the previously known tetracyclines lay in Ring C, since degradation by acid and degradation by alkali both involve initially Ring C.[5,6,7,8] The ultraviolet absorption spectra,

(2) A. P. Doerschuk, B. A. Bitler and J. R. D. McCormick, THIS JOURNAL, **77**, 4687 (1955).

(3) This brings to three the number of positions in the tetracycline molecule at which a simple change of substituents has been possible without an appreciable reduction of the *in vitro* antibacterial activity against *S. aureus* from that of tetracycline: C.5, H to OH; C.6, CH_3 to H; C.7, H to Cl or Br. Other simple changes, such as 2-carboxamido to 2-cyano or inversion of C.4 configuration, diminish this activity by twenty-fold or greater.

DEMETHYLTETRACYCLINES. STRUCTURE STUDIES

Sir:

The isolation and characterization of a new series of highly active tetracycline antibiotics has been reported recently.[1] In this communication degradation studies are presented showing that the parent compound of this series is 6-demethyltetracycline.[2]

In a preliminary experiment 7-chloro-6-demethyltetracycline (I) was distilled with a highly active zinc dust[3] giving naphthacene ($\lambda_{max.}^{CHCl_3}$, 420 mμ, 446 mμ, 477 mμ). Under the same conditions chlorotetracycline gave a distillate whose ultraviolet spectrum [$\lambda_{max.}^{CHCl_3}$, 425 mμ (broad), 452 mμ (broad), 476 mμ, 485 mμ] was indicative of a mixture of naphthacene and 5-methylnaphthacene. These data coupled with the analytical results[1] indicating that these new antibiotics had one less carbon atom than the known tetracyclines[4] suggested that the C.6 methyl group of the tetracycline nucleus was missing in the new series. This was confirmed immediately by numerous Kuhn–Roth determinations on I and related compounds, all of which gave zero values. In this determination the familar tetracyclines all gave appreciable C-methyl values.[4b,5]

That the structure of I was the same as chlorotetracycline in all other respects[6] was shown by several reactions. Heating in concentrated hydrochloric acid aromatized the C ring of I giving an anhydro compound (II) in good yield, $[\alpha]^{25}D$ +105° (0.467% in methyl cellosolve); m.p. 205–210° (dec.), (*Anal.* Calcd. for $C_{21}H_{19}N_2O_7Cl$: C, 56.44; H, 4.29; N, 6.27; Cl, 7.94. Found: C, 56.39; H, 4.60; N, 5.83; Cl, 7.81; *C-methyl, 0.0*). This was considered to be good evidence for an hydroxyl group on C.6 and a hydrogen atom on C.5a. The ultraviolet absorption spectrum of II [$\lambda_{max.}^{0.1\,N\,HCl}$, 223 mμ (ε 30,200), 272 mμ (ε 52,500), 430 mμ (ε 8,050)] was quite similar to the known anhydrotetracyclines[7] but exhibited a hypsochromic shift characteristic of an aromatic compound having one less alkyl substituent.[8] The acid stability of II eliminated the possibility of C.5 bearing an hydroxyl group.[4b]

That I and the known tetracyclines have the same A ring, was shown by oxidation of I in *N* NaOH with oxygen to give dimethylamine and 3,4 - dihydroxy - 2,5 - dioxocyclopentane - 1 - carboxamide[9a] (III) identical with the compound obtained similarly from tetracycline and chlorotetracycline.[7b] From the same reaction was obtained a new compound (IV), $[\alpha]^{25}D$ +2.5° (2.00%, methanol), m.p. 194–195° (*Anal.* Calcd. for $C_{13}H_{11}O_7Cl$: C, 49.62; H, 3.52; Cl, 11.27. Found: C, 49.88; H, 3.80; Cl, 11.26; *C-methyl, 0.0*). On treatment of IV with diazomethane, a methoxydimethyl ester (V) was formed, m.p. 119.5–120.5° (*Anal.* Calcd. for $C_{16}H_{17}O_7Cl$: C, 53.86; H, 4.80; Cl, 9.94; CH_3O, 26.10. Found: C, 53.59; H, 5.08; Cl, 10.12; CH_3O, 26.66). Compound V was hydrolyzed to a methoxydiacid (VI), m.p. 210–217° (*Anal.* Calcd. for $C_{14}H_{13}O_7Cl$: C, 51.15; H, 3.98; Cl, 10.79. Found: C, 50.82; H, 4.09; Cl, 10.9) which was converted to a methoxy anhydride (VII), m.p. 242.5–243° (*Anal.* Calcd. for $C_{14}H_{11}O_6Cl$: C, 54.12; H, 3.57; Cl, 11.41. Found: C, 54.16; H, 3.82; Cl, 11.56). The infrared absorption spectrum of this latter compound had bands typical of a glutaric anhydride. Compounds IV–VII had ultraviolet and infrared absorption spectra characteristic of phthalides. Since acid permanganate oxidation of IV gave tricarballylic acid[9b] in good yield, it was postulated that IV is β-(4-chloro-7-hydroxyphthalide-3)-glutaric acid, corresponding to the 3-methyl compound[9] obtained in similar fashion from chlorotetracycline[7b] thus indicating that the B rings of both compounds must be the same. With the isolation of dimethylamine, III and IV the 21 carbons and 2 nitrogens in I were accounted for.

Proof that the D rings of I and of chlorotetracycline were the same and also confirmation of the tertiary nature of C.6 in I was obtained by a series of reactions used in a degradation of chlorotetracycline.[4a] Reduction of I with zinc dust and acetic acid yielded a dedimethylaminodeoxy compound (VIII), m.p. 212–217° (dec.) (*Anal.* Calcd. for $C_{19}H_{16}O_7NCl$: C, 56.23; H, 3.97; N, 3.45; Cl, 8.74. Found: C, 56.20; H, 3.66; N, 3.80; Cl,

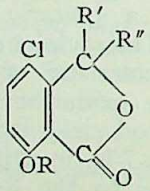
DEMETHYLTETRACYCLINES. SYNTHESIS OF A DEGRADATION PRODUCT

Sir:

In an accompanying communication[1] there is described a new series of antibiotics closely related to the tetracyclines, both in antibacterial activity and in structure. In a second accompanying communication[2] evidence has been presented that these new antibiotics differ from the parent compounds only in that they lack a methyl group at the 6-position of the tetracycline nucleus.

We now wish to report the synthesis of a degradation product which proves that the arrangement of substituents in the D ring and in portions of the C ring of demethylchlorotetracycline is the same as in chlorotetracycline except for the C-6 methyl group. This compound is 4-chloro-7-hydroxyphthalide (R = R′ = R″ = H) which is analogous to 4-chloro-7-hydroxy-3-methylphthalide (R = R′ = H, R″ = CH_3), obtained by the same degradative route from chlorotetracycline.[3]



The starting point for the synthesis is 4-chloro-3-hydroxy-7-methoxy-3-methylphthalide (R = R′ = CH_3, R″ = OH) whose synthesis has already been reported from this laboratory.[4] This compound was oxidized with potassium permanganate in 0.5 *N* sodium hydroxide at 90° for one hour to yield the 4-chloro-3-hydroxy-7-methoxyphthalide-3-carboxylic acid (R = CH_3, R′ = OH, R″ = COOH) in 67% yield. This compound has been isolated as a degradation product of chlorotetracycline and was named there as the tautomeric keto-acid, 6-chloro-3-methoxyphthalonic acid.[5] The reduction of this compound with sodium borohydride in *N* sodium hydroxide yielded 4-chloro-7-methoxyphthalide-3-carboxylic acid (R = CH_3, R′ = H, R″ = COOH) in 90% yield; m.p. 175–176° with effervescence; $\lambda_{max}^{0.1\,N\,HCl}$ 216 mμ (ε 32,200); 240 mμ (ε 8,240); 313 mμ (ε 5,220). $\lambda_{max}^{0.1\,N\,NaOH}$ (after standing one hour)[6] 214 mμ (ε 31,500); 285 mμ (ε 2,190).

Anal. Calcd. for $C_{10}H_7O_5Cl$: C, 49.5; H, 2.9; Cl, 14.6. Found: C, 49.5; H, 3.2; Cl, 14.8.

The phthalidecarboxylic acid was then decarboxylated by heating 5–10 minutes just above its melting point to yield 4-chloro-7-methoxy-phthalide (R = CH_3, R′ = R″ = H) which was sublimed at 175° (760 mm.); yield, 70%; m.p. 167–168° $\lambda_{max}^{0.1\,N\,HCl}$ 215 mμ (ε 37,300); 236 mμ (ε 8,830); 308 mμ (ε 4,560); $\lambda_{max}^{0.1\,N\,NaOH}$ (after standing one hour)[6] 286 mμ (ε 2,190).

Anal. Calcd. for $C_9H_7O_3Cl$: C, 54.4; H, 3.6; Cl, 17.9. Found: C, 54.8; H, 3.7; Cl, 17.7.

The methyl ether was cleaved by refluxing in 48% hydrobromic acid for 2.5 hours. The product, 4-chloro-7-hydroxyphthalide (R = R′ = R″ = H), crystallized from the hydrobromic acid on cooling in 70% yield and was then sublimed at 100° (15–20 mm.). The m.p. was 158–159° and there was no depression upon admixture with the degradation product.[2] The ultraviolet and infrared spectra were identical; $\lambda_{max}^{0.1\,N\,HCl}$ 235 mμ (ε 8,400); 308 mμ (ε 4,150); $\lambda_{max}^{0.1\,N\,NaOH}$ 254 mμ (ε 8,400); 343 mμ (ε 6,180).

Anal. Calcd. for $C_8H_5O_3Cl$: C, 52.1; H, 2.7; Cl, 19.2. Found: C, 52.2; H, 3.2; Cl, 19.0.

(6) Upon standing in 0.1 *N* sodium hydroxide for an hour or less the long wave length absorption maximum undergoes a hypsochromic shift which is reversible by acidification. This is assumed to be attributable to the opening and closing of the lactone ring and will be dealt with in more detail in a subsequent publication.

α,α′-DIGLYCEROPHOSPHATE IN PLANTS

Sir:

We have observed a P^{32}-labeled compound in hydrolysates of *Scendesmus* phosphatides which contained more than a third of the lipid phosphorus. The same phosphate ester also possessed as much as 90% of the alcohol-soluble non-lipid phosphorus of *Scenedesmus* cultured at low light intensity in media containing P^{32}. The cellular concentration of the ester, calculated from its P^{32} activity and the nutrient specific activity, was as high as 10^{-3} *M*. The same compound in lower concentrations occurred in the only two species of higher plants (clover) tested. It was isolated by chromatography on Whatman No. 1 paper with R_f = 0.36 in phenol–water and R_f = 0.11 in butanol–propionic acid–water.[1] These R_f values correspond to those recorded by Dawson[2] for an unknown in rat liver extracts.

The ester was half hydrolyzed during two minutes at 100° in 1.0 *N* nitric acid to give only one P^{32}-labeled product which was identified as glycerophosphate by paper chromatography and electrophoresis. The unknown was anionic in the *p*H range 2–12 and readily separable from the known glycerophosphoryl esters of the phospholipids.

Scenedesmus-C^{14} was cultured and the unknown was isolated and identified with the P^{32}-labeled compound. Acid hydrolysis produced equal activities of glycerophosphate and glycerol which was identified by its R_f values and by quantitative periodate oxidation to formaldehyde and formate. Periodate oxidation of the ester indicated an α,α'-structure. Synthetic α,α'-diglycerophosphate[3] was prepared and found inseparable from the radioactive unknown by paper chromatography and electrophoresis. Its identical hydrolysis rate was determined by neutron activation chromatography of the products.

Tetraacetyl bis-(L-α-glyceryl) phosphates have been synthesized by Baer.[4] Polyglycerophosphate structures in several lipids have been reported[5,6,7] but diglycerophosphate has not been identified previously. Its symmetry, simplicity and acid lability to give the usual products of lipid hydrolysis apparently have postponed its identification as a metabolite. Its occurrence in the glyceryl phosphatides will be reported.

We are indebted to Dr. R. J. Suhadolnik for invaluable assistance in the early stages of the identification. This work was supported by the National Science Foundation, the Atomic Energy Commission and the Pennsylvania Agricultural Experiment Station.

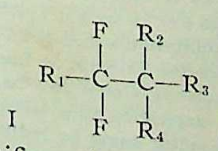
NUCLEAR MAGNETIC RESONANCE SPECTRA. HINDERED ROTATION AND MOLECULAR ASYMMETRY[1]

Sir:

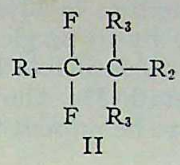
The elegant and unequivocal demonstration of non-equivalent fluorine atoms in certain *gem*-difluoro compounds of type I with the aid of their nuclear magnetic resonance spectra has been interpreted as indicating restricted rotation about the central C–C bond of I.[2]



I

	R_1	R_2	R_3	R_4
Ia	Br	H	Cl	Br
Ib	Br	F	Cl	Br
Ic	Br	H	Br	C_6H_5
Id	Cl	H	Cl	C_6H_5

Significantly, spectra for the "freely rotating" substances with "equivalent" *gem*-fluorines were not produced at temperatures up to 200°.[2] This behavior suggested to us the possibility that aliphatic compounds of type II might be resolvable into reasonably stable optical antipodes at room temperature since the barriers for rotation about the central C–C bond of II a-c should be substantially greater than for Ia-d.

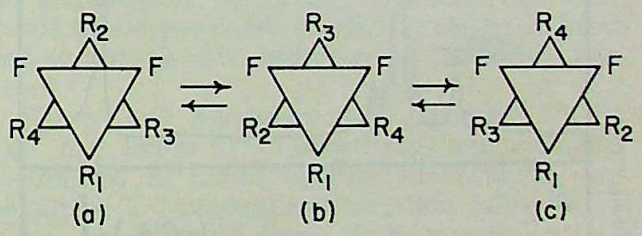


II

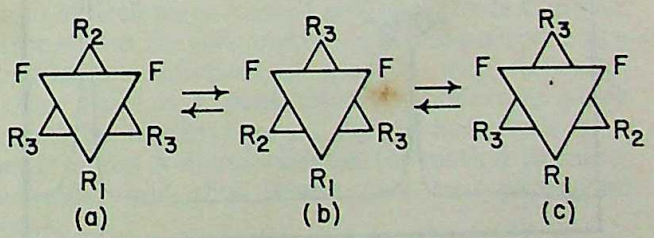
	R_1	R_2	R_3
IIa	Br	F	Br
IIb	Br	Br	Cl
IIc	Br	C_6H_5	Br

This expectation was not realized. The nuclear magnetic resonance spectra of IIa-c showed *equivalent gem*-fluorines down to −30°. Thus IIa shows doublet CF_2 and triplet CF absorptions separated by 440 c.p.s. with J equal to 18–19 c.p.s. The results indicate that there is rapid rotation at room temperature about the central C–C bond in IIa-c and, by inference, in Ia-d also.[3]

The solution to the apparent paradox is that the chemical shift between *gem*-groups as in compounds like I is not necessarily averaged by rapid rotation *unless the residence times of the molecule in each of the various rotational conformations (III) are equal.* The *gem*-group does not have equivalent atoms in any of the configurations IIIa, b or c. Therefore



III



IV

unless the residence times in each configuration are equal, the chemical shift difference between the *gem*-fluorines will not average out in the general case.[4] Since the relative residence times will be temperature dependent, the apparent degree of non-equivalence of the fluorines will vary with temperature as is observed.[2]

With more symmetrical compounds like II, rapid rotation at > −30° will average the chemical shifts of the *gem*-difluorines since the residence times (and populations) for the two configurations with non-equivalent fluorines (IVb,c) must be

(1) Supported in part by the Office of Naval Research.
(2) J. J. Drysdale and W. D. Phillips, THIS JOURNAL, **79**, 319 (1957).
(3) Drs. W. D. Phillips and J. J. Drysdale have informed us that they have independently made similar observations on fluorine compounds of related structure.
(4) In some situations, the spin–spin coupling between the non-equivalent fluorines, or other similarly located atoms, may be so large as to swamp out the chemical shift and give to all intents and purposes a single resonance line.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

equal since they are optical antipodes. IVa may have a very different residence time but has equivalent fluorines. At low temperatures in CS_2 solution, IIb and IIc show evidence of slow rotation about the C–C bond.[3] Thus at −80°, IIb appears to "freeze" to about a 1.4:1 mixture (analysis by line heights) of IVa (identifiable by its single resonance) and the *d,l*-pair IVb,c (identifiable by its quartet of resonance lines). With IIc, the rotational isomer IVa appears only to be present to the extent of about 10% at −80°.

Similar observations have been made for proton spectra of a few[4] compounds similar to I and II with $-CH_2-$ in place of $-CF_2-$. Compounds related to I like methyl 2,3-dibromo-2-methylpropanoate show "abnormal" spin–spin splittings for the $-CH_2-$ absorptions while those related to II like 1,2-dibromo-2-methylpropane give normal patterns; *cf.* Fig. 1. With substances like these, rotation about the C–C single bonds are unquestionably rapid.

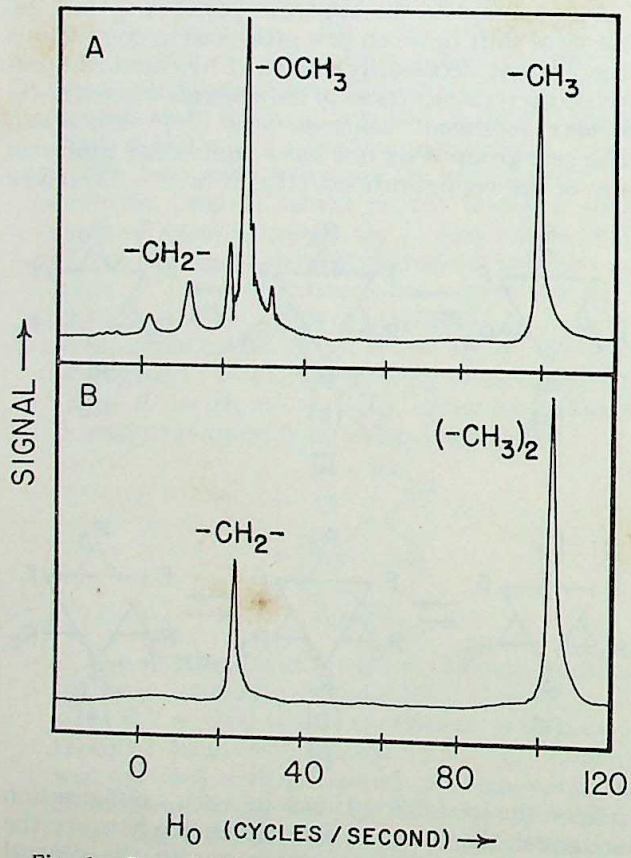


Fig. 1.—Pure liquid n.m.r. spectra of A, methyl 2,3-dibromo-2-methylpropanoate (J for coupling between *gem*-hydrogens at 3-position ~10–11 c.p.s.); B, 1,2-dibromo-2-methylpropane, taken with Varian Associates High Resolution Nuclear Magnetic Resonance Spectrometer, 12-in. magnet equipped with Super Stabilizer and at room temperature and 40 mc. Zero of reference scale was water absorption.

The importance of these observations is several fold. First, they establish beyond doubt that the residence times and populations for the various possible rotational configurations of compounds like I are not equal; second, with the aid of the reasoning used previously,[2] it becomes possible in principle to estimate, and perhaps determine, the population of the several configurations even though these are being rapidly interconverted. Third, populations of configurations may be measured directly for favorable cases by "freezing in" at low temperatures. Finally, a new and extraordinarily simple means is provided for possible detection of a carbon attached to a group without a plane of symmetry by observation of nuclear magnetic resonance spin–spin couplings without recourse to resolution into optical antipodes.[5]

(5) The method does not strictly provide a means for locating asymmetric atoms. Thus, 2-methyl-2-nitropropanediol shows nonequivalent methylene hydrogens although it is not capable of resolution into optical antipodes. However, each of the methylenes is attached to a group which has no plane of symmetry.

NEW LINES IN THE X-RAY DIFFRACTION PATTERN OF ORTHORHOMBIC SULFUR. "AMORPHOUS" (μ)-SULFUR

Sir:

In connection with another problem[1] we had occasion to purify some sulfur by a recommended[2–4] method.[5] On comparing the X-ray diffraction pattern with the ASTM card file[6] for orthorhombic sulfur, we were surprised to find several extra lines in our diffraction pattern.[7] Since different radiation sources were used[8] one might expect differences in relative intensity values but not in the number and positions of diffraction peaks. We found later that the sulfur we purified was not completely soluble in carbon disulfide and thus considered the possibility that the new lines we observed might be due to the presence of this insoluble sulfur.[9] Thus we determined the diffraction pattern

(6) ASTM X-Ray Powder Data File, Special Technical Publication No. 48-F, 1957.

(7) Our data have been deposited with Dr. G. W. Brindley, Editor, "ASTM X-Ray Powder Data File," College of Mineral Industries, Pennsylvania State University, University Park, Pa., and list the d values and intensities of reflection.

(8) The ASTM samples were run with MoKα radiation and film whereas we used Cu Kα radiation and a recording North American Philips X-ray diffractometer.

(9) The insoluble sulfur as determined by repeated extraction with carbon disulfide until there was no further loss in weight (within 0.2 mg.) was 3.25%. This is close to the equilibrium value of 3.75% at 121° listed in J. W. Mellor, "A Comprehensive Treatise on Inorganic and Theoretical Chemistry," Vol. X, Longmans, Green and Co., New York, N. Y., 1930, p. 47. Following a suggestion in a letter from Dr. Fanelli that the amount of insoluble sulfur could be reduced by heating at 125° overnight followed by slow cooling, the amount of insoluble sulfur was reduced to 2.49% after one such treatment using a ten-hour cooling period (heating mantle control). After the work in this paper was completed, a paper appeared (N. H. Hartshorne and M. Thackray, *J. Chem. Soc.*, 2122 (1957)) in which the amount of insoluble sulfur was reduced by "annealing at 100° for two days" (see also Kang Mo reference on this point).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of sample of insoluble sulfur prepared according to the method in ref. 9. This diffraction pattern[7] was remarkably similar to that of orthorhombic sulfur. It is clear that this insoluble sulfur must have a crystalline structure. Since the line widths were comparable in the two cases, we conclude that the crystal size must be similar (since the half-width of the peak is proportional to particle size). This insoluble sulfur is commonly referred to as amorphous sulfur[10] or μ-sulfur and is thought to consist of long-chain polymers having molecular weights ranging from 18,000 to 73,000.[11] The only differences we have been able to observe between the diffraction patterns of the insoluble sulfur and orthorhombic sulfur are (1) differences in the relative intensities of several of the lines[7] and (2) the insoluble sulfur and the orthorhombic sulfur show a few lines not present in each others pattern; for example, lines at 2.99 Å. (insoluble) and 2.62 Å. (orthorhombic). The significance of these small differences is not clear at present. It is of course possible for polymeric materials to be in a crystalline form; however, one might expect a greater difference in the diffraction patterns of polymeric μ-sulfur and orthorhombic sulfur.

It is interesting that Das in a recent summary of his work[12] (some of it unpublished) has found an orthorhombic X-ray powder diagram for milk of sulfur (which has commonly been described as an amorphous modification) and also the same for colloidal sulfur prepared by the reaction of sulfur dioxide and hydrogen sulfide. In view of our findings and those of Das, it would seem advisable to discontinue the use of the term "amorphous" sulfur for these crystalline forms. The insoluble sulfur in the present paper could more aptly be referred to simply as "insoluble sulfur" or μ-sulfur.

The X-ray diffraction patterns were obtained on a North American Philips X-ray diffractometer using a rotating sample holder of the type previously described.[13] This sample holder minimizes the possibility of orientation effects in powdered samples and thus makes it possible to obtain a more complete and accurate diffraction pattern.

The authors express their appreciation to the Texas Gulf Sulphur Co., Newgulf, Texas, for a fellowship to J. S. K. under which this work was done; to Dr. R. Fanelli of the Texas Gulf Sulphur Co., New York, for helpful information; and to Baroid Division, National Lead Co., Houston, Texas, for the use of the X-ray diffractometer.

CHEMISTRY OF THE NEOMYCINS. I. A PARTIAL STRUCTURE FOR NEOBIOSAMINES B AND C[1]

Sir:

Though the isomeric antibiotics neomycins B and C have been investigated extensively and widely employed clinically (as a mixture of the two isomers),[2] the structures of these compounds thus far have resisted complete elucidation. We wish to report here evidence that the neobiosamine[3] portion of both neomycins B and C consists of a diaminohexosido-pentose. In an accompanying Communication it is shown that the same pentose, D-ribose, is found in both isomers.[4]

Methanolysis of neomycin C gave neamine[2b] and methyl neobiosaminide C,[3] the latter, crude product, was carefully chromatographed and isolated as a mixture of its anomeric α- and β-glycosides [*Anal.* Calcd. for $C_{11}H_{21}N_2O_7(OCH_3)$: C, 44.44; H, 7.46; N, 8.64. Found: C, 44.60; H, 7.72; N, 8.55] and characterized as its derivative, methyl N,N′-dibenzoylneobiosaminide C, m.p. 250–252° [*Anal.* Calcd. for $C_{11}H_{19}N_2O_7(OCH_3)(COC_6H_5)_2$: C, 58.63; H, 6.00; N, 5.27. Found: C, 58.52; H, 5.77; N, 5.01]. These analytical values are in excellent agreement with the formulation of neobiosamine C as $C_{11}H_{22}N_2O_8$, a disaccharide composed of diaminohexose and pentose moieties, but do not support the formula $C_{11}H_{22}N_2O_7$, which would be a disaccharide containing desoxydiaminohexose and pentose moieties, as previously proposed.[3]

The α- and β-anomers were separated ($[\alpha]^{25}D$ 113° and $[\alpha]^{25}D$ 61°, respectively) and each was hydrolyzed in dilute hydrochloric acid to neobiosamine C (identical mutarotation value, $[\alpha]^{25}D$ 104°), which gave a single strong papergram spot [R_f 0.227 (TBAW)],[5] both reducing and ninhydrin-positive. The formation of a single compound from hydrolysis of methyl neobiosaminide C argues strongly for the formulation of neobiosamine C as a diaminohexosido-pentose, cleaved with difficulty, rather than as a pentosido-diaminohexose, which would be readily cleaved during hydrolysis to a pentose and a diaminohexose (or methyl diaminohexoside) and thus would give two papergram spots.

Similar arguments obtain for neobiosamine B. Both α- and β-anomers ($[\alpha]^{25}D$ 13° and $[\alpha]^{25}D$ −17°, respectively) of methyl neobiosaminide B [*Anal.* Calcd. for $C_{11}H_{21}N_2O_7(OCH_3)\cdot H_2O$: C, 42.10; H, 7.66; N, 8.19. Found: C, 41.82; H, 7.42; N, 7.95] are hydrolyzed to constant rotation ($[\alpha]^{25}D$ + 33°) and a single strong papergram spot [R_f 0.251 (TBAW)]; thus neobiosamine B also may be formulated as $C_{11}H_{22}N_2O_8$, a diaminohexosido-pentose.

In the accompanying Communication[4] the pentose moiety is shown to be the same for both neobiosamines B and C. The disaccharides presumably differ then in their diaminohexose moieties and may be assigned the partial formula Ia, and methyl neobiosaminides B and C, Ib. Since neomycins B and C both contain neamine they may be formulated as Ic.

$$\underset{\text{Pentose}}{R—O—C_5H_6O(OH)_2—O—}\underset{\text{Diaminohexose (B or C)}}{C_6H_7O(OH)_2(NH_2)_2}$$

Ia, b, c

Ia, R = H
Ib, R = CH_3
Ic, R = $C_{12}H_{25}N_4O_5$ (neamine)

We wish to express our appreciation to the Public Health Service for a research grant (No. E-1278) in support of this work, and to the Upjohn Company for the generous gift of neomycin samples.

CHEMISTRY OF THE NEOMYCINS. II. THE PENTOSE MOIETY

Sir:

In the preceding Communication[1] it was shown that the neobiosamine portion of both neomycin B and neomycin C consists of a diaminohexosidopentose. We present here evidence that the pentose moiety in both neobiosamines B and C is D-ribose.

Methyl N,N′-dibenzoylneobiosaminide-C[1] was hydrolyzed with dilute aqueous hydrochloric acid at reflux to give a mixture of products. Purification by partial precipitation, ion exchange resins and chromatography gave a neutral, salt-free carbohydrate fraction, which was shown by color tests, papergrams and rotation to be D-ribose. The compound is an aldopentose[2] since its papergram gives an orange-brown color when developed with *p*-dimethylaminoaniline and trichloroacetic acid[5] and a red color when developed with aniline acid phthalate,[6] but no gray-green color (indicative of a ketopentose and found in model papergrams of ribulose and xylulose) when developed with orcinol and trichloroacetic acid.[7] In simultaneous papergrams (at least two chromatograms in each solvent system) with the four aldopentoses and two ketopentoses, the material was shown to give R_f values quite close to those of ribose, but very different from those of the other aldopentoses and the ketopentoses [ribose, R_f 0.553 (TBAW), 0.630 (PhNC), 0.368 (BAW); hydrolysate pentose, R_f 0.547 (TBAW), 0.630 (PhNC), 0.364 (BAW)].[8] The observed rotation of solutions of the pentose is negative, establishing the compound as D-ribose, rather than the L-isomer, which would give positive rotations.

The pentose obtained from hydrolysis of methyl N,N′-dibenzoylneobiosaminide B also has been shown to be D-ribose by a precisely analogous procedure, involving papergram color tests, R_f values, mutarotation data and osazone form. The R_f values are: ribose, 0.596 (TBAW), 0.308 (BAW); hydrolysate pentose, 0.598 (TBAW), 0.309 (BAW).[9] The mutarotation value of the isolated pentose was −17.1°, that of D-ribose, determined simultaneously, −17.6°. The moss-like crystal form of the osazone of the hydrolysate pentose, m.p. 158°, was the same as that of ribosazone, m.p. 159–162°, very different from the needles of xylosazone, m.p. 162–164°.[10]

Since the pentose from both neobiosamines is D-ribose and neomycins B and C both contain neamine,[3] the formulas of neobiosamines B and C, of methyl neobiosaminides B and C, and of neomycins B and C may be represented by Ia, Ib and Ic, respectively. The difference between the isomeric antibiotics presumably lies in the diaminohexose moieties. The structures of the diaminohexoses, their position of linkage to ribose, the position of ribose attachment to neamine and questions of pyranose *vs.* furanose ring structure will, it is hoped, be the subjects of future publications.

$$\underset{\text{D-Ribose}}{R—O—C_5H_6(OH)_2—O—}\underset{\text{Diaminohexose (B or C)}}{C_6H_7O(OH)_2(NH_2)_2}$$

Ia, b, c

Ia, R = H; Ib, R = CH_3; Ic, R = $C_{12}H_{25}N_4O_5$ (neamine)

We wish to express our appreciation to the Public Health Service for a research grant (No. E-1278) in support of this work, and to the Upjohn Company for the generous gift of neomycin samples. We also wish to thank Professor W. A. Wood for helpful advice and suggestions.

are well known. Chlorine is known to form hydrogen bonds under favorable circumstances,[3] but chlorine compounds analogous to the alkali metal bifluorides have not been reported. We now wish to report the compound CsCl·HCl, obtained by simply passing hydrogen chloride into rather concentrated aqueous cesium chloride solutions.

In a typical run 2 g. of cesium chloride was dissolved in 1.5 ml. of water and hydrogen chloride was bubbled through the solution with intermittent cooling. As the solution approached saturation with respect to hydrogen chloride, about 1 g. of the new compound was precipitated as colorless to pale yellow anisotropic needles. The solid lost hydrogen chloride and reverted to isotropic cesium chloride when attempts were made to dry it in air or *in vacuo*; but the compound could be obtained with only slight loss of hydrogen chloride when drying was carried out at 30° in a stream of hydrogen chloride. Several samples dried in this way gave ratios Cs:H:Cl varying from 1:0.7:1.4 to 1:1.0:2.0.

Examined in their mother liquors under the polarizing microscope, the crystals were observed[4] to be perfect orthorhombic prisms, with $2V \sim 70°$, moderately high birefringence, and positive optic sign. As the HCl concentration in the system decreased with time, the needles were transformed first into an anisotropic polycrystalline phase, and eventually into isotropic CsCl.

Cesium appears to be unique among the alkali metals in its tendency to form an "acid chloride." Attempts to prepare similar compounds of rubidium and potassium so far have led only to the normal chlorides. We wish to advance the hypothesis that the new cesium compound contains HCl_2^- anions with a hydrogen-bonded structure (Cl—H· · ·Cl$^-$) analogous to that of the HF_2^- ion; and further, that the HCl_2^- ion forms isolable crystalline salts only with very large cations. Other compounds which may contain the HCl_2^- anion are the "dihydrochlorides" by pyridine and other tertiary amines,[5] and the remarkably stable siliconium chloride–hydrogen chloride salts.[6] Structural studies on $CsHCl_2$ are in progress.

THE DEGRADATION OF LEUCINE-DERIVED CAROTENES

Sir:

In previous papers on the incorporation of labeled leucine into carotene by *Phycomyces blakesleeanus*, we have shown that only the 4-C of leucine is incorporated in sufficient quantity to permit its occurrence in each isoprene unit.[1] Incorporation of the 1-C is insignificant, and for the 3-C and 2-C atoms it is too low to account for the increased synthesis of β-carotene in the presence of leucine,[2] so that the selective use of an intact residual C_5 decarboxylated fragment of leucine becomes untenable.

We have therefore located some of the labeled leucine carbons in the carotene molecule in an attempt to explain the unique role of the 4-C atom.

The labeled carotene specimens, each *ca.* 3.5 mg., diluted with carrier to 19 to 32 mg. were insufficient for a complete analysis such as Grob and Bütler[3] performed. They were sufficient for recovery of the acetic acid obtained by chromic acid oxidation,[4] 6 moles of which are yielded per mole of carotene. The carboxyl groups are derived from the 5,5, 9,9, 13, and 13 carbons, and the methyl groups from corresponding side chains.

The acetic acid was decarboxylated in the Schmidt reaction to give CO_2 and methylamine. The CO_2 was converted to $BaCO_3$ and counted. The methylamine, crystallized as the hydrochloride, was burned and the CO_2 handled in the same way.

The *dl*-leucine labeled in positions 2, 3 and 4 and the β-carotene were prepared as described previously.[1,2] At the temperature of boiling water, we oxidized[5] about 20 mg of β-carotene, from which 3.5 to 5.3 mg. is radioactive.

The acetic acid obtained by four successive distillations was titrated by NaOH, 0.1 *N*. The yield of acetic acid varied from 75 to 85%. The calculated quantities of NaN_3 and H_2SO_4 were added to the CH_3COONa, obtained by evaporation of the solution (42 mg. NaN_3 and 0.9 ml. H_2SO_4 for 40 mg. CH_3COONa).[6] The liberated CO_2 was collected as $BaCO_3$. Then the methylamine was distilled into concd. HCl, crystallized as hydrochloride and burned; the CO_2 was collected as $BaCO_3$. The results are tabulated:

Leucine[a]	Total carotene, mg.	Radioactive carotene, mg.	CO_2 c.p.m.[b] per mg. $BaCO_3$	CH_3NH_2·HCl, c.p.m.[b] per mg. $BaCO_3$
4C	20.1	3.5	298 ± 11.0	4.2 ± 1.1
2C	20.2	3.5	53 ± 7.6	1.6 ± 0.8
3C	32.4	3.5	1.8 ± 0.4	10.1 ± 2.7
3C	19.6	5.3	2.0 ± 0.6	7.2 ± 1.3

[a] The counts added to the media differed in each case. [b] The standard deviation was computed to include self-absorption, weighing and counting errors.

The radioactivity of the 4-C is concentrated in the carboxyl group. Thus, the 4-C of leucine is located in positions 5,5, 9,9, 13 and 13 of the carotene molecule.

This strongly suggests that leucine provides an iso C_3 fragment in which the 4-C is centrally located. The distribution for the 2-C of leucine is the same as for the 4-C. Therefore we may assume that a C_2 fragment, also provided by leucine, can

be incorporated, though to a lesser extent than the C_3 fragment since the total incorporation of activity from the 2-C of leucine is limited.[2] This is explicable by dilution from a C_2 metabolic pool.

By contrast, the 3-C is found primarily in the methyl of the acetic acid. This does not rule out the possibility that this carbon may also be found elsewhere in the chain, and several choices still exist as to the pathway followed, which we hope to evaluate when warranted by additional data.

BOOK REVIEWS

Actions Chimiques et Biologiques des Radiations. Deuxième Serie. I. Les Effets Chimiques Produits par les Rayons Ionisants en Phase Gazeuse. By W. MUND. **II. Phénomènes de Luminescence Provoqués par les Rayonnements de Grande Énergie.** By M. AGENO. **III. Introduction a la Dosimétrie des Radiations.** By N. MILLER. Edited by M. Haïssinsky. Masson et Cie. Éditeurs, 120, boulevard Saint-Germain, Paris-6e, France. 1956. vi + 224 pp. 16.5 × 24.5 cm. Price, Broché, 2.800 fr.; Cartonné toile, 3.400 fr.

This second collection of works consists of related sections on the chemical and physical aspects of ionizing radiations. This series, supplementing the first,[1] deals with the radiation chemistry of gases, with luminescence phenomena and with the dosimetry of ionizing radiations. Each section is written in French by an authority in the field.

The calculation of energy loss by α-particles in gases, the chemical action of low energy electrons and the ionization potentials of simple gases are basic topics treated by Dr. Mund in Part I. Negative ion formation and the methods for differentiating between free radicals and ions in the primary process are also briefly discussed. Mechanisms and some experimental data are given for the radiolysis of inorganic gases such as ammonia, hydrazine, hydrogen sulfide, the halogen acids, ozone, the nitrogen and carbon oxides, and of several organic vapors. Special attention is devoted to the hydrogen–deuterium exchange reaction. Emphasis throughout this section is on the extensive works of Mund and his collaborators. Reaction mechanisms are discussed in terms of free radical reactions and, unfortunately, no assessment is made of the possible contributions of molecule–ion reactions in gas phase radiation chemistry.

Dr. Ageno, in part II, succinctly summarizes the physical aspects of luminescence and compares the effects obtained by ultraviolet light and ionizing radiations. This section of the book is complete and the material is presented in logical order. All phases of luminescence phenomena from the experimental methods, luminescent yields of a large number of substances to the mechanism are covered. Progress in this field is very rapid. As a result, some recent data are missing and some of the older data on mean lives of organic scintillators (Table VI, p. 120) require revision.

Introduction to the Dosimetry of Radiations is an excellent, concise treatment of the physical and chemical methods of dosimetry by Dr. N. Miller in Part III. No attempt is made to describe radiotherapy dosimetry nor the instruments used in dosimetry. The dissipation of energy in matter by charged particles, by electromagnetic radiation and by ionization in gases is outlined. The chapter on relative methods consists of a discussion of several aqueous, organic and luminescent glass dosimeters and of their relative merits. The absolute methods of dosimetry such as calorimetry, charge collection, nuclear reactions in solution and ionization are more completely explained. Useful conversion factors and the oxidation yields of ferrous sulfate for different kinds of radiations are given in the Appendix.

Chemists, physicists, biologists and radiologists interested in the chemical and physical actions of ionizing radiations will welcome this volume, since material particularly applicable to dosimetry by ionization, scintillation and chemical methods is presented. An English edition will find wide appeal.

EDWIN J. HART

Nouveau Traité de Chimie Minérale. Edited by PAUL PASCAL, Membre de l'Institut, Professeur honoraire a la Sorbonne. Volume X. **Azote—Phosphore.** By R. DUBRISAY and P. PASCAL. Masson et Cie. Éditeurs, Libraires de l'Académie de Médecine, 120 Boulevard Saint-Germain, Paris 6, France. 1956. xxxix + 963 pp. 18 × 25.5 cm. Price, Broché 6.600 fr., Cartonné toile 7.500 fr.

This volume (No. X) is the second to appear of the nineteen volumes projected for the complete treatise. A look around a library's reference shelves discloses that the nitrogen-phosphorus sections of the other large handbooks are now from twenty to thirty years old, which should assure the present treatise a warm welcome. In harmony with the general plan of the treatise, it has been necessary to compress the industrial aspects of the writing in order to make room for the host of new physico-chemical results and interpretations which have developed during the last half-century. A special aid to French readers is afforded by the List of Libraries both Parisian and Provincial (100 in all) in which the relevant Journals may be found, with an indication in each case of the extent to which the available files are complete. Bibliographic references are grouped by tens under general subjects at the end of each section of the book, and most of them purport to cover the literature up to the summer of 1955. At the bottom of each page of text is a reminder of the page where the relevant bibliography can be found. A variety of checks in matters of detail, including comparison with the necessarily much briefer treatments in Yost and Russell's Systematic Inorganic Chemistry (Prentice–Hall, Inc., New York, 1944) indicate that the present volume is in all ways a worthy example of this type of writing —so enormously time-consuming and difficult, and yet so necessary to the progress of science. The material on nitrogen, prepared by the Editor, occupies about 700 pages, while M. Dubrisay has contributed about 215 pages on Phosphorus. In the final chapter (18 pages), M. Pascal returns with a treatment of the organophosphorus compounds. Indexes and other matters bring the total to 963 pages. Printing and make-up are excellent and clear, and the few errors mostly involve minor misreadings of foreign terms in the bibliographies. American users familiar with French will find this a much handier and more selective source of information than Gmelin, though perhaps not quite so complete, when sections of equal date are compared.
